Main Index

Welcome to KLayout's documentation

The documentation is organized in chapters. For a brief introduction read the User Manual. 'Various Topics' is a collection of brief articles about specific topics. For Ruby programming see the 'Programming Ruby Scripts' chapter and for a complete Ruby class reference see the 'Class Index'.

1. KLayout User Manual

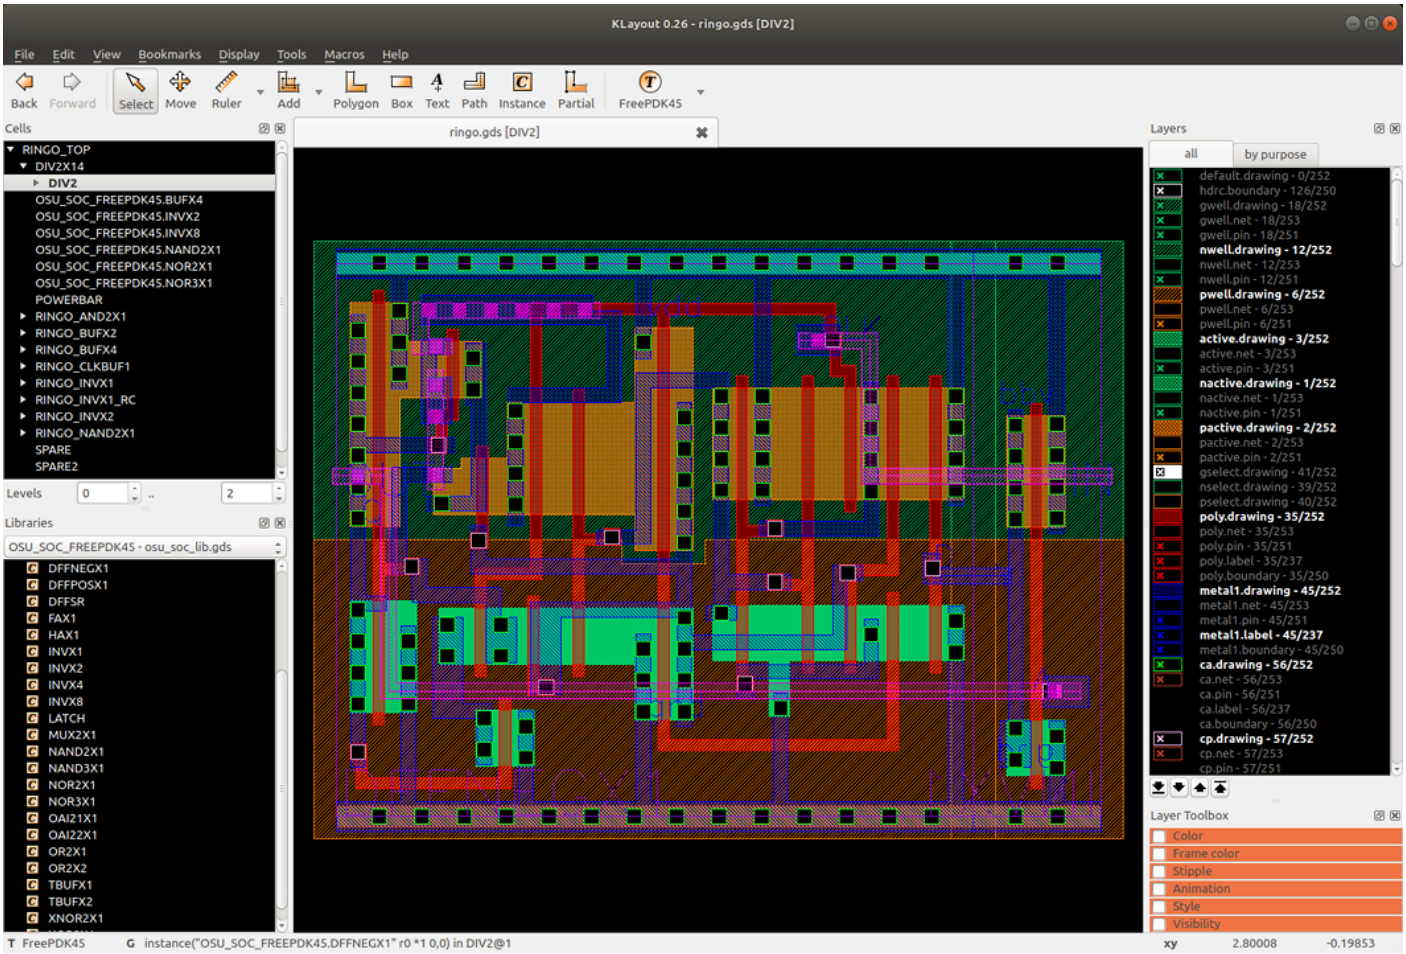
This is KLayout's main user manual. The manual is organised in major topics:

1.1. KLayout Basics

Welcome to KLayout's user manual. This is the manual chapter covering the basic features of KLayout. The following subtopics are available:

1.1.1. The Main Window

The main window is divided into three parts: the left area is the hierarchy browser and navigator, the center part of the canvas and the right part is the layer list with the layer toolbox. The individual components can be rearranged, so the arrangement described is just the default arrangement. You can move a component to a new place by dragging it with its title bar to some other place or detach it from the main window to form a floating separate window.

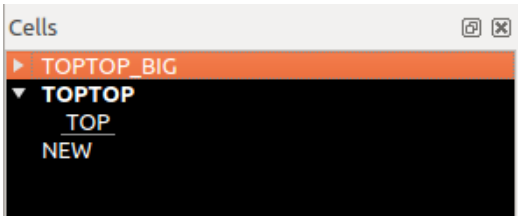


Left Part - The Hierarchy Browser, Library View and Navigator

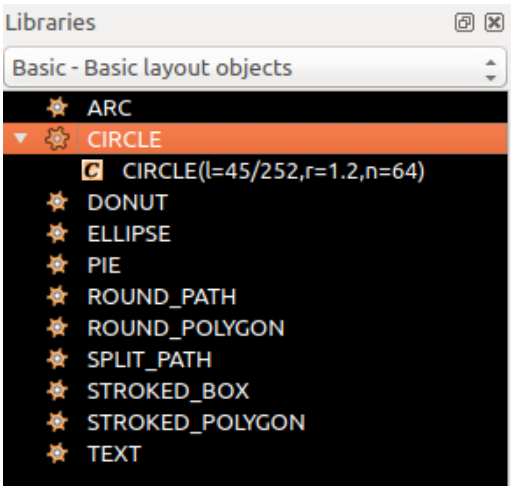
The left panel is the hierarchy browser which shows the cell hierarchy and - optionally - the navigator window that shows an overview over the whole layout.

In the hierarchy browser, cell nodes can be expanded showing the child nodes. The "current cell" is the one shown in the center panel. It is drawn in bold font. One or multiple cells can be selected. The selected cells are the ones, the various functions act on. The "context cell" is the cell which is the "active cell" on which drawing happens. The context usually is the same than the current cell, but by descending into the hierarchy, the child cell of the current cell can be made the context cell. It is shown in underlined font.

In the following example, "TOPTOP_BIG" is selected, "TOPTOP" is the current cell and "TOP" is the context cell:

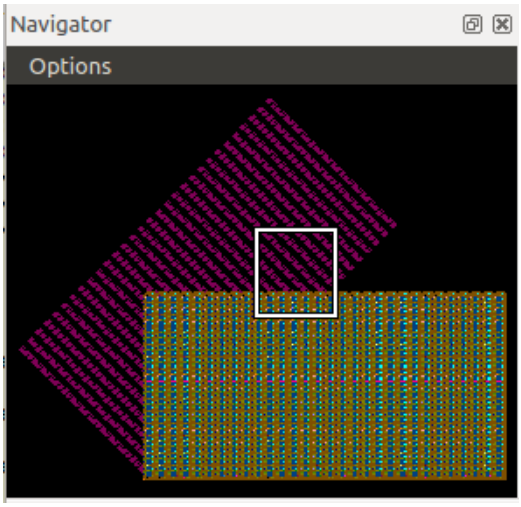


The sub-panel below the hierarchy browser is the library view. This view shows the libraries registered in the system and their content:



The library view is used to browse and place library cells, which can be normal cells or PCells. Read more about the library view here: The Library View.

The navigator is invisible by default but can be activated by checking the "Navigator" menu item in the "View" menu. The navigator shows an overview image of the whole cell and a box indicating the clip shown in the center panel:



Center Part - The Canvas

The center panel is the actual canvas. There, the layout is drawn. To zoom in, click with the right mouse button and drag a rectangle that will become the new area shown. Select items by left-clicking or dragging a selection rectangle with the left mouse button pressed. A variety of edit and display modification feature is supplied, for example the ability to add rulers or background images.

Right Part - The Layer List and Layer Style Controls

The right panel is shows the layer list or layer tree. By default, it shows a plain layer list, but the are manifold ways to configure the list, i.e. grouping, styling, adding tabs to easily switch between different setups etc.

The layer tree specifies what and how layout is drawn. Entries can be deleted or configured freely - this does not affect the layout itself. Essentially, the layer list can be entirely independent from the layout and omit layers from the layout or add (empty) layers that are not actually part of the layout. In this scenario, a layer list typically reflects a set of drawing layers with a certain technology-dependent meaning. This list provides a styled layer view for an otherwise undecorated layout file. The layers can be reordered, so their drawing priority is changed. The top layer will be drawn first, while others will be drawn later. Hence the first layer is likely to become obscured by following layers.

Modification operators can be attached to layers - for example, the drawn layout can be transformed geometrical (i.e. translated, rotated, scaled, mirrored) and layout can be selectively drawn when certain conditions for user properties apply.

Below the layer list, a set of control panels is located. The control panels are minimized per default. They can be expanded by clicking on the header bar. These controls form the "Layer Toolbox" where you can modify the layer styles. The styles selected in the layer toolbox will affect the layers selected in the layer list.

Multiple layouts can be shown together. Either they can be overlayed or they can be shown in separate views. In this case, a tab panel appears at top of the main window. Selecting a tab switches between the layouts. Layers for different layouts appear as annotated layers in the layer list - for example "1/0@1" for layer 1, datatype 0, first layout and "1/0@2" for layer 1, datatype 0 and second layout.

1.1.2. Loading A File

In the "File" menu, choose

- "Open" to close the current view and open a new layout instead of the currently loaded one
- "Open in Same Panel" to open a new layout in addition to the currently loaded one
- "Open in New Panel" to open a new layout in a new view

Either way, a file selection dialog will appear where a file can be chosen for loading. After choosing the file and clicking "Ok", the file is loaded.

The program will automatically determine the type of the file. Currently, OASIS, GDS2, DXF, CIF, LEF/DEF and a text version of GDS2 are supported. Gerber PCB data can be read with some preparations too (see Import Gerber PCB Files). If the file is gzip/zlib compressed, it will be uncompressed automatically.

Certain options can be specified for the file loader using the reader option pages. To open the reader options dialog, choose "Reader Options" from the "File" menu. This dialog allows specification of certain options for all "Open" actions, for example:

- Confine the reader to a certain set of layers. All other layers are not read.
- Disable reading of text objects. Text objects don't carry geometrical information for masks and can be discarded this way.
- Disable reading of user properties. If properties are not required, the memory consumption can be reduced by disabling properties.
- Certain GDS specific options which mainly control the level of compatibility with other tools.
- Other formats may offer other options too. Specifically rich formats such as DXF or LEF/DEF can be configured in manifold ways. Different tabs show options for different formats or format groups.

Using "File/Reload", the currently loaded file can be re-read from disk. Usually this is not required, because KLayout will automatically check whether the file has changed and offer to load it.

By picking a file from the "Open Recent" list in the "File" menu, a previous file can be loaded again.

Files can be given to KLayout on the command line and are loaded automatically. Multiple files can be specified. They are shown in different pages by default. To load multiple files into the same page, add a "-s" option to the command line. "http:" or "https:" can be specified on the command line as well. In this case, KLayout will download the files from the given URL.

Files and URL's can be dragged and dropped on the KLayout main window. KLayout will then load and show these files.

Layout files can be associated with technologies. Technologies allow associating a layout with additional data, such as libraries, macros, net tracer settings, layer properties etc. Read About Technology Management for details.

1.1.3. Managing The Panels And Loaded Layouts

Choose "Close" in the "File" menu to remove a layout of a panel and close the panel unless there are still layouts loaded. If multiple layouts are loaded into the current panel, a dialog appears. This allows selecting one or many layouts for closing. "Close All" will close all panels.

Choose "Clone" from the "File" menu to duplicate a panel. A new panel will be created that is an exact copy of the current one. Both, the current and the new panel are views to the same layout. This way, only one copy of the layout is held in memory.

Choose "Pull In Other Layout" to combine other layouts already loaded into the current panel. Basically, KLayout allows viewsing a layout in multiple panels, either on its own in different configurations or together with other layouts. "Pull In Other Layout" allows configuration of a panel to show another layout which has been loaded into another panel. In that sense it's the reverse of closing one layout from a panel showing multiple layouts.

1.1.4. Choosing A Cell

To show a certain cell, select the cell in the cell hierarchy in hierarchy browser to the left. Then, right-click in the cell tree to bring up the context menu and choose "Show as top" or simply select the cell with the middle mouse button.

To select a cell by name, choose "Select Cell" in the "Display" menu. A dialog will appear that allows selecting a cell by name or choosing it from an alphabetically sorted list. Additionally, this dialog allows navigating the cell tree by moving to one of the child or parent cells.

1.1.5. Choosing A Hierarchy Depth

By default, only the bounding box of the cell selected is shown. This corresponds to zero hierarchy levels being shown. If you select one more level of hierarchy (Levels 0 to 1), this content of the child cells of the current cell are drawn, but grandchildren (children of child cells) are drawn as boxes. Increasing the hierarchy levels will draw more and more details of child cells until all cells below the current cell are drawn in detail.

To select more hierarchy levels

- Select "Full Hierarchy" from the "Display" menu or press the "*" key to show all hierarchy levels
- Select "Box Only" from the "Display" menu or press the "0" key to show only the bounding box (the default)
- Select "Top Level Only" from the "Display" menu or press the "1" key to show the top level elements
- Select "Increment Hierarchy" from the "Display" menu or press the "+" key to show one more hierarchy level
- Select "Decrement Hierarchy" from the "Display" menu or press the "-" key to show one hierarchy level less
- Use the hierarchy level entry fields below the cell list to change the current minimum or maximum level

1.1.6. Configuring The Cell List

Two modes are provided for the cell list: a tree view (the default) and a flat cell list. To switch to flat mode, check the "Flat Cell List" option in the cell panel's context menu.

If multiple layouts are loaded, the cell lists of the individual layouts are shown separately. The drop-down box above the cell lists will select the current cell tree to show. An alternative mode is available in which the cell lists are shown beside each other in the cell tree panel. This mode is enabled by choosing the "Split Mode" option in the cell panel's context menu. In split mode, you can click on the headers to select the current cell tree. The current cell tree plays a role in some cases, for example for the layout operations available in the "Layout" submenu of the "Edit" menu.

In addition, three sorting modes are provided: alphabetically by name and by cell size (bounding box area), descending and ascending. The cell size is supposed to reflect the design level: library and leaf cells are usually small which macro blocks are usually large. By using cell size sorting in ascending order, the leaf cells will be shown first. To change the sorting, check the corresponding option in the "Sorting" submenu of the cell panel's context menu.

1.1.7. The Library View

Beside the cell list, a library view is provided as a support view for the layout panel. This sub-panel displays the libraries available and allows browsing the cells and PCells inside a library.

By default, the library view is shown below the cell tree. You can rearrange the views by dragging them at their title bar and docking them in other places of the main window. To reset the window arrangement to the default configuration, use "Restore Window" from the "View" menu.

The library view shows the cells and PCells of one library. To select a library, choose it from the selection box at the top of the library view.

PCells are shown with a small "gear" icon in the library view. If PCells are instantiated, the variants in use are shown as entries below the PCell entry.

In edit mode, cells can conveniently be placed by dragging them from the library view to the layout canvas. If a PCell variant is dragged, another instance of this PCell variant is created. If a PCell master is dragged, KLayout will pop up the PCell parameter definition dialog on drop.

1.1.8. Hiding Cells

Independent of the hierarchy levels shown, cells can be hidden. In this case, the cell is now shown but rather the bounding box is shown. To do so, select the cell from the cell list and choose "Hide" from the context menu. To show a cell again, choose "Show". To make all cells visible again, choose "Show All".

1.1.9. Zooming Into The Layout

Select the zoom area with the right mouse button in the layout canvas.

Press the button, drag the box to the desired position and release the button.

To zoom in (enlarge) drag the box right and down. To zoom out (shrink) drag the box up and left. To choose a new center, single-click the new center point with the right mouse button.

Additionally, these functions are available from the menu or by hotkeys:

- Pan to the left, right, top or bottom using the arrow keys or choosing one of these functions from the "Display" menu.
- Fill the whole selected cell into the window by pressing "F2" or choosing "Zoom Fit" from the "Display" menu
- Zoom in or out by a fixed amount by pressing "Enter" or "Shift+Enter" or choosing "Zoom In" or "Zoom Out" from the "Display" menu
- Zoom in and out by using the mouse wheel if available. The current mouse location will stay fixed, while the surrounding layout will be enlarged or reduced in size
- Press "Shift" while dragging the mouse with the right mouse button pressed will drag the layout similar to what happens in recent map service web applications

1.1.10. Global Rotation and Flip

KLayout offers an option to flip or rotate the whole window. This is a useful option for example to view mask data which a mirrored image of the chip.

To access this option, choose the desired transformation from one of the options available in the "Global Transformation" submenu of the "Display" menu.

1.1.11. Returning To A Previous View

Choose "Last State" from the "Display" menu to return to the last window shown. Choose "Next state" to switch to a more recent state again.

1.1.12. Bookmarking Views

Views (window, cell) can be bookmarked for later retrieval. Choose "Bookmark This View" from the "Bookmarks" menu. A name is required to be entered for the bookmark. The bookmark will then appear in the "Goto Bookmarks" list.

The list of bookmarks defined can be loaded or saved by using the "Load Bookmarks" and "Save Bookmarks" functions from the "Bookmarks" menu.

The bookmark list is available as a dockable tool window as well: check the "View/Bookmark List" option to enable this dock window. The bookmark list by default is shown at the bottom right side of the layout view.

Dockable Bookmark List

To navigate to a bookmark from the dockable bookmark list, double-click the entry. From the context menu (right mouse click) you can select these functions:

- **Follow Selection**: if this option is checked, the selected bookmark will immediately change the view accordingly. With this option, you can browse the bookmark list with the arrow keys while the view updates automatically.
- **Manage bookmarks**: opens the bookmark management dialog (same as from the "Bookmarks" menu).
- **Load bookmarks** and **Save bookmarks**: loads or saves the bookmarks to a file (same function as from the "Bookmarks" menu).

1.1.13. Descending Into A Cell With Context

A cell can be shown either isolated (this is the default, if the cell is the current cell), embedded (as a subcell of the current cell) or as the current cell in the context of another direct or indirect parent cell. In the latter mode, the cell is highlighted while the context cell is shown in dimmed or another, user-defined color.

To highlight a cell in a context, first choose the context cell. Then select a shape or a cell instance within the cell to show in the context and choose "Descend" from the "Display" menu or press "Ctrl+D". Now, the first child cell leading to the selected shape is highlighted, while the surrounding shapes of the parent cell (the previous current cell) is shown in dimmed colors. Choose "Descend" repeatedly to descend further into the hierarchy until the selected shape or instance is on the level of the current cell. The current cell is show underlined in the cell tree, while the context cell is shown in bold font in the cell tree as usual.

The reverse of this operation is "Ascend" (or "Ctrl+A") available from the "Display" menu.

The way how the context layout is shown can be adjusted in the setup dialog on the "Background" tab.

1.1.14. The Layer List (Layer Views)

An important concept in KLayout are the layer views. KLayout displays the layers of a layout by default in a list on the right side of the main window. This list however, does not directly reflect the layers in the layout database. Instead this list is a collection of "views". A view is a description of what is to be displayed and how.

Essentially, the entries in the layer list are pointers to layers in the database, together with a description how to paint the shapes on these layers (the "layer properties").

The pointer is the "source" of a layer view. This is typically a GDS layer and datatype, but can be a layer name (for DXF for example). There are also abstract sources (such as cell boundaries) and the sources can include selectors or modifiers. Selectors are used to only display shapes with certain user properties or from certain hierarchy levels. Modifiers transform the shapes before they are drawn for example. The source is defined by a "source specification" - this is a string describing the database layer and selectors and modifiers. A simple source string is "1/0" which is for GDS layer 1, datatype 0 without and selectors or modifiers. To change the source, use "Change Source" from the layer list's context menu.

See Transforming Views And Property Selectors for some source specification string applications and more details.

Beside the source, a layer entry has a display name. This is an arbitrary text providing a description for the user. By default - when no such name is present - the source of the layer will be displayed. To change the display name, use "Rename" from the layer list's context menu.

Plus of course, the layer views have many options to specify the drawing style, animations and decorations.

The concept of separating views from the database layers opens some interesting options:

- Layer views can refer to individual layouts from multi-layout views (through the "@1", "@2", ... notation in the source). Hence, multiple layouts can be mixed in a single layer list.
- Layers can be present in the list which do not need to be present in the database. Such a layer is shown as empty. This is important as in GDS an empty layer is equivalent to non-existing. Still you may want to have it shown in the layer list - the views offer this option.
- Vice versa, database layer may not be listed in the layer list if no corresponding layer view is present. This way, auxiliary or debug layers can be omitted from the layer list. A "wildcard specification" is available to make sure, all layers are shown if you need to see all.
- Multiple tabs can be present to provide multiple views on the same layouts. This is just an alternative set of layer views.
- Layer grouping, sorting etc. are just operations on the views, no database change is involved.

The concept on the other hand is slightly counter-intuitive at first. Here are some hints:

- Renaming a layer does not change the source - if you rename a layer to something like "1/0", you are likely to fool yourself thinking this is layer 1, datatype 0.
- Changing a layer view's source does not change the database too - it will just change the pointer. To change a layer's information in the database, use Edit/Layer/Edit Layer Specification.
- Deleting a layer from the layer list does **not delete** the layer from the database. Use Edit/Layer/Delete Layer instead.
- Additing a new layer does not immediately create the layer in the database. Only once you draw something on that layer, it is generated in the database.

1.1.15. Choosing A Layer Color

Select the layer or the layers for which to change the color and open the color chooser panel in the layer panel to the right. If the color chooser is not visible, select the small check box in the "Color" header bar. Then the color chooser is expanded.

To change the color, click on the desired color. To select a color not offered in the list, select the "More Colors" button. A color choose dialog will open.

To choose the color of the frame to draw around the shapes, without changing the fill color, use the "Frame Color" chooser panel.

Layers can be "dimmed" by making their color darker or brighter so they contrast less with the background. To do so, choose "Dark" or "Bright" from the color panel. Pressing the button multiple times makes the colors darker or brighter each time. The brightness or darkness can be reset with the "Reset" button.

1.1.16. Telling Used From Unused Layers

In some applications, the layer list will grow very large and keeping track of the important layers may be hard. KLayout provides support for that task in two ways: KLayout checks whether a layer carries any information and displays the layers in a different way in the layer list, if it is empty.

Two ways of checking the information content of a layer are provided: either a layer is said to be empty if the current cell does not have any shapes on it. Alternatively, a layer can be identified to be empty by checking if any shape is shown in the current view (more precisely if any shape's bounding box overlaps with the current view rectangle). The latter mode can be selected in the layer list's context menu with the option "Test For Shapes in View".

If a layer is determined to be empty, it is either grayed out or it is now shown at all. The latter option keeps the layer list short and is selected with "Hide Empty Layers" from the layer list's context menu.

1.1.17. Choosing A Line Style

Line styles control how the outline of the shapes is drawn. The default is a solid line. Available line styles are dotted lines, dashes lines and custom styles. To choose a certain line style, select the layer or the layers for which to change the style and choose the line style from the "Style" panel.

New styles can be created with the "Custom Style" button. A line style editor will come up that allows creating and editing of new styles. The predefined pattern cannot be changed. To apply a new style, select "More" from the style selection panel and choose the new style from the list. The custom styles are saved with the layer display properties.

1.1.18. Animating Layers

Layers can be animated, i.e. made blinking or the fill pattern scroll. Select the layer or the layers for which to change the animation style and choose the animation style from the "Animation" panel. For blinking mode, two phases can be selected: "Blink" and "/Blink". Choosing different phases for two layers makes the layers appear alternatively.

1.1.19. Changing The Display Style

The line width of the element's frame can be changed by using the width buttons on the "Style" panel after having selected the layers to apply the change on. "0px" removes the line, "1px" draws a single-pixel wide line (the default), "2px" a somewhat thicker line and so on.

"Simple" is the normal draw mode while "Marked" draws a cross on each vertex of the element. The cross size is constant so the shapes stay visible even on large scale where the elements would otherwise become single pixels.

A layer can be configured to draw a diagonal cross on rectangles. To enable this style, select "Cross" from the "Styles" toolbox. To disable it, choose "No Cross". The cross drawing will add to the fill pattern and applies to rectangles only.

1.1.20. Changing The Layer Visibility

The selected layers can be made invisible by choosing the "Hide" option on the "Visibility" panel. Choosing "Show" makes the layers visible again.

Also, double-clicking a visible layer in the layer list toggles the layer's visibility.

To make a layer "transparent" (i.e. let the other layers show through), select "Transp." on the "Visibility" panel. To make it opaque again, select "Opaque" (the default).

1.1.21. Valid And Invalid Layers

Starting with version 0.23, KLayout offers "invalid" layers: invalid layers can be visible, but don't participate in selection and snapping. They just act as some kind of background drawing.

Layers can be made invalid by choosing "Make invalid" from the layer's context menu. Layers can be made valid again by choosing "Make valid". Invalid layers are marked with a small "x" in the layer list.

1.1.22. Organizing Layers Hierarchically

Layers can be organized hierarchically. For example, certain layers can be grouped together. Choose "Group" in the context menu of the layer list (right-click the layer list). The selected layers will be replaced by a tree node that represents these layers. Click on the tree node to expand or collapse this group.

Once layers are grouped, they can be hidden or made visible with a single double-click on the node representative. The node representative also controls the appearance of the layers in the group: if a color or style is assigned to the representative, it overrides the respective style of all layers contained in the group. This way for example, the color of the layers contained in the group can be changed at once. To remove a color override of a node representative, set the color to "None".

To resolve a group, select the group representative and choose "Ungroup" from the context menu.

A variety of automatic grouping methods is provided. For example, the "Regroup views by layout index" from the layer context menu will collect all layers and put them into one group per layout shown in the panel.

1.1.23. Using Multiple Layer Setups With Tabs

With version 0.21, a new feature was introduced. Using tabs in the layer panel it is very simple to switch between different setups.

A layer tab can be created by choosing "New Tab" from the "Tabs" submenu in the layer panel's context menu (right mouse button click). A new tab will appear at the top of the layer properties panel. Initially this tab will be a copy of the current setup. Any edits on the layer properties will apply to this tab only. When switching to a different tab, the layout view will reflect the new tab's settings. That way, different setups can be prepared and easily exchanged.

When the layer properties are saved, the layer properties file will contain all tabs. Thus, a multi-page setup can easily be stored and retrieved.

The initial title of the tab will be the tab number. The title can be set with the "Rename Tab" function in the "Tabs" submenu of the layer panel's context menu. To remove a tab, choose "Remove Tab".

1.1.24. Removing And Adding Layers To The Layer Set

The layers shown in the layer list are rather "pointers" to the actual layout layers and not representing the actual layers. Because of this, these layers are more precisely referred to as "views". Layers can be removed and created again without affecting the actual layout data.

To create a layer, choose "Insert View" from the layer context menu (right mouse button click on the layer list). Then, an input dialog prompts for the source specification. The source specification tells, from which actual data layer to take the displayed data from. The most simple form of a source specification is "layer/datatype" (i.e. "5/0") or the layer name, if an OASIS layer name is present. This specification can be enhanced by a layout index. The first layout loaded in the panel is referred to which "@1" or by omitting this specification. The source specification "10/5@2" therefore refers to layer 10, datatype 5 of the second layout loaded in the panel.

Source specifications can be wildcarded. That means, either layer, datatype or layout index can be specified by "*". In this case, such a layer must be contained in a group and the group parent must provide the missing specifications. For example, if a layer is specified "10/*" and the parent is specified "*/5", the effective layer looked for will be "10/5". Unlike the behaviour for the display styles, the children override (or specialize) the parent's definition in the case of the source specification.

The layer list can be cleaned up to remove layer views that do not correspond to actual layout layers using the function "Clean up views" from the context menu. Similar, layers that are present in the layout but for which there is no view can be added using the "Add other views" method.

1.1.25. Transforming Views And Property Selectors

The source specification described in the section before is much more powerful than just allowing to describe the data source. In addition to that, the layer can be geometrically transformed and the display can be confined to shapes that belong to a certain class described by a property selector.

A geometrical transformation is specified by appending a transformation in round brackets to the layer/datatype source specification. The format of this transformation is (in any order):

```
( [<dx>,<dy>] [r<angle> | m<angle>] [*<mag>] )
```

For example, "(r90)" specifies a rotation by 90 degree counter-clockwise. "(0,100.0 m45 *0.5)" will shrink the layout to half the size, flip at the 45 degree-axis (swap x and y axes) and finally shift the layout by 100 micron upwards.

A detailed explanation of the transformation syntax can be found in Transformations in KLayout.

Transformations accumulate over the layer hierarchy. This means, that if a layer is transformed and the layer is inside a group whose representative specifies a transformation as well, the resulting transformation is the combination of the layer's transformation (first applied) and the group representative's transformation.

Multiple transformations can be present. In this case, the layout is shown in multiple instances.

A particular application is to regroup layers by layout index and assign a transformation to the group representative belonging to a certain layout such that the layouts get aligned.

The property selector is specified in square brackets. A selector combines several expressions of the form "<property>==value>" or "<property>!=<value>" with operators "&&", "||", "!" and allows usage to round brackets to prioritize the evaluation of these operators:

```
[ <expr> ]
```

In GDS2 files, the property is always named with a integer value which is written with a single hash characters (i.e. "#43". The value of a GDS property is always a string. A string is either written as a text atom or can be enclosed in single or double quotes. The following is an example for a valid property selector for GDS files:

```
10/5 [#43==X]
```

With this source specification, the layer will show all shapes from layer 10, datatype 5 which have a user property with number 43 and value string "X". A more complex example is this:

```
10/5 [!(#43==X&&(#2==Y||#2==U))]
```

With OASIS files, the properties can be named with a string. In this case, the property selector can be "[prop==X]" for example. In addition, the value can be a an integer or a double value. This is reflected by the choice of the value: "[prop==#200]" will check, if the property named "prop" has an integer value which is 200. In the same fashion, "[prop==##0.5]" checks, if the property "prop" has a double value and this is 0.5.

Property selectors combine over a layer hierarchy. This means, that if a group representative specifies a property selector and a layer in this group specifies a selector as well, only those shapes will be shown that meet both criteria.

A general description for the source notation is found here: About Layer Sources.

1.1.26. Specifying Explicit Hierarchy Levels For One Layer Or A Layer Group

By default, only the hierarchy levels that are selected in the hierarchy level selection boxes are shown, i.e. if levels 0 to 1 are selected, just the top level shapes and instances are shown. This selection can be modified for certain layers or layer groups. To specify a different hierarchy selection for a certain layer, use an optional source specification element, the hierarchy level selector:

#[<lower-level>][`..` <upper-level>]

Upper and lower level can be omitted. In this case, the respective level is not overridden. The upper level can be '*' which means: every level that is available. If just one level and no ".." is given, it is taken as upper level and the lower level is set to zero.

Some examples might illustrate this:

`#*`	Display all hierarchy levels
`#0..1`	Display top level only
`#..5`	Override upper level with 5
`#2..`	Override lower level with 2
`#..*`	Override upper level setting by "all levels"

Modifications of this notation are provide in order to support more use cases. Instead of specifying a single number for the level, the following alternative notations are supported:

`(1)`	Relative specification: Hierarchy level 1 related to the current cell's level. The effective specification differs in "Descend" mode where the current cell is on a lower hierarchy level than the context cell which is the top cell drawn.
`<1`	Constrained specification: Hierarchy level 1 or less if the upper or lower default level set in the user interface is less.
`>1`	Constrained specification: Hierarchy level 1 or greater if the upper or lower default level set in the user interface is greater.
`(>1)`	Combined specification: Hierarchy level 1 related to the current cell's level or less.
`>*`	Equals the currently set maximum hierarchy level.

For example:

`#(0)..(1)`	The top level of the current cell (works also in "Descend" mode).
`#>0..<1`	Everything exactly on top level unless the top level is not selected in the controls.
`#>1..<*`	Everything below the context cell's top level unless not selected by the user interface controls.
`#(>1)..<*`	Same than before but related to the current cell, not the context cell.

1.1.27. Loading And Saving The Layer Sets

The visual layer properties can be saved to a file using the "Save Layer Properties" function from the "File" menu. This list can be loaded again using the "Load Layer Properties" function.

1.1.28. Creating A Screenshot

To save the canvas as a PNG file, choose "Screenshot" from the "File" menu or press the "Print" key. A file dialog box will appear in which the file can be specified where the screenshot is saved to.

1.1.29. Doing Measurements

A measurement can be performed by clicking on the ruler icon in the toolbar and selecting "Ruler" from the drop-down options. Left-click on a point in the layout and then left-click again to specify the second point. A ruler will be shown that indicates the distance measured.

A more convenient way is provided with the single-click measurement ruler. Select "Measure" from the drop-down options of the ruler symbol. In this mode, a single click will set a ruler to the specified position. This feature will look for edges in the vicinity of the ruler and set the ruler to connect the neighboring edges. The ruler is attached perpendicular to the edge next to the initial point.

You can mark a position with a single click by selecting the "Cross" ruler type. Clicking at a location will place such a ruler. The ruler shows the x and y coordinate.

The "Multi-Ruler" allows concatenating multiple rulers into a single object. Click and the first point to start such a ruler. Then click on more points to add new segments to the ruler. Each segment is shown as an individual ruler with tick marks and a length. Finish the sequence with a double-click.

The "Angle" ruler allows angle measurements. Three clicks are required to define a "V" like arrangement of two rulers. The angle enclosed by the two lines forming the "V" is shown in the ruler.

Another special ruler, the "Radius" ruler is also a three-click type. Specify three points to define a circle. The ruler shows the radius of this circle and the circle outline.

Rulers can be configured in manifold ways. Use "Rulers And Annotations Setup" in the "Edit" menu to open the ruler configuration dialog. A ruler can be made to snap to edges of objects by selecting "Snap to edge/vertex". Ruler orientations can be constrained by using the "Angle Constraint" options. The number of rulers can be limited using the "Limit number of annotations" setting.

While drawing or moving one point of a ruler, the direction constraint can be overridden with the Shift and Ctrl keys: pressing Shift while moving the mouse will enforce orthogonal constraint, Ctrl will enforce diagonal constraint while pressing both will release any direction constraint.

All rulers can be cleared using the "Clear all rulers" function from the "Edit" menu.

Ruler dragging can be canceled with the "Esc" key or using the "Cancel" function from the "Edit" menu.

Rulers can be moved by selecting "Move" mode with the speedbar buttons in the toolbar or "Move" from the "Mode" sub-menu in the "Edit" menu. Then left-click and drag the ruler or the ruler end point that should be changed.

Rulers can be deleted selectively by selecting a ruler in "Select" mode and pressing "Delete".

Rulers can be modified in a variety of ways. For example, rulers can be shown as arrows. To edit the properties of a ruler, double-click the ruler or select it and use "Properties" from the "Edit" menu. See Ruler Properties for a description of the properties.

Multiple templates can be configured to be available for rulers. Each template defined will be shown in the "Ruler" mode toolbar button's drop-down menu. If a template is selected, new rulers produced from this template will inherit the template's properties. Templates are managed in the ruler setup page ("Setup" from the "File" menu) or "Ruler And Annotation Setup" from the "Edit" menu.

1.1.30. Ruler Properties

These are the properties that can be configured for rulers:

- **Labels:** depending on the outline of the ruler, up to three labels an be present. Each label can be configure individually to either show a text or the measurement values. The main label is always present, X and Y labels are only present, if the ruler has an explicit vertical or horizontal component (all outline styles except "diagonal"). For the main label the position of the label can be specified ("P" setting): the label can be made to appear on the first or the second point or in the middle of the ruler. The Alignment of the labels can be specified too: whether the appear left or right-aligned or centered.
- **Style:** the style determines how the ruler or its components are drawn. This can be "ruler-like" (with ticks), arrow style, a plain line or with cross markers at the end.
- **Outline:** the outline determines how the two points forming the ruler are connected to render the ruler shape. This is either just one line ("diagonal"), a horizontal and a vertical line (in some outline styles combined with the diagonal line) or a box given by the two points of the ruler. A special outline is the ellipse which draws an ellipse inside the box defined by the ruler.
- **Angle constraint:** the orientation of the ruler can be restricted in several ways, i.e. just being horizontal. By default, the ruler uses the global setting. It can however be configured to provide its own constraint.
- **Object snapping:** each ruler can be configure to snap to the closest object edge or vertex. By default, the rulers use the global setting. It may be disabled however for each ruler.
- **Mode:** in normal mode, two clicks are required to define a ruler: to set the first point and to set the second one. In "Single click" mode, a single click will set both points to the same. In "Auto measure" mode, the points will be determined by looking for edges in the vicinity of the click point and adjusting the points accordingly.

The "Label format" is an arbitrary text with embedded expressions that may represent a measurement value. Each such expression starts with a dollar sign, followed by the expression string. The expression syntax supportis the basic operations ("*", "/", "+", "-" ..), bitwise operations ("|", "&", ..), the conditional operator ("x:y?z") as well as some functions, i.e. "abs", "sqrt", "exp". It includes a "sprintf" function. These are some examples:

- **$X**: The value of the X variable (the horizontal distance, see below for a complete list of variables).
- **$(sprintf('%.2f',X))**: The value of the 'X' variable formatted as two digit fixed precision value.
- **$(abs(X)+abs(Y))**: The manhattan distance of the ruler.
- **$min(X,Y)**: The minimum of X and Y.

A description of the expression syntax and the functions available can be found in About Expressions.

This is a list of all variables available:

- **D:** The length of the ruler in micron units.
- **L:** The manhattan length of the ruler in micron units.
- **U:** The x-position of the ruler's first point in micron units.
- **V:** The y-position of the ruler's first point in micron units.
- **P:** The x-position of the ruler's second point in micron units.
- **Q:** The y-position of the ruler's second point in micron units.
- **X:** The horizontal extension of the ruler in micron units.
- **Y:** The vertical extension of the ruler in micron units.
- **A:** The area enclosed by the ruler (if it was a box) in square millimeters.

- **G:** The angle enclosed by the first and last segment of the ruler (used for angle measurement rulers).

1.1.31. Adding Images

For some applications it is necessary to show flat pixel data together with the layout. That can either be a SEM image taken or some output of a simulation tool. KLayout provides a way to add images to the display and show them below the drawn layout.

Currently, images can be read from any commonly used image format available in Qt (i.e. PNG, JPG, TIF ...). Color and monochrome images are supported. Internally an image is stored as a matrix of float values and it is possible to write custom importers using RBA.

To add an image, use the "Add Image" function from the "Edit" menu. An image property dialog will appear where the image can be specified. Choose an image using the "Browse" button next to the file name box.

An image has a variety of properties which mainly affect the way it is displayed:

- **Pixel size:** The size of one pixel in micron units. This affects the total size of the image.
- **Center:** This is the point where the center of the image is placed (in micron units).
- **Rotation:** An arbitrary angle by which the image is rotated.
- **Shear/Perspective Tilt:** shear and perspective tilt angles. Although it is possible to specify these angles explicitly it is far easiert to use the landmark adjustment feature to align an image with a layout.
- **Mirror flag:** If this option is checked, the image is mirrored at the bottom edge before it is rotated.
- **Pixel value range:** The pixel value corresponding to minimum and maximum. For normal 8 bit image formats, these values are 0 and 255. They can be adjusted which allows brighten or darken images. For float images (i.e. simulation data), this value should reflect the bounds of the output values, i.e. 0.0 and 1.0 for normalized data.
- **Color mapping:** For monochrome images, the values are converted to colors with a mapping function. The image properties page contains a tab for specifying an arbitrary mapping of data values to colors. This is achieved by placing color sample points on the data range axis and assigning colors to them. Double click at the axis to set new points, click on them to select them and adjust their color with the color box. Select and press "Del" to delete a sample point.
- **Brightness, Contrast and Gamma:** Three sliders for changing these values are provided on the respective tab.
- **RGB channel gains:** Additionally, each color channel can be weighted with a given factor on the respective tab.

Once an image is placed, it can be moved and resized using the "Move" function. The images properties can be adjusted using the "Properties" function from the Edit menu or double-clicking at the image.

With KLayout 0.22, it is possible to define landmarks which can be set at arbitrary positions in the image and aligned with corresponding layout features by dragging them to the desired target location. See Using Landmarks To Align Images for details.

An arbitrary number of images can be placed on the layout view. To store the setup, save the session using the "File/Save Session" function.

1.1.32. Using Landmarks To Align Images

"Landmarks" are arbitrary positions in the image. You can define such positions graphically in an image and then, within the layout view, use the defined landmarks as handles to align an image with a layout. Depending on the number of landmarks defined, you can use this feature to compensate the shift of an image, rotation, shear or even perspective distortion.

Landmarks are defined in the landmark editor. Open the landmark editor by pressing the "Define" button in the image properties dialogs.

The landmarks editor shows the image in the left panel and a list of the landmarks already defined int the right panel. You can zoom around the image view using the same methods than in KLayout's layout view (mouse wheel, middle mouse button, zoom box with right mouse button).

To add a landmark choose "Add" mode. Then click at the desired position of the new landmark. It will be shown in the image as a small target cross symbol. To delete a landmark, choose "Delete" mode and click on the landmark to delete. You can also select a landmark from the list and enter Delete mode. In that case, the currently selected landmarks are deleted.

To move a landmark, enter "Move" mode and move the landmark. Please note that the move operations follows KLayouts "pick and place" philosophy, so you have to click with the mouse twice: once to pick the landmark and second to drop it. The advantage of this approach is that you can zoom while dragging the landmark.

It does not make much sense to define more than 4 landmarks because for more the transformation derived from the landmarks is overdetermined. For best accuracy it is important to select landmark positions that span a large region. In particular, landmarks should not be too close and three landmarks should not form a line.

Dependent on the number of landmarks, KLayout can adjust the following parameters of the image:

- **1 Landmark**: displacement
- **2 Landmarks**: displacement, rotation and magnification
- **3 Landmarks**: displacement, rotation, magnification and shear
- **4 Landmarks**: displacement, rotation, magnification, shear and perspective distortion

Once the landmarks are defined, they can be used to adjust the image's display transformation. To do so, enter "Move" move in KLayout. When the mouse is over the image, the landmark symbols are shown and can be picked with the mouse. When you pick up a landmark and move the mouse, KLayout will adjust the image transformation and display the image frame according to the new transformation. When you drop the landmark, the image will be transformed accordingly.

Depending on the number of landmarks, KLayout can adjust either some or all transformation parameters such as displacement, angle etc. such that the other landmarks stay on the same position. In some cases that may not be desired. For example, if four landmarks are defined and one of them is moved, the result may be an extreme perspective distortion. Usually one would do a coarse adjustment by roughly adjusting the position and magnification and use the perspective transformation only to fine-adjust the image finally.

Hence, KLayout allows reduction of the degree of freedom it has when adjusting the transformation. While you drag a landmark, you can use these modifier keys:

- **Shift**: Only adjust displacement
- **Ctrl**: Adjust displacement, rotation and magnification
- **Shift+Ctrl**: Adjust displacement, rotation, magnification and shear

1.1.33. Browsing Shapes

A simple shape browser allows browsing all shapes on a layer. To do so, select the layer or layers to browse in the layer list and choose "Browse shapes" from the "Tools" menu.

A browser dialog will appear that lists the cells, shapes and cell instances. Selecting a cell will display all shapes in the cell in the middle list and the cell's instances with respect to the top cell in the right list.

If a shape is selected, the layout canvas highlights this shape by drawing a marker box around the shape and zooming to the shape. How the shape is shown can be configured on the "Configure" tab of the shape browser dialog or on the respective page in the "Setup" dialog.

Another feature that among many other things allows inspection of shapes is the "Search and replace" function (see Search and Replace).

1.1.34. Browsing Instances

All instances of a cell can be browsed by selecting the cell in the cell list (not making it the new top), and choosing "Browse instances" from the "Tools" menu. A simple instance browser comes up that shows all cells that the given cell is instantiated in and how the cell is instantiated.

Another feature that among many other things allows inspection of instances is the "Search and replace" function (see Search and Replace).

1.1.35. The Marker Browser

KLayout offers a generic concept of storing error markers or related information. This concept is called the "Report database" (RDB). An arbitrary number of report databases can be associated with a layout view. Usually, each database refers to a certain layout but that is not a strict requirement.

A report database primarily is a generic collection of "values", which can be strings or other items. Usually, a value is a collection of geometrical objects which somehow flag some position or drawn geometry. Multiple of such values comprise a "marker item". The report database associates these marker items with additional information:

- **Tags:** Flags that indicate certain conditions. The marker browser uses a couple of predefined tags like "important", "waived" and "visited" which can be set or reset by the user indicating whether a marker item is considered important or an error has been waived.
- **Image:** A marker can be assigned a screenshot image which serves for documentation purposes.

Marker items are organized into categories. Each marker item must be associated with a category. Categories themselves can be organized hierarchically, i.e. categories can be split into sub-categories. This offers a way of improving the organisation of such categories.

Marker items are usually associated with a cell, i.e. where a error was detected. By default, a marker item is simply associated with the top cell.

The report database uses a proprietary format based on XML which is capable of storing the annotations provided by the database. It is possible however to import Calibre DRC ASCII format files.

The marker browser is a tool to browse a report database associated with a view. The marker browser can be started using the "Marker Browser" function in the "Tools" menu. The marker browser tracks whether a marker has already been visited similar to the "read" flag in a mail client. This allows tracking of a review session. The "visited" state is reflected in the database file.

In the marker browser, use the "Open" button to load a XML database file or import files from other formats. Choose "Reload" to reload a file and "Save As" to write a database in XML format.

The marker browser offers three panels:

- **Directory:** This panel lists the categories and cells of the database. Categories or cells with unvisited markers will be shown in bold font. Such with no markers at all are shown in green color. It is possible to suppress these categories or cells by deselecting "Show All" in the directory's context menu. To have the lists sorted by marker count, click at the header of the count column.
  Multiple categories or cells can be selected. In that case, the markers panel will show the markers of all selected cells or categories.
- **Markers:** This panel lists the markers in the selected category and/or cell. A length of the list is limited and can be changed on the configuration page ("Configure" button on the marker browser or in the setup dialog). Various tags are shown in this panel as well. The list can be sorted in various ways by clicking at the respective header.
  When a marker is selected in this list, it will be highlighted in the layout, provided a suitable layout is associated. The way a marker is highlighted and how the view is adjusted can be specified on the configuration page.
- **Info:** This panel summarizes the information for the selected marker. If a screenshot was associated with the marker it is shown here. Click on the thumbnail image to show it in a separate window in the original size.

Similar to the shape and instance browsers, the marker browser offers navigation buttons to select the next marker, category or cell.

The marker browser supports "tagged values": each marker can be associated with a value that has a name. Such values can be imported from RVE files where they are called properties. Tagged values are generated by certain generators and can represent measurement values or similar. When tagged values are present, they will be shown in the markers list. The markers can be sorted by these values by clicking on the appropriate header.

1.1.36. Technology Management

A new feature of KLayout 0.22 is technology management. Technology management summarizes features which require a certain interpretation of a layout. In particular, layout layers are assigned a physical meaning, for example via layers or active area layers in CMOS technologies. Since that interpretation often is depending on the technology the product will be fabricated with, the ability to provide multiple setups is summarized as "technology management".

The "Technology Manager" in the "Tools" menu is the user interface that allows creating, deleting and editing of technology setups. Read more about the technology manager in About Technology Management

1.1.37. Selecting Rulers, Shapes Or Instances

Rulers, images, shapes or instances can be selected by either clicking on the shape, instance, ruler or image in "Select" mode or by dragging a selection rectangle with the left mouse button pressed. In this case, all objects inside the selection rectangle will be selected.

Pressing the Shift key in addition to selecting shapes, instances or other objects will extend the current selection. Pressing Ctrl key will remove the given objects from the selection.

For layout objects (shapes and instances), it is possible to select the objects through the hierarchy or on the level of the current cell only (top level objects only). By default, objects are selected through the hierarchy. That means, objects in child cells can be selected. By extending the selection over multiple instances of a cell, the same object can be selected multiple times. While editing objects inside a child cell may be a desirable feature, this can lead to confusing effects in the end. Hence, it may to more intuitive to only work on top level, i.e. on the current cell. To enable this mode, check the "Select Top Level Objects Only" menu item in the "View" menu or the same in the edit mode options dialog (F3).

In top-level only mode, instances of cells are selected only if the cells have a visual appearance. This is the case, if they contain at least one shape on a visible layer for example. If they are empty with respect to the visible layers, they cannot be selected. If the cell's box is shown, because the hierarchy levels shown are confined a sufficiently small interval, the cell instances will always be selected.

Images and rulers are simple objects not embedded in a hierarchy and can be selected by clicking at them or enclosing them in the selection box.

Object properties can be inspected or edited (if allowed) by opening the properties dialog. To edit or inspect the properties of selected objects, choose "Properties" from the "Edit" menu. A dialog will open which shows the properties for the first selected object. To proceed to the next object push the "Next" button, to go back to the previous object push the "Previous" button.

Depending on the application mode, the properties of the selected objects may be edited too. To apply changes to the current object, choose "Apply". To apply the changes and close the dialog, choose "Ok". To apply the changes to the current object and all other selected objects of the same kind, choose "Apply To All" (if applicable). To close the dialog without applying any changes, choose "Cancel".

"Apply To All" will try to apply the changes in some smart way to other objects. For example, for boxes, and change of the box dimensions will be applied in the same way (same shift in the four directions) than for the current object. If the width of a path has been changed, the same width will be applied to all other paths and so forth.

For shapes and instances, the "User properties" can be edited too. "User properties" are arbitrary properties attached to shapes and instances. They consist of a key (preferably a number for GDS2 compatibility) and a value (preferably a string in GDS2). Multiple properties of that kind can be attached to one object. User properties can be edited by pushing the "User Properties" button which will open a dialog that allows editing of the properties. If this dialog is closed with "Ok", the user properties will be kept, but applied to the layout object only after pressing "Apply"/"Ok" or "Apply To All". The latter will apply the new properties to all other shapes of the same kind.

Finally, for shapes and instances, the "Instantiation" button will show the instantiation path of the shapes or instances.

The layer of a shape cannot be changed through the properties dialog. To move a shape to a different layer, use "Change Layer" from the "Selection" sub-menu in "Edit".

1.1.38. More Configuration Options

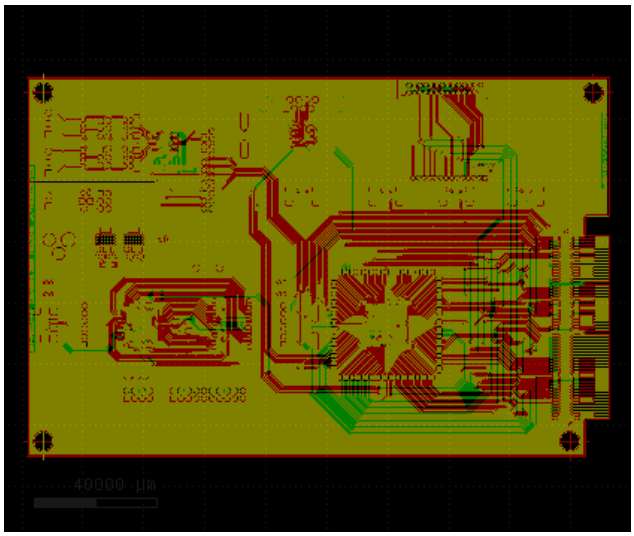
The option dialog available with the "Setup" function from the "File" menu offers numerous configuration options from background to rulers configuration.

In this dialog for example, the color palette can be edited, so that different colors are available or the stipple palette can be configured. In addition, it is possible to define the order how these colors or stipples are assigned to layers initially and which colors are not used for layer coloring.

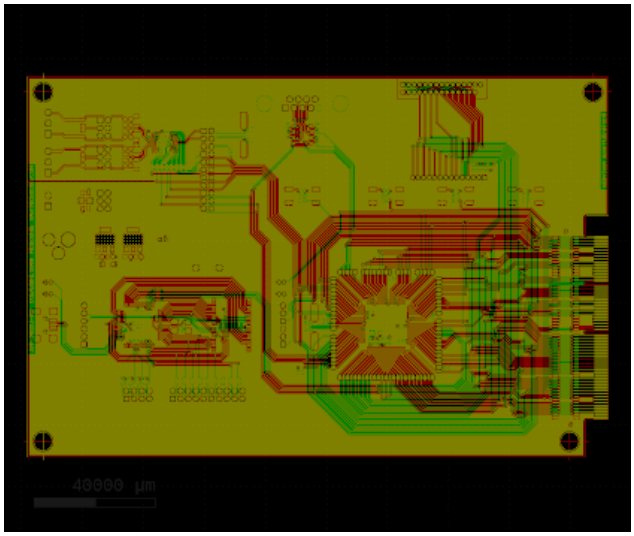
A particular useful feature is the oversampling scheme. Oversampling is provided as an option to enhance the image quality. The image is rendered at a higher resolution and then downsampled to the screen resolution. In effect, lines appear thinner and more details can be resolved. As a negative side effect currently the stipple pattern becomes finer and the crosses in marker mode are smaller. On the other hand the resolution effect can be quite impressive.

Oversampling can be enabled on the "Display/General" page in the setup dialog. 2x and 3x oversampling is provided. The following screenshots illustrate the effect of oversampling:

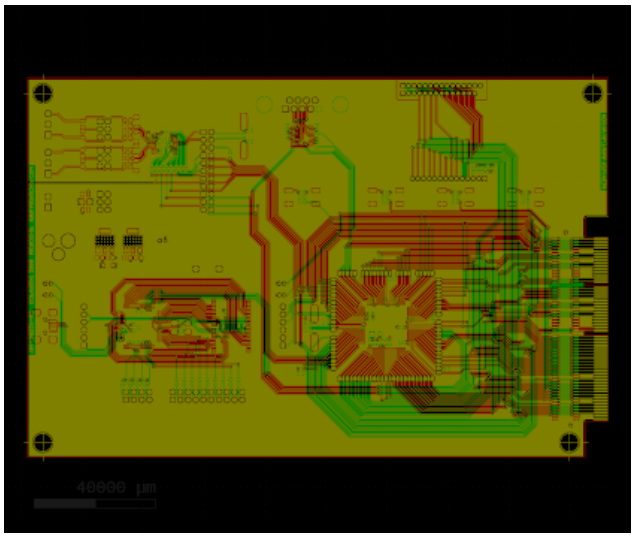
Normal (1x)



2x oversampling



3x oversampling



1.1.39. Undo And Redo

Most operations such as changing of layer colors can be undone using the "Undo" function from the "Edit" menu. Analogous, the operations can be redone again using the "Redo" function from the "Edit" menu.

1.1.40. Saving A Layout Or Parts Of It

A layout or a subcell of it can be saved to either GDS2 or OASIS. To save a layout, choose "Save As" from the "File" menu. To save just a cell, select the cell in the cell tree (it does not need to be the currently shown one) and select "Save Current Cell As" from the context menu (right mouse button) of the cell tree.

A file dialog will pop up to select the file name to which to write the cell or layout. After a file has been selected, an option dialog will be shown to specify further options. In this dialog, it is possible to constrain saving to a subset of layers, i.e. just visible ones. Also, the database unit can be changed or the layout can be scaled by a given factor.

For OASIS, a compression level can be specified. At a level of 0, no particular attempt is made to compress shapes. At higher levels, shapes are classified and array compression is tried. The higher the level, the more attempts are made to compress shapes into arrays. In particular for flat layouts, compression of shapes requires some memory and slows down OASIS writing considerably.

1.1.41. Saving And Restoring A Session

A session can be saved and restored later. A "session" involves the files loaded, bookmarks, annotations, layer settings, hierarchy settings, images and application setup. Sessions are stored as XML files with the suffix ".lys".

To save a session, choose "Save Session" from the "File" menu. To restore a session, choose "Restore Session". KLayout can be started with a certain session using the "-u" option from the command line followed by the session file. On Windows installations, session files are registered as being opened automatically by KLayout.

1.1.42. Further View Options

The "View" menu offers some more options to tune the display:

- **Show Grid**: This is a fast access method for the respective configuration option. Unchecking this menu entry hides the grid lines and the scale bar.
- **Grids**: this submenu allows fast access to the current grid setting. You can choose from one of the default grids that are configured on the "Default Grids" page in the "Application" section of the setup dialog. Grids are mainly used for editing geometry but also for snapping rulers if they are configured to do so.
- **Show Texts**: when this option is unchecked, texts are not drawn. That applies to text objects and user properties. Drawing is somewhat faster when texts are not drawn.
- **Show Cell Frames**: when this option is unchecked, cell frames from hidden cells or cell below the hierarchy levels selected are not drawn.
- **Show Layers Without Fill**: when this option is checked, the shapes are drawn without fill. Hence the layout is shown in a kind of wire frame. This option is intended to temporarily disabling the fill pattern. Keeping this option checked may be confusing because setting a fill pattern may not have any effect then.
- **Synchronized Views**: with this option, all views (tabs) in the main window are synchronized, i.e. they show the same region of the layout. This option can be useful if two layouts are loaded in different views for clarity, but identical regions need to be inspected.
- **Select Top Level Objects**: this menu item gives a quick access to the respective editor option. If this option is checked, only objects from the top level are selected. This is in particular important for editing because editing a subcell can cause effects in other places there that cell is instantiated but no edit is intended.
- **Toolbar**, **Navigator**, ...: disable or enable the respective tool windows.
- **Highlight Object Under Mouse**: with this option checked, the object under the mouse is highlighted temporarily if the mouse hovers over that object. Since that can be confusing in some (rare) cases, this menu item provides quick access to that configuration option.

1.2. Editing Functions

Welcome to KLayout's user manual. This is the manual chapter covering the editing features of KLayout. The editor features are available only if KLayout is started in editor mode. The following subtopics are available:

1.2.1. Edit Mode

Editor functions can only be used if KLayout runs in edit mode. KLayout can be put into editing mode by simply supplying the "-e" option on the command line:

`klayout -e` [<input file>] [`-l` <layer properties file>]

Accordingly, with the command line option "-ne", non-editable mode can be enforced.

On Windows, there are start menu entries for editor and viewer mode. Klayout can be configured to use editing mode as default when started. To enable editing by default, check the "Edit mode" check box on the "Application" tab in the setup dialog ("File/Setup").

In editing mode, some optimizations are disabled. This results in somewhat longer loading times and a somewhat higher memory consumption. The actual increase strongly depends on the nature of the input file: for example, OASIS shape arrays are not kept as such in editing mode and resolved into individual shapes.

1.2.2. Basic Principles Of Editor Mode

This section covers the basic working principles of editor mode.

1.2.2.1. Pick And Drop Principle

Most drawing programs employ the click-and-drag paradigm: left-click on an element and drag it to the destination keeping the mouse button pressed. Although being pretty intuitive, this principle has one disadvantage: it is hard to do something other than dragging, while you keep the mouse button pressed. In particular this means: no zooming (or would you like to press the right mouse button as well, draw the zoom box and then release just the right mouse button ...?). In order to allow zoom and potentially other operations, KLayout employs the pick-and-drop-principle.

In pick-and-drop, you pick an element by clicking at it with the left mouse button, move it (without any mouse button pressed) and drop it (by left-clicking at the target position). Since the mouse button is not pressed, the mouse is free for other operations: just the dragged item is "sticking" to the mouse cursor.

In addition, while dragging the object, Shift and Ctrl keys can be used to force certain direction constraints or override the ones specified in the options (i.e. "move" or "edit" options): The Shift key forces KLayout into orthogonal mode: movements are restricted to horizontal or vertical unless not applicable. The Ctrl key forces KLayout into diagonal mode: movements are restricted to horizontal, vertical or the diagonal axes. Ctrl plus Shift will release all directional constraints - movements will be allowed in any direction.

1.2.2.2. Basic Editor Options

Most tools being using in editing mode have certain options, i.e. when drawing a path, the width and extension mode has to be specified. There exists a general setup dialog for editing options. It can be opened using "Editor Options" from the "Edit" menu or using the F3 shortcut (unless overridden).

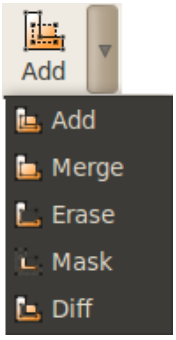
In the dialog there is always a generic settings tab and - depending on the tool chosen - a tool specific tab. On the generic tab, these settings can be changed:

- **Editor grid:** Every editing operation is confined to that grid. It can be either disabled, aligned with the global grid (used i.e. for rulers and display) or specified explicitly. It can even be anisotropic - i.e. there can be a different grid in y than in x direction.
- **Connection angle constraint:** When a connection is drawing, i.e. a segment of a path or an edge of a polygon, this mode determines, if the segment or edge is confined to certain directions. In "Any Angle" mode, there is no such confinement. In "Diagonal" mode, the edge or segment can be vertical, horizontal or in one of the two diagonal directions. In "Manhattan" mode, only horizontal and vertical edges or segments are allowed.
- **Movement direction constraint:** When something a dragged (i.e. moved), this mode determines if the movement is confined to certain directions. In "Any Direction" mode, there is no such confinement. In "Diagonal" mode, the movement can be vertical, horizontal or in one of the two diagonal directions. In "Manhattan" mode, only horizontal and vertical movements are allowed.
- **Top level selection mode:** In top level selection mode (when the check box is checked), only elements on the level of the currently shown cell are selected ("top level" refers to the top level of the currently shown cell here). That means, that if shapes from a subcell are selected, the whole instance of this subcell is selected.
  In hierarchical selection mode (when the check box is not checked), elements are selected from subcells are well. This mode allows in-place editing of subcells which is a powerful feature but also creates strange side effects if other instances of this cell changes as well.

Whenever you change something in the settings dialog, use "Apply" or "Ok" to apply your changes.

1.2.2.3. Background combination modes

KLayout offers several ways to combine the shapes drawn with shapes that are already there. The mode can be selected with the "Select background combination mode" tool button in the tool bar:



These are the modes available:

- **Add**: this is the default mode: the drawn shape will simply be added to the existing shapes.
- **Merge**: in this mode, the drawn shape will be merged with the existing shapes. This operation will always render a polygon that is the drawn shape merged with any polygons that touch or overlap the drawn shape. Paths will be converted to polygons always. This mode is equivalent to a boolean "OR" operation.
- **Erase**: in this mode, the drawn shape will be subtracted from the existing shapes. This mode can be used to create notches or slits in shapes touching or overlapping the drawn shape. The drawn shape will vanish. This mode is equivalent to a boolean "NOT" operation.
- **Mask**: in this mode, the drawn shape will act as a mask for existing shapes. Only the parts overlapping the drawn shape will remain. This mode is equivalent to a boolean "AND" operation.
- **Diff**: finally, in this mode, the drawn shape will invert existing shape. This mode is equivalent to a boolean "XOR" operation.

1.2.2.4. Selection

The basic entity that some operations work with is the "selection". This is basically a set of shapes of instances on which an operation should be applied. A selection can be established by either clicking on a element in "Select" mode or by dragging a selection rectangle. When the mouse is released, all elements inside the selection rectangle are selected.

The selection set can be modified by adding elements (press the Shift button in addition to selecting elements), by removing elements (press Ctrl in addition) or by toggling the selecting (press Shift and Ctrl in addition: remove already selected ones and add new ones).

1.2.2.5. Partial Mode

"Partial editing" is a powerful feature that allows modification of shapes. Edges or segments of polygons resp. paths can be moved, vertices, edges or segments from polygons or paths can be deleted and new points can be inserted into polygons and paths. "Partial editing" can be applied to a complex partial selection: Multiple edges or vertices can be selected and deleted or moved.

The normal selection works "full element". In this mode, the whole shape is being moved or deleted. Only in full element mode, shapes or instances can be sent to the clipboard.

1.2.3. Basic Editing Operations

This section covers some basic operations when editing layout.

- Creating A Layout From Scratch
- Creating A New Layer
- Creating A New Cell
- Creating A Polygon
- Creating A Box
- Creating A Text Object
- Creating A Cell Instance
- Moving The Selection
- Other Transformations Of The Selection
- Partial Editing
- Moving Shapes To A Different Layer
- Other Layer Operations
- Copy And Paste Of The Selection
- Delete A Cell
- Rename A Cell
- Copy And Paste Of Cells

1.2.3.1. Creating A Layout From Scratch

To start with a fresh, empty layout, choose "New" from the "File" menu. A form is opened that requires you to specify some basic parameters. These are:

- **Top cell:** this is the name of the first (and only) cell that will be present in the layout.
- **Database unit:** this is the database unit (the conversion factor between integer coordinates and micron units. This is basically the "resolution" of the layout.
- **Initial window size:** this is the size of the initial window shown, when the top cell is opened the first time. Since the initial view is empty, there is no geometrical guidance. By specifying an initial size, at least the "canvas" dimensions are known.

If a default layer properties file is specified in the setup dialog ("Application" tab), this is loaded into the layer view list automatically. Without such a file, the layer list is empty at the beginning and layers must be created with "Layer/New" from the "Edit" menu, before any shapes can be drawn.

1.2.3.2. Creating A New Layer

You can create new layers using the "Layer/New Layer" function from the "Edit" menu. You are prompted to enter GDS layer and datatype numbers and optionally an OASIS layer name. On "Ok", the layer will be created and will be inserted into the layer panel.

1.2.3.3. Creating A New Cell

You can create new cells using the "New Cell" function from the hierarchy panel's context menu (right mouse click on the cell hierarchy panel). You are prompted to enter the new cell's name (a cell with that name must not exists yet) and a window size. The window size is the initial dimension of the view when the new cell is shown. Apart from that it does not have any meaning.

1.2.3.4. Creating A Polygon

Select "Polygon" mode from the toolbar. Choose a layer from the layer panel in which to create a new polygon. Left-click at the first vertex of the polygon. Move the mouse to the next vertex and place a new one with a left mouse button click. Move to the next vertex. Depending on the connection mode, the edges created are confined to certain directions. See Basic Editor Options for a detailed description of the modes. Use the "editor options" dialog (F3 shortcut) to change the mode, even during editing.

Double-click at the final point to finish the polygon. Press the ESC key to cancel the operation.

A polygon will never be "open": there are always edges connecting the current vertex with the initial one. Depending on the mode, this final connection is either a straight line or a combination of edges. In "diagonal mode", there are manifold possibilities to create a final connection in a more or less smart way. The program uses some heuristics to determine one feasible combination. Although this heuristics is not infinite smart, it should be easy to lead the algorithm to the desired solution, by pointing the mouse into the desired direction.

1.2.3.5. Creating A Box

Select "Box" mode from the toolbar. Choose a layer from the layer panel in which to create a new box. Left click at the first point, move the mouse to the second point and finish the box by left-clicking at the second point. Press the ESC key to cancel the operation.

Hint: A box, once created, will remain a box. For example, it is not possible to delete one vertex of it, thus forming a triangle. This is only possible for polygons.

1.2.3.6. Creating A Text Object

Select "Text" mode from the toolbar. The editor options dialog will open that additionally prompts for the text string. Don't forget to click "Apply" to take over the current string. If the dialog has been closed unintentionally, it can be reopened with the F3 shortcut.

To actually draw the text, move the mouse to the desired location and left-click to place it.

A text can be given a size which is stored in a GDS2 file (OASIS files do not provide this feature). The size of the text is only shown in the layout if a scalable text font is selected (the "Default" font is not scalable) and text scaling is enabled. In order to do so, choose a scalable font from the "Text font" selection box in the "Display" tab of the setup dialog and check the "Apply text scaling and rotation" box in the same tab.

The text can also be rotated, which is shown as well only if text scaling and rotation is enabled. To rotate a text while placing it, click the right mouse button. This will rotate the text by 90 degree counterclockwise.

1.2.3.7. Creating A Cell Instance

Select "Instance" mode from the toolbar. The editor options dialog will open that additionally prompts for some instance parameters. The most important one of course is the cell that shall be placed. Geometrically, the rotation angle can be specified, the mirror option can be set and the instance may be specified as a regular array. As an array, the instance represents multiple placements of the cell, arranged in regular grid which is specified by the two axis vectors and instance counts in each direction. Don't forget to click "Apply" to take over the current settings. If the dialog has been closed unintentionally, it can be reopened with the F3 shortcut.

To place the instance, move the mouse to the desired location and left-click to place it. While moving, the right mouse button can be used to rotate the instance by 90 degree counterclockwise. Press the ESC key to cancel the operation.

Starting with version 0.22, KLayout supports libraries. Libraries provide cells from the outside of the layout. These cells are imported into the layout and a copy is stored inside the layout. Still, KLayout maintains the reference to the original layout, so if the library changes, the cell will be replaced when the layout is loaded again. Cells imported from a library appear as "Library.Cell" in the cell tree and the layout. Here, "Library" is the library name and "Cell" is the cell name.

The library is selected from the pull-down box to the right of the cell name. You can use the "..." button to browse the cells available in the selected library.

Libraries are a convenient way to provide common layout building blocks. In addition, KLayout now also supports PCells (parametrized cells). Such cells do not have a static content, but instead they are created dynamically from a piece of code using a set of parameters specific for the PCell type. For example, a circle has two parameters: the layer where the circle should appear and the radius of the circle.

PCells are provided by libraries. If a PCell is selected from a library, the instance properties page also offers a panel to edit the PCell parameters. What parameters are available depends on the type of PCell.

KLayout comes with a standard library "Basic" which offers some basic curved shape types and a text generator.

KLayout offers a unique feature for the PCell implementation: a PCell can employ "guiding shapes". "Guiding shapes" are shapes that do not appear as layout themselves but are used by the PCell to derive its geometry from. For example the "rounded path" PCell of the "Basic" library uses a path as a guiding shape. This path is manipulated to obtain the final shape.

Guiding shapes are drawn on the cell box layer and can be manipulated with the normal shape manipulation functions (in particular move and partial edit). Also, the shape properties can be edited via the "Edit/Properties" function.

To learn more about libraries, read About Libraries. Read About PCells for details about PCells.

1.2.3.8. Moving The Selection

The whole selection can be moved in "Move" mode. If some elements are already selected, choose "Move" mode and select a reference point by left-clicking at the position. The reference point will be used as the "dragging handle" - each element is moved relative to this position. In no elements are selected when entering move mode, simply click at the element to move and place it somewhere else with a left mouse click.

While moving, the whole selection can be rotated by 90 degree counterclockwise with a right mouse button click. The ESC key will cancel the operation.

For movements, the movement direction constraint apply. See Basic Editor Options for details about the modes available. For example, in manhattan mode, only horizontal and vertical movements are allowed. The global movement constraint can be overridden by pressing Shift (orthogonal), Ctrl (diagonal) or both Shift and Ctrl (any angle) while moving the mouse.

If a move distance and direction is known numerically, "Move By" from the "Edit/Selection" menu can be used. A dialog will open that allows specification of the horizontal and vertical move distance in micrometers. Positive values move to the top or right and negative ones to the bottom or left. This dialog also applies to partial mode, so that edges or parts of a layout can be moved precisely by a certain distance in a certain direction.

In the same way, "Move To" allows one to reposition the selection to a certain point. The point which is positioned can be chosen relative to the bounding box of the selection. If first example, the lower-left corner of the selection is picked as the reference point and a certain position is given in the dialog, the selection is moved such that the lower left position of its bounding box will match the given coordinate.

1.2.3.9. Other Transformations Of The Selection

The selection can be flipped at x- or y-axis, rotated as a whole or moved by a certain distance using the functions available in the "Selection" submenu of the "Edit" menu. For example, "Flip Vertically" flips the selection at the x-axis. A selection can be rotated by an arbitrary angle using the "Rotation By Angle" function from the "Selection" submenu.

1.2.3.10. Partial Editing

When objects have to be modified after the have been created, partial editing comes into play. "Partial" refers to the fact that just parts of a polygon or path are edited. For example, just one vertex or an edge of a polygon can be moved. Partial editing mode also allows deleting single vertices or edges or to insert new ones. In partial editing mode, multiple edges or vertices can be selected, even a whole shape can be selected and can then be moved or deleted.

When moving the selected parts, the movement direction constraint applies. See Basic Editor Options for details about the modes available. For example, in manhattan mode, only horizontal and vertical movements of parts are allowed. Again, the global movement constraint can be overridden by pressing Shift (orthogonal), Ctrl (diagonal) or both Shift and Ctrl (any angle) while moving the mouse.

To enter partial mode, click on the "Partial" button in the toolbar. Parts (edges or vertices) can then be selected either by simply clicking at them or by dragging a selection rectangle. As in normal selection mode, the modifier buttons Shift and Ctrl can be used to add a selection to the existing one or to remove elements from the existing selection. Partial selection is subject to the "top level only" constraint (see Basic Editor Options for a description of the top level selection mode).

Simply clicking at an item immediately enters "move" mode. In this mode, you can position the element at the desired target location and place it there by left-clicking at the position. Press "ESC" to cancel the operation. When a complex selection is made, move mode is entered by clicking at one of the selected items (the edges or vertices, not the shape to which they belong).

When moving parts, certain constraints apply, i.e. single edges can only be moved perpendicular to their current position. In addition, the movement is confined to the editing grid.

The selected items can be deleted by using the "Delete" function from the "Edit" menu or pressing the "Delete" key. If not enough vertices remain to form a valid object, the object is deleted (i.e. a polygon with less then 3 points).

By double-clicking at an edge or path segment, an additional point is created on this edge at the cursor's position. You can create a "bend" on a path by placing two new vertices on that segment and moving the connecting segment between these vertices away from the former center line. This basically requires two double-clicks on the path's centerline, a single click on the newly formed segment and a single click to drop it at the new position.

1.2.3.11. Moving Shapes To A Different Layer

The selected shapes can be moved to a different layer as a whole. For this, choose "Change Layer" from the "Selection" submenu of the "Edit" menu. All selected shapes are moved to the layer that is the current one (marked with a rectangle) in the layer list. The shapes will not be moved across the hierarchy but just inside their cell.

All layers (source and target) must be located in the same layout. To move shapes to a different layout, use copy & paste.

1.2.3.12. Other Layer Operations

The layer specification can be edited using the "Edit Layer Specification" method from the "Layer" submenu inside the "Edit" menu. A dialog is shown in which the layer, datatype and (OASIS) name of the layer currently selected in the layer panel can be edited. On save, the shapes are then mapped to the new layer.

A layer can be cleared (either cellwise, on a cell's hierarchy or for all cells) using the "Clear Layer" method from the "Layer" submenu inside the "Edit" menu.

Layers can be copied (duplicated) using "Copy Layer" from the "Layer" submenu inside the "Edit" menu and deleted completely using "Delete Layer".

1.2.3.13. Copy And Paste Of The Selection

Of course, copy and paste is supported as usual. Shapes can be copied between layouts: by opening two layouts, shapes can be moved from one layout to another. The shapes are mapped to the same layer than they have been on in the source layout. If a layer does not exist yet in the target layout, it is created.

Shapes in the selection are simply copied to the clipboard in the way they appear in the current cell. This means, if the shapes are pasted into a different layout they are put on the same position, but flat into the current cell. This provides a way to flatten a hierarchy: choose "hierarchical selection mode" in the editor options dialog (deselect "top level only"), select the shapes to flatten and copy everything to a different cell.

In non-hierarchical selection mode ("top level only" selection mode) or by clicking on a cell frame when the hierarchy levels are limited, instances can be selected as well. When copying instances to the clipboard, two possible methods exist:

- **Shallow copy:** In this mode, just the instance is copied. When it is pasted into any target layout, the target cell of the instance is looked up and instantiated.
- **Deep copy:** Not only the instance but the instantiated cell is copied as well. When pasting that into a different layout, the target cell will be created as well. If a cell with that name already exists, a variant is created and instantiated.

1.2.3.14. Delete A Cell

To delete a whole cell, select the cell in the hierarchy browser and choose "Delete Cell" from the context menu (right mouse button). This time, three possible modes are offered:

- **Shallow delete:** Just the cell (its shapes and instances) are deleted, not any cells referenced by this cell. Since cells might no longer be referenced after that, they may appear as new top cells in the layout.
- **Deep delete:** The cell and all its subcells are deleted, unless the subcells are referenced otherwise (by cells that are not deleted). In this delete mode a complete hierarchy of cells can be removed without side effects.
- **Complete delete:** The cell and all its subcells are deleted, even if other cells would reference these subcells.

1.2.3.15. Rename A Cell

To rename a cell, select the cell in the hierarchy browser and choose "Rename Cell" from the context menu (right mouse button). You are prompted for a new name which must not exist yet.

1.2.3.16. Copy And Paste Of Cells

Whole cells can be copied to the clipboard as well. To copy a whole cell, select the cell in the hierarchy browser (make sure the focus is in that window) and choose "Copy" or "Cut" from the "Edit" menu. To paste such a cell into a target layout, choose "Paste" from the "Edit" menu.

Two copy modes are provided: deep and shallow copy. When "copy" or "cut" is chosen and the cell instantiates other cells, a dialog will been shown in which the mode can be selected:

- **Shallow copy**: In shallow mode, only the cell itself will be copied. No copies of the child cells will be created. If a cell copy is created, the cell will call the same cells than the original cell. If a cell is copied to another layout (in a different tab), the child cells will not be carried along and "ghost" cells will be created or existing cells with the same name will be used as child cells.
- **Deep copy**: In deep copy mode, the cell plus its child cells are copied. All cells will be carried along and when pasting the cell, copies of all children will be created as well.

When a cell is pasted into another layout and there is a "ghost cell" with that name, the pasted cell will replace the ghost cell. If there is a normal cell with that name, a new cell variant will be created and the name of the pasted cell will be changed by adding a suffix to create a unique name.

Copying a cell in deep copy mode from one layout to another provides a way to merge two layouts into one: simply copy the top cell of the first layout into the second one and instantiate both in a new top cell for example.

1.2.4. Advanced Editing Operations

This section covers the more advanced features of editor mode.

- Layout Transformations
- Search and Replace
- Hierarchical Operations: Flatten Instances, Make Cell From Selection, Move Up In Hierarchy
- Creating Clips
- Flatten Cells
- Resolving Arrays
- PCell Operations
- Layer Boolean Operations
- Layer Sizing
- Shapewise Boolean Operations
- Shapewise Sizing
- Object Alignment
- Corner Rounding
- Cell Origin Adjustment
- Create Cell Variants

1.2.4.1. Layout Transformations

Some functions are available to transform a whole layout. Whole-layout transformations are applied to all cells in a way that every cell will be modified in the same way. This feature is specifically useful for scaling layouts. It is worth noting that scaling a layout this way does not produce instances with magnifications.

The layout transformation functions are available in "Edit/Layout" (flip, rotate, scale, move).

1.2.4.2. Search and Replace

KLayout offers a "search and replace" function which provides a basic search and search+replace, but also a very generic and powerful extended feature called "custom queries" (see below for that). The search and replace dialog can be found in the "Edit" menu under "Search and replace".

The dialog provides four tabs in the left panel: "Find", "Delete", "Replace" and "Custom". The functionality of these four tabs is explained below.

The left side of the dialog will hold results for operations which deliver a result, for example the "Find" operation. The result is a list which displays various items, depending on the nature and parameters of the operation. If the item represents a layout object, for example a shape or a cell instance, the items selected in the list are highlighted in the layout to indicate their position. The length of the list is limited to avoid performance degradation for very long lists. The number of items shown can be configured on the configuration page.

The configuration page which allows configuration of the search and replace dialog's behavior is shown when the "Configure" button at the left bottom corner is pressed. It can be found as well in the setup dialog under "Browsers", "Search Result Browser".

Find

The functionality of the "Find" tab is simple: Various conditions can be specified and all objects matching that condition are listed when the "Find" button is pressed.

The parameters of that function involve: Object type, cell scope and object specific conditions. The object type is either "Instances" or a shape object. For shapes, the shape type can be confined to "Box", "Polygon", "Path" or "Text" which enables specific features.

The cell context can be one of:

- **Current cell**: look in the current cell and none else. Child cells are ignored.
- **Current cell and below**: look into the current cell and all child cells, where all instances of the children are considered.
- **All cells**: look into every cell individually, but don't consider the way the cells are instantiated.

Depending on the object type various parameters are available to be included in the condition. Each condition applies to one specific parameter and is usually composed of an operator (less, less than, equal ...) and a value against which the value of the parameter is checked. Length and area values are given in micron or square micron units.

String values can be matched against glob pattern using the tilde ("~") match and non-match ("!~") operators. Glob pattern are the ones used for file names on the command line and use "*" for an arbitrary sequence of characters and "?" for a single arbitrary character. Here are some examples for glob pattern:

A*	The string must start with a capital "A"
A	The string must contain a capital "A" somewhere
ABC?	"ABC" followed by any character
N{AND,OR}	"NAND" or "NOR"
A[0-9]	"A" followed by a digit
A[^0-9]	"A" followed by a non-digit

If the value field is left empty, no check is made on that parameter. All conditions which are checked must be fulfilled to make the object listed on the results page.

Delete

Similar to the find page, this function asks for an object type, a cell context and object specific conditions.

If the "Delete All" button is pressed, all selected objects are deleted.

If the "Select+Delete" button is pressed, the selected objects will first be shown in the result page, similar to the "Find" function. Then, some or all of them can be selected and deleted by pressing the "Delete" button below the list.

Replace

Similar to the find page, this function asks for an object type, a cell context and object specific conditions. In addition, the function allows specification of replacement values for the parameters. If an entry field is left empty for the replacement value, no replacement is made.

For strings with glob pattern matching, name parts can be reused in the replacement string. For example, if the operator is "~" on a text's string and the match string is "A(*)", the replacement string can be set to "B\1". "\1" means the value of the first bracket in the match string, hence this setup replaces all leading "A"'s by "B".

If the "Replace All" button is pressed, the replacement parameters are set on all selected objects.

If the "Select+Replace" button is pressed, the selected objects will first be shown in the result page, similar to the "Find" function. Then, some or all of them can be selected and the replacement is made on them the "Replace" button is pressed below the list.

Custom queries

The full power of this dialog is unleashed when using that page. Custom queries are not only able to provide the functionality of the three other pages (find, delete and replace), but provide functionality far beyond that simple scenarios.

Custom queries are statements resembling SQL statements with embedded expressions and a rich language to describe shape or cell instantiation details. A in-depth description can be found here: About Custom Layout Queries.

The custom query dialog page offers an entry field to enter the query and below an "Execute" button to run it. The most recently used queries can be pulled back into the edit field using the drop-down box below the edit field. Custom queries can be saved under a given name and reused. The list of saved queries can be manipulated with the buttons right to it. See the button's tooltips for a description of the button's functionality.

If the tab is switched to another tab and back, the custom query will be updated reflecting the query corresponding to the current functionality selected on the other tab.

1.2.4.3. Hierarchical Operations: Flatten Instances, Make Cell From Selection, Move Up In Hierarchy

Klayout provides several operations that move shapes or instances up and down in hierarchy. All these operations are accessible through the "Edit" menu in the "Selection" sub-menu.

- **Flatten instances**: Replace the selected instances by the contents of the instantiated cell. KLayout will ask, if all levels or just the first level of the cell should be expanded. If all levels are expanded, the cell will be resolved into a set of shapes in the current cell's hierarchy.

- **Move up in hierarchy**: Applies only to selections inside child cells of the current cell (thus does not make sense if 'top level only' selection mode is active). The selected shapes and instances are brought up to the current cell's level and removed from the original cell.
  A non-destructive way of moving a shape up in the hierarchy is to copy and paste the shape. This does an explicit flattening of the shapes selected when inserting them.
  Hint: the current implementation removes the selected object from its original cell. Since it only creates new copies for the selected instances, the object ist lost for all other instances of the cell. This may create undesired side effects and it is likely that this behaviour will change in future implementations.

- **Make cell from selection**: Removes the currently selected objects and places them into a new cell whose name can be specified.

1.2.4.4. Creating Clips

KLayout provides a utility to create rectangular clips from a given cell. One or more rectangles can be specified. The current cell is cut along the edges of these rectangles. For each rectangle, a new cell is created containing the clipped content for the rectangle. Finally, if more than one rectangle is specified, all the clips are combined into a master top cell which appears as a new top cell in the cell hierarchy.

The clips can be either specified by coordinates, taken from another layer (which must contain boxes which then are copied into the output as well) or taken from the rulers. In the latter case, the rulers' start and end points are taken as the corners of the clip rectangles. It is convenient therefore to create a new ruler type with a box appearance for this purpose.

Clips are done hierarchically: child cells are clipped as well, potentially creating variants (which may be shared by several clips). This way, large clips can be created from large layouts in an efficient way. **Hint:** Clipping will not work exactly if the layout contains cell instances with arbitrary rotation angles such as 45 degree.

1.2.4.5. Flatten Cells

A "flat" cell is a cell without hierarchy. This means that the cell contains only shapes, but no instances of child cells. Flat cells are disconnected from other cells, hence flattening is a way to "freeze" the contents of a cell: when a cell is flat, changing any other cell does not have an effect on this cell or in other places of the cell. On the other hand, flat cells store each shape individually, hence cannot make use of data compression be reuse of geometry.

A hierarchical cell can be flattened by choosing "Edit/Cell/Flatten Cell" or "Flatten Cell" from the cell list context menu. The flatten operation offers some options, i.e. the number of hierarchy levels to flatten and how to deal with child cells which become obsolete through this operation ("orphan cells"). By enabling this "prune" option, all child cells are removed when they are no longer needed. Otherwise, new top level cells will appear in that case - these are the cells which are not longer instantiated.

"Flatten" can also be applied to instances. In that case, the cell instance is removed and replaced by the objects inside this cell. So instance flattening is a way to pull the contents of a cell into the parent cell. One reason for doing so is to make the cell contents accessible for editing, without having to change the child cell itself. This prevents potential side effects when editing a cell would make the edits visible in other places.

Instance-wise flattening is available by choosing "Edit/Selection/Flatten Instances". Again, options are available to choose the number of hierarchy levels to flatten and how to treat orphan cells.

1.2.4.6. Resolving Arrays

Instance arrays are handy to produce large regular arrangements of cells. Sometimes it is necessary to resolve these arrays - for example to remove or modify a single instance from the array. One way to achieve that is to create cell variants (see Create Cell Variants, but this feature will also create a copy of the instantiated cell.

The "Resolve Arrays" function available in "Edit/Selection" allows resolving of an array into individual instances which then can be edited individually.

1.2.4.7. PCell Operations

PCells can be created from shapes if the PCell is derived from a "guiding shape". Specifically the Basic library PCells support derivation from guiding shapes with a few exceptions. So for example, a round-cornered polygon can be created from a normal polygon by selecting the polygons, choosing "Edit/Selection/Convert To PCell" and selecting the "Basic.ROUND_POLYGON" for the PCell.

PCells can be converted to normal cells by choosing "Edit/Cell/Convert Cell To Static" or "Edit/Layout/Convert All Cells To Static". Normal (static) cells can be edited individually but do no longer offer parameters to control the look of the cell.

1.2.4.8. Layer Boolean Operations

KLayout now comes with a set of boolean operations. These operations are available in the "Layers" submenu of the "Edit" menu ("Boolean Operations" and "Merge" functions). A dialog will open that allows specification of mode, input layer(s), output layer and certain other options.

- **AND**: intersection. The output layer will contain all areas where shapes from layer A and layer B overlap.
- **A NOT B**: difference. The output layer will contain all areas where shapes from layer A are not overlapping with shapes from layer B.
- **B NOT A**: difference. The output layer will contain all areas where shapes from layer B are not overlapping with shapes from layer A.
- **XOR**: symmetric difference. The output layer will contain all areas where shapes from layer A are not overlapping with shapes from layer B and vice versa.

In addition, a **MERGE** operation is provided, which is a single-layer operation that joins (merges) all shapes on the layer. As a special feature, this operation allows selecting a minimum overlap count: 0 means that output is produced when at least one shape is present. 1 means that two shapes have to overlap to produce an output and so on. This does not apply for single polygons: self-overlaps of polygons are not detected in this mode.

All operations can be performed in three hierarchical modes:

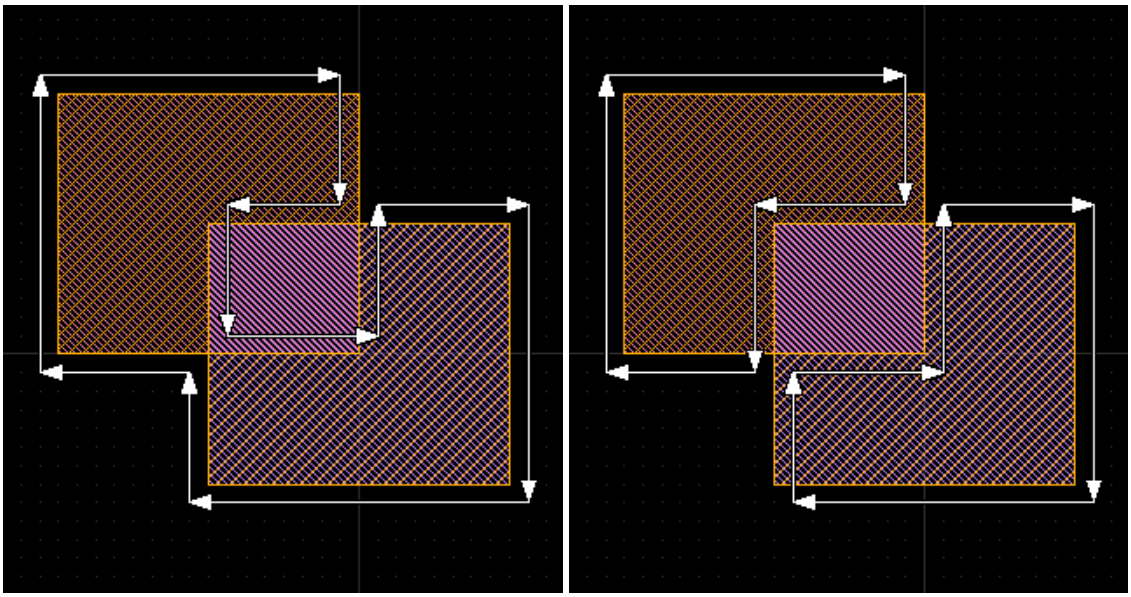
- **Flat**: Both layers are flattened and the results are put into the current top cell.
- **Top cell**: perform the operation on shapes in the top cell only.
- **Cellwise**: perform the operation on shapes of all cells below the current top cell individually. This mode is allowed only if the layouts of both inputs and output are the same.

For the first two modes, the source and target layout can be different, provided that all layouts are loaded into the same view. This allows combining layers of different layouts. For example to compare them using a XOR function.

As a special feature, KLayout's boolean implementation allows choosing how "kissing corner" situations are resolved. KLayout allows two modes:

- **Maximum coherence**: the output will contain as few, coherent polygons as possible. These polygons may contain points multiple times, since the contour may return to the same point without closing the contour.
- **Minimum coherence**: the output will contain as much, potentially touching polygons as possible.

The following screenshots illustrate the maximum coherence (left) and minimum coherence (right) modes for a XOR operation between two rectangles.



The boolean operations are currently implemented flat and based on a full-level edge representation. This means, that the complete layer is flattened (if "flat" mode is requested) and converted into a set of edges which the processor runs on. This will lead to huge resource requirements for very large layouts and is not recommended for such applications currently.

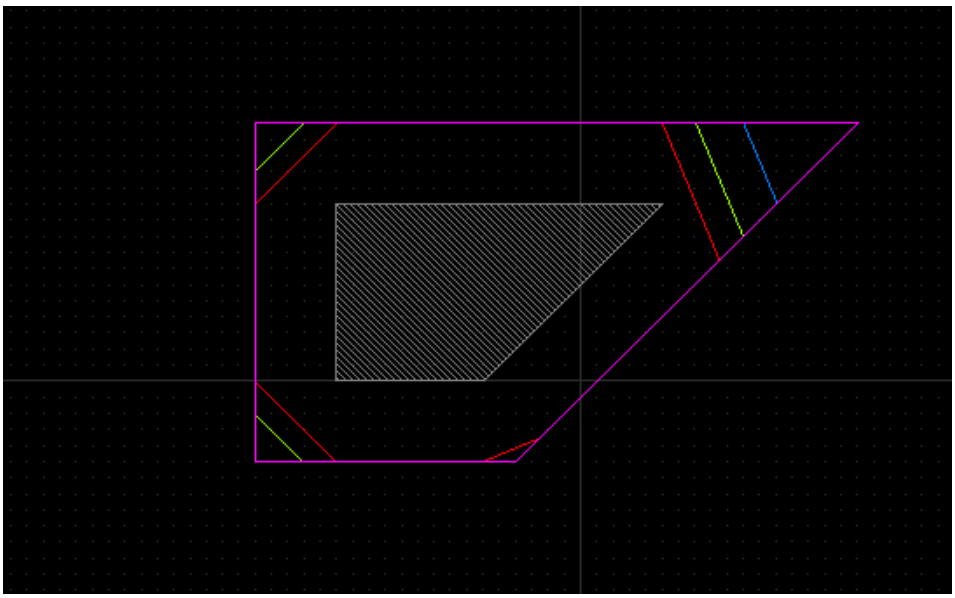
The boolean processor is based on an iterative approach to cover grid snap effects which makes it highly accurate but somewhat slower than a single-pass scanline implementation. Performance penalty is about 2x (two times slower) compared to an efficiently implemented single-pass algorithm.

1.2.4.9. Layer Sizing

A sizing operation allows growing or shrinking of the shapes of a layer by a given offset, which is applied per edge. Positive values will enlarge the shapes while negative values will shrink the shapes. The offset can be given separately for horizontal and vertical direction. However, the sign of both values must be identical (i.e. "0.5,0" or "1.0,0.2", but not "0.2,-0.2").

The sizing function can be found in the "Layers" submenu of the "Edit" menu. A dialog will open that allows specification of input and output layers, sizing value in micron: a single value for same sizing in x and y direction or comma-separated list of two values (i.e. "0.2,0.1").

As for the boolean operations, hierarchical mode and kissing corner resolution can be specified (see Layer Boolean Operations for a description of these modes). In addition, the cutoff strategy for sharp edges can be chosen from strict to virtually unlimited. The following screenshot demonstrates the effect for "strict" (red) to "weak" (purple) cutoff modes.



1.2.4.10. Shapewise Boolean Operations

Boolean operations are also available on selected shape sets. These operations use the concept of "primary" and "secondary" selection. The primary selection contains all shapes that are selected in the first step. The secondary selection contains all shapes that are selected in additional steps using the "Shift" modifier key.

The following operations are available in the "Selection" submenu of the "Edit" menu:

- **Merge**: merge all shapes in the primary and secondary selection and write the results to the layer of the primary selection.
- **Intersection**: Compute the intersection (AND) of primary and secondary selection and write the results to the layer of the primary selection.
- **Subtraction**: Compute the difference (A NOT B) of primary (A) and secondary (B) selection and write the results to the layer of the primary selection.

1.2.4.11. Shapewise Sizing

The selected shapes can be sized with a given enlargement and shrink distance, similar to the layer operation but with less options. The sizing function can be found in the "Selection" submenu of the "Edit" menu. A dialog will open that prompts for the sizing value (one value for same sizing in x and y direction in micron or two comma-separated values for different sizing in x and y direction).

1.2.4.12. Object Alignment

This operation use the concept of "primary" and "secondary" selection. The primary selection contains all shapes that are selected in the first step. The secondary selection contains all shapes that are selected in additional steps using the "Shift" modifier key.

The object alignment function allows aligning of all objects in the secondary selection to the objects in the primary selection (i.e. objects in the primary selection define the reference points but are not moved). An "object" can be a shape or an instance of a cell. Cell instances are referred to by their bounding box which can be either computed from the visible layers alone or from all layers.

Alignment can be specified differently in horizontal and vertical direction. Horizontal alignment can be "none" (no change), "left" (align left sides), "center" (align centers) or "right" (align right sides). Vertical alignment can be "none", "bottom", "center" or "top".

The alignment function can be found in the "Selection" submenu of the "Edit" menu. A dialog will open which allows specification of the alignment mode and bounding box computation mode for cell instances.

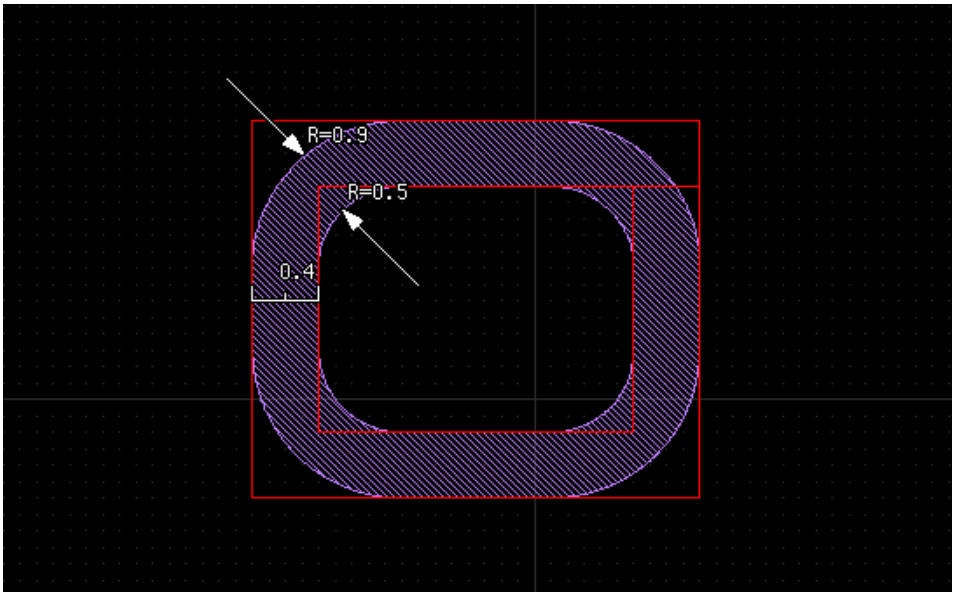
1.2.4.13. Corner Rounding

In some applications, i.e. power devices, it is desirable to have round corners instead of sharp corners to limit the electrical field. Klayout now offers a convenient way to create such structures. The basic idea is to draw the structures with sharp, 90 degree corners and then "soften" the corners by rounding them to a given radius. The resulting polygons can then be written to GDS files, even though GDS does not have the concept of "soft" (or circular) geometries.

The interesting part is: **the corner rounding function can be re-applied on such geometries on a polygon basic**. That means, that even if such a modified polygons are saved to GDS or otherwise modified, the original geometry can be reconstructed and the corner radius can be changed. No special geometrical objects or special GDS annotation is required to achieve this. This requirement imposes some (probably weak) limitations:

- The number of points per corner must not be too small (currently at least 32 on the full circle)
- The original geometry must not exhibit sharp corners and the original segments must be at least twice the corner radius in length.
- The corner segments must be perceivable as such, i.e the angle between adjacent edges must be "nearly" 180 degree. This imposes some restrictions on the minimum length of such a segment and on the accuracy by which they can be expressed in database units. This boils down to a certain length limit in terms of database units.

The following screenshot illustrates the round corners function. As can be seen in this example, it is necessary to allow a different radius specification for "inner" and "outer" corners.



The corner rounding function operates on selected shapes. It can be found in the "Selection" submenu of the "Edit" menu. A dialog will open which allows specification of the radius values and the desired resolution. If the selected polygon already has rounded corners, the corner rounding will be removed and the original polygon reconstructed before the new corner rounding is applied. By specifying "0" for the radius, the original sharp corners will be recovered.

1.2.4.14. Cell Origin Adjustment

The cell origin is important for a cell because this point is the instantiation anchor for cell instances. The cell origin adjustment function allows shifting the origin to a certain place relative to a cell's bounding box. This can be either the center, a corner or the middle of an edge of the bounding box. The bounding box can either be computed from all or just from the visible layers.

If the "Adjust instances in parents" check box is clicked, the instances of the cell will be adjusted in the opposite direction. Hence, the cell effectively does not change, but locally the origin of the layout will be shifted.

The cell origin adjustment function can be found in the "Cell" submenu of the "Edit" menu.

1.2.4.15. Create Cell Variants

KLayout offers a feature that is very useful when you want to edit a single instance of a cell rather the cell itself. Editing a cell means that the changes applied to the cell appear at all places where this cell is placed. That may not be desired - if you want to modify a layout in one particular place you may not want to have side effects at other places.

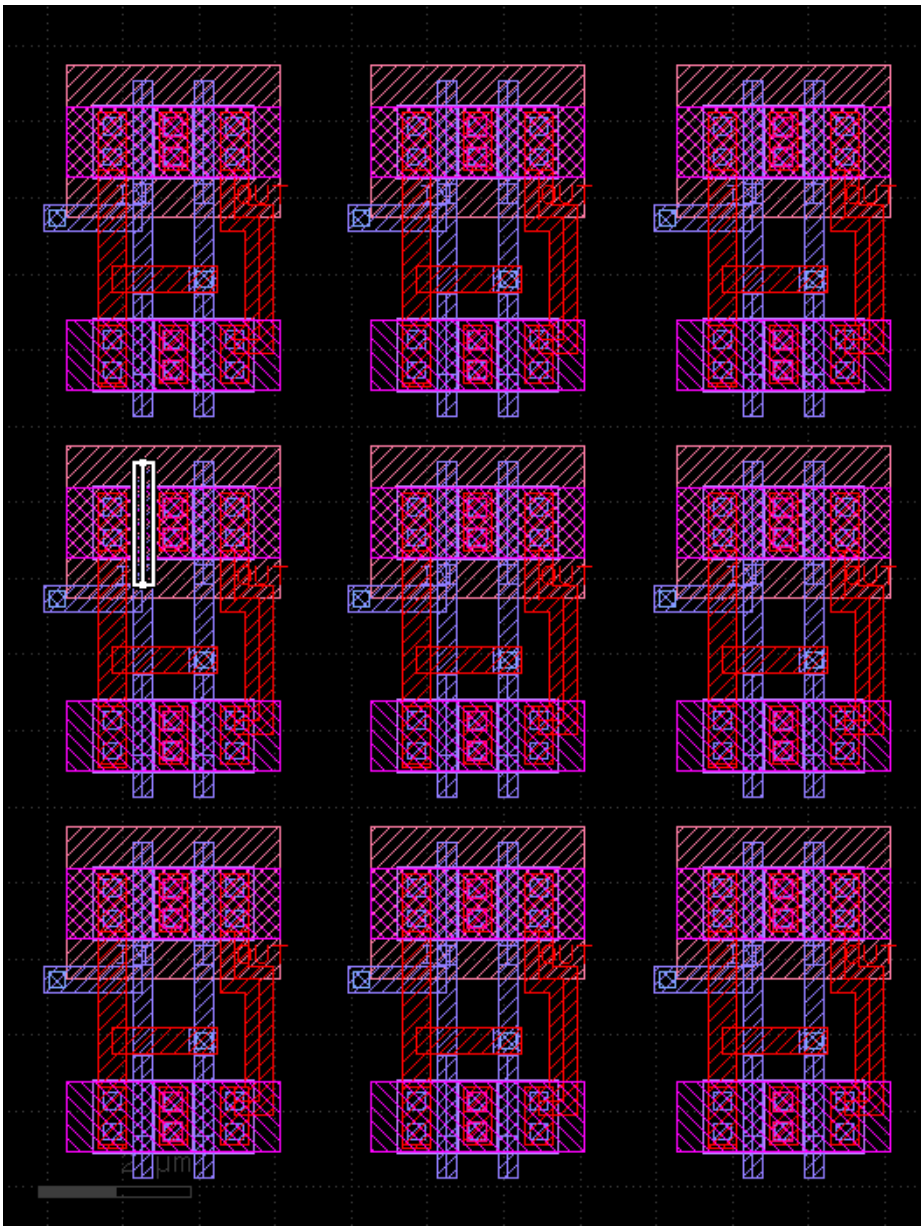
The usual way of achieving that is to copy a cell, replace a particular instance by the new cell and edit the new cell. This can be tedious, in particular if there is an array instance where just one instance must be modified. In that case, the array has to be split so the single instance is isolated before it can be replaced with a new cell.

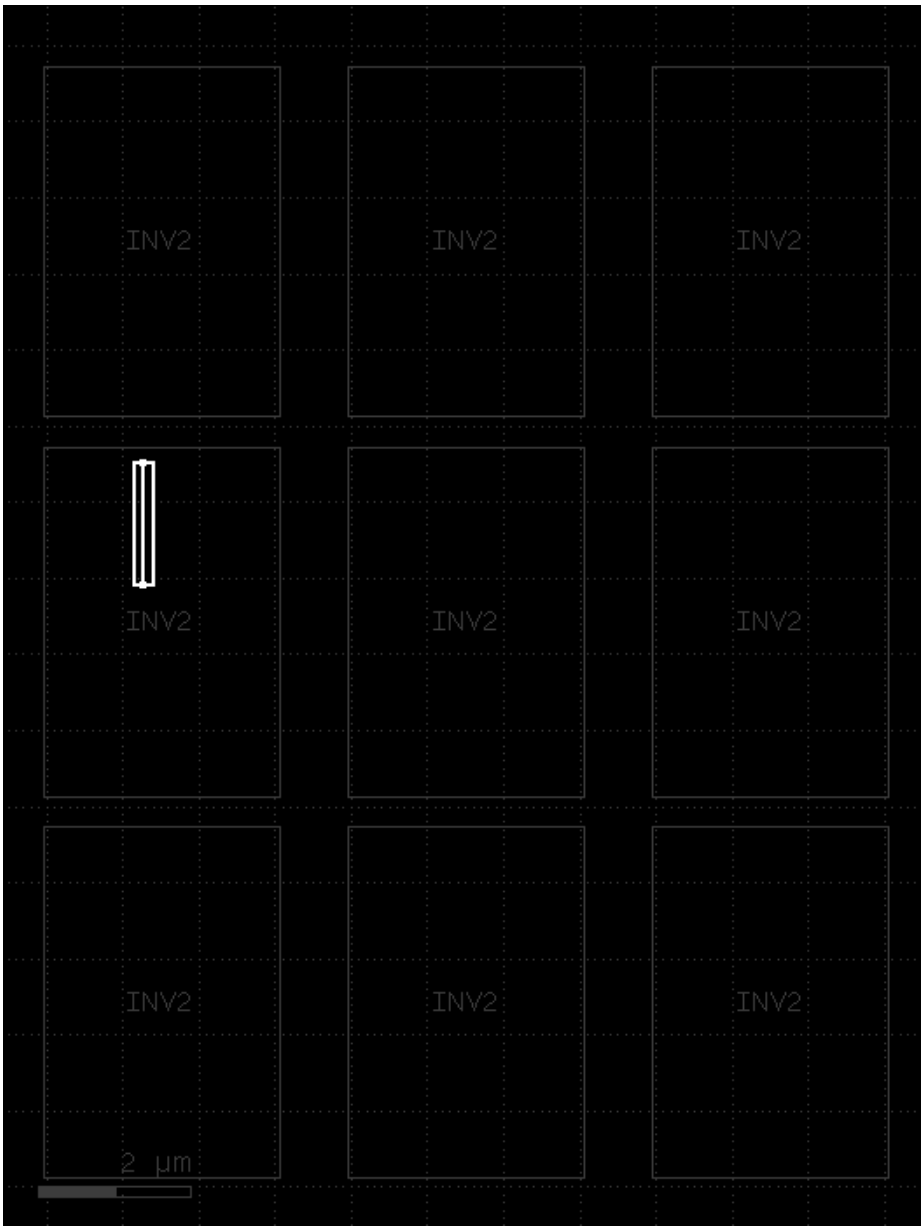
KLayout offers a feature that automates this task. It is found in the "Edit/Selection/Make Cell Variants" menu. It basically works like this: For all selected objects it will follow the hierarchy up to the current cell. It will create new cell copies for all cells found along that path and use these new cells instead of the original ones.

The effect is, that after using "Make Cell Variants", the selection can be modified (i.e. deleted) without having any undesired side effects.

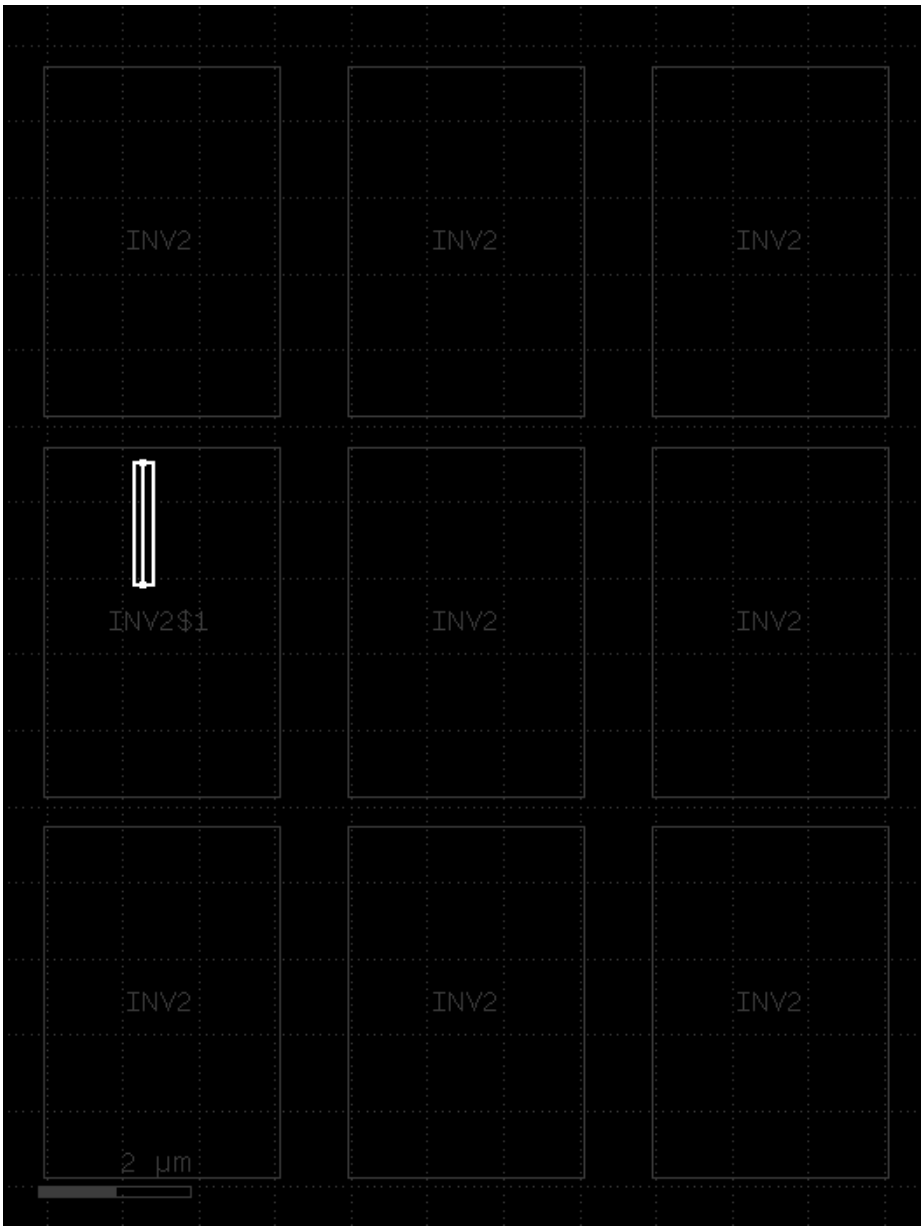
This feature can also transform array instances and isolate certain instances of the array. The following screenshots demonstrate that feature.

This is the initial situation: a cell is instantiated 9 times in a 3x3 array and one shape inside one of these instances is selected. The two following screenshots show the full-level hierarchy view and just the top level hierarchy to demonstrate that the cell is placed 9 times.

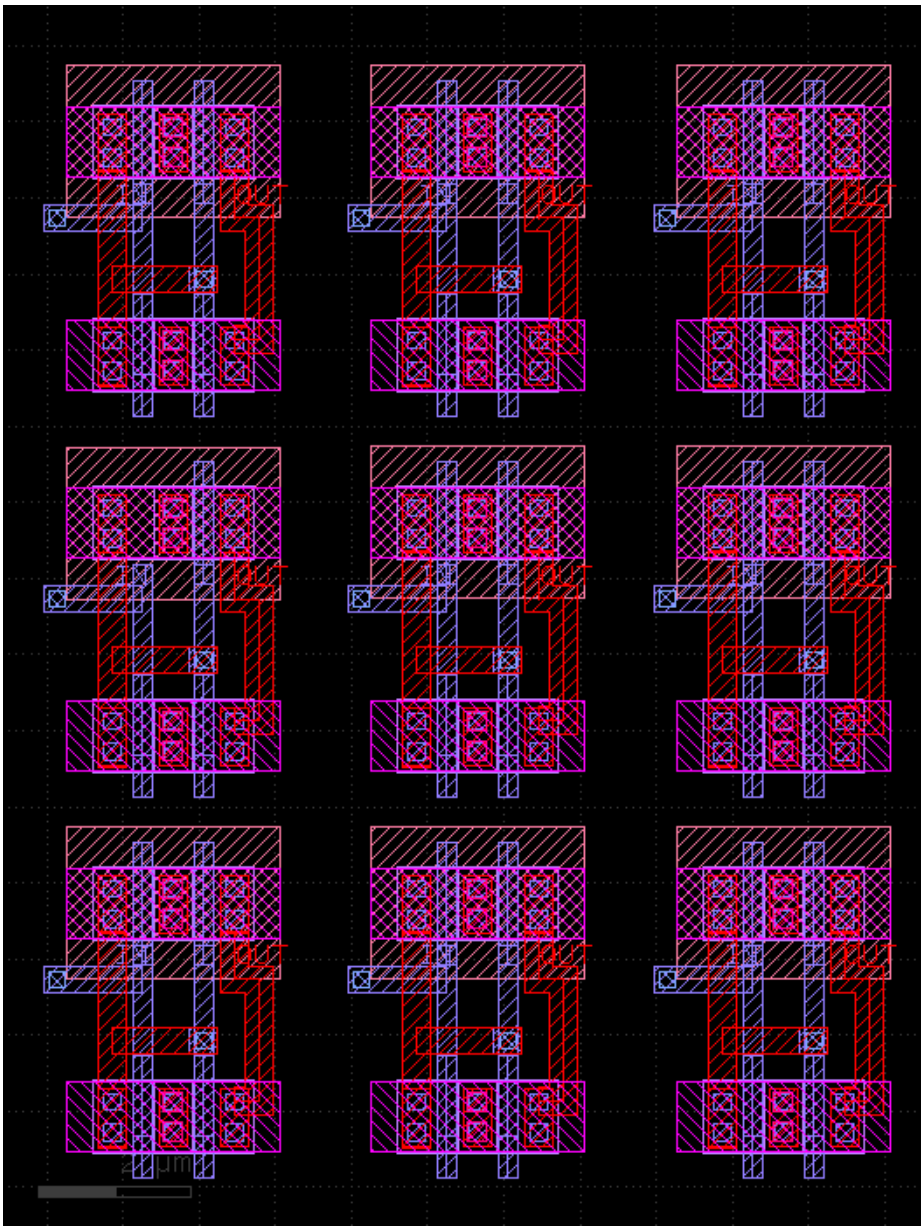




If that shape would be deleted, it would disappear in all instances. Imagine that is not intended. You can now use the "Make Cell Variants" feature to create a cell variant for the one instance that we have selected the shape in. After we did so, one instance is replaced by a copy of the cell which is called "INV2$1". The picture looks like this:



We can now delete the single shape without any side effect on the other instances:



1.3. Advanced Topics

This section describes some more advanced features of KLayout:

1.3.1. The XOR Tool

The XOR tool performs a geometrical XOR (also ANOTB and BNOTA for asymmetric differences) on two layouts by performing the respective boolean operations layer by layer. The XOR tool is started using "XOR Tool" from the "Tools" menu). Currently, the tool compares all or just the visible layers. Currently, it compares layers from one layout vs. the identical layers from the other layout.

The current implementation employs a flat XOR processor. This limits the application somewhat to small and medium sized layouts and does not make use of hierarchy, which basically excludes applications for very hierarchical layouts (i.e. memory arrays). The memory footprint associated with the flat approach can be mitigated by using the tiling feature which performs the operation on a tile with limited size. This does not reduce the run times but the memory requirements.

The XOR tool allows specification of tolerances. Basically a tolerance is an undersizing step following the boolean operation. This way, small markers can be suppressed. This is particular useful to remove markers resulting from tiny differences between the layouts being compared. Multiple tolerances can be specified. In that case, multiple undersize steps are performed to create sets of layers with different tolerances each. For example, a tolerance specification of "0,0.001,0.005,0.010" will create four sets (marker categories) containing all difference markers and others for markers indicating differences larger than 1nm, 5nm and 10nm.

Tiling can be enabled by entering a tile size into the entry box. For semi-flat layouts such as standard cell blocks, a tile size of 1000 micron is a good starting point. The choice of the tile size mainly determines memory requirements.

The XOR tool allows sending the output either to a marker database or to another or one of the input layouts. The mode can be selected with the "Output" drop-down box. If output is sent to one of the original inputs, it is mandatory to specify a layer offset which maps the original layer to a new layer. An offset of "1000/0" for example means, that differences between shapes on layer "16/0" will be sent to "1016/0" for the first tolerance category and "2016/0" for the second.

Finally, the XOR can be confined to a region. This saves time if differences in parts of the layout are of interest. To select a region use the drop-down box next to "From region":

- **All:** Do an XOR on the whole area (default)
- **Visible region:** Confine the XOR to the visible part of the layouts
- **Clipped to ruler:** Draw one or many rulers to specify the region to which the XOR shall be confined. Each ruler specifies a region given be the extension of the ruler. If you use a box-type ruler, the ruler gives a better visualization of the region

1.3.2. The Diff Tool

As the XOR tool, the Diff tool performs a comparison of two layouts. In contrast to the XOR tool, it does a cell-by-cell and object-by-object comparison and reports differing cells, instances and geometrical objects. In effect, the comparison is more strict and not purely geometry-related. It does not verify the identity of the layouts on mask level but rather the exact identity of the objects that comprise the layout file. On the other hand, the Diff tool usually detects the actual changes rather than their effect on geometry.

Usually, that kind of comparison is very sensitive to "cosmetic" changes, i.e. cell renaming. KLayout's Diff tool tries to mitigate this effect with these features:

- Before it does the cell-by-cell comparison it tries to detect cells which have been renamed by comparing their instantiation. That way, it can compare the right cells even though their names may be different. The basis of that functionality is a cell matching algorithm. This algorithm compares cells by taking into account their bounding boxes, shape counts per layer, number of instances and other parameters. The algorithm will choose a partner cell which matches closest with respect to these parameters. If that scheme fails, it is possible to revert to name matching by unchecking the option "Don't use names to match cells".
- It allows some level of control over the strictness of the compare. For example, cell arrays can be expanded before the individual instances are compared. By default, some second-order information like users properties or certain text properties is not compared.
- The diff tool can also work in "XOR" more. In that mode, the differences found are used to provide input for a subsequent, polygon-only XOR step. The result is a fair approximation of a true, as-if-flat XOR which delivers a superset of the true XOR's results. It may report some locations as being different which if fact are not, but it will not fail to report differences where there are some. Compared with the XOR tool's functionality, some options are missing (i.e. tolerance), but the performance is much better.

The Diff tool is found in the "Tools" menu. In this dialog:

- Select layout A and B in the "Input" section.
- Uncheck "Don't use names to match cells" to revert to pure name matching. Cells which have been renamed will not be compared against then.
- Check "Run XOR on differences" to select the "XOR mode".
- Check "Summarize missing layers" to have missing layers reported as one difference instead of one per shape.
- Check "Detailed information" to receive detailed information about every difference. Without that option, only the number of differing shapes or instances is reported.
- Check "Expand cell arrays" to compare individual instances of array instances.
- Check "Exact compare" to include second-order information (i.e. user properties, text orientation) in the compare.

The Diff tool will create a marker database and show the results in the marker database browser.

1.3.3. The Fill (Tiling) Utility

The fill utility creates a regular pattern of fill unit cell instances in certain areas of a layout. This feature is usually referred to as "tiling" or "fill". It is based on a rectangular unit cell which is repeated in x- and y-direction to fill the available space. In most cases, the intention is to fill empty areas in the layout to enhance the layout uniformity for a better process performance.

Before the fill utility can be used, a fill cell must be prepared in the layout that is filled. The dimension of the cell are defined by a box drawn on an arbitrary layer. This box must represent the "footprint" of the cell. This is the space that one instance will cover in the region to be filled.

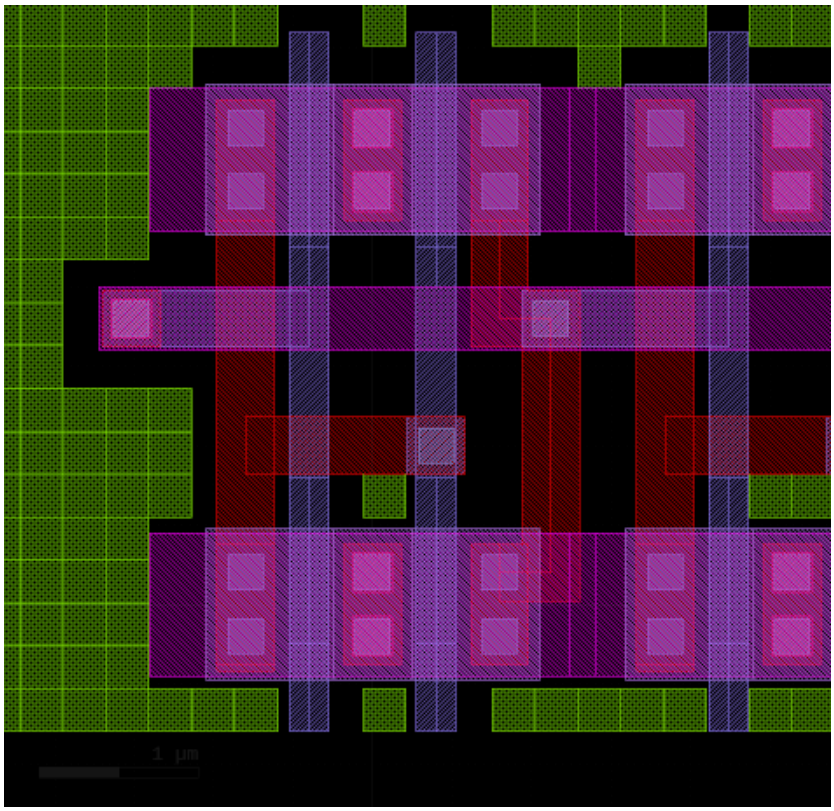
The fill utility is found in the "Utilities" sub-menu of the "edit" menu and is available in edit mode only. To use this utility, open the dialog and

- Select the outer boundary of the fill region ("what to fill"). Available choices are: Full cell, the interior or the polygons on a given layer, the interior of all selected polygons, a single box or an area defined by a ruler.
- Specify if the fill area should keep a certain minimum distance to the border of the fill region.
- Specify the regions within the fill region which must not be filled. Available choices are: All layers (don't create fill over any polygon drawn), all visible layers (don't create fill over any polygon visible), all selected layers or don't exclude anything.
- If the fill tiles must keep a certain minimum distance from the exclude regions, specify that distance in the "Spacing around exclude areas" entry field.
- Specify the fill cell and the boundary layer which defines the cell's footprint in the "Fill Cell" group.

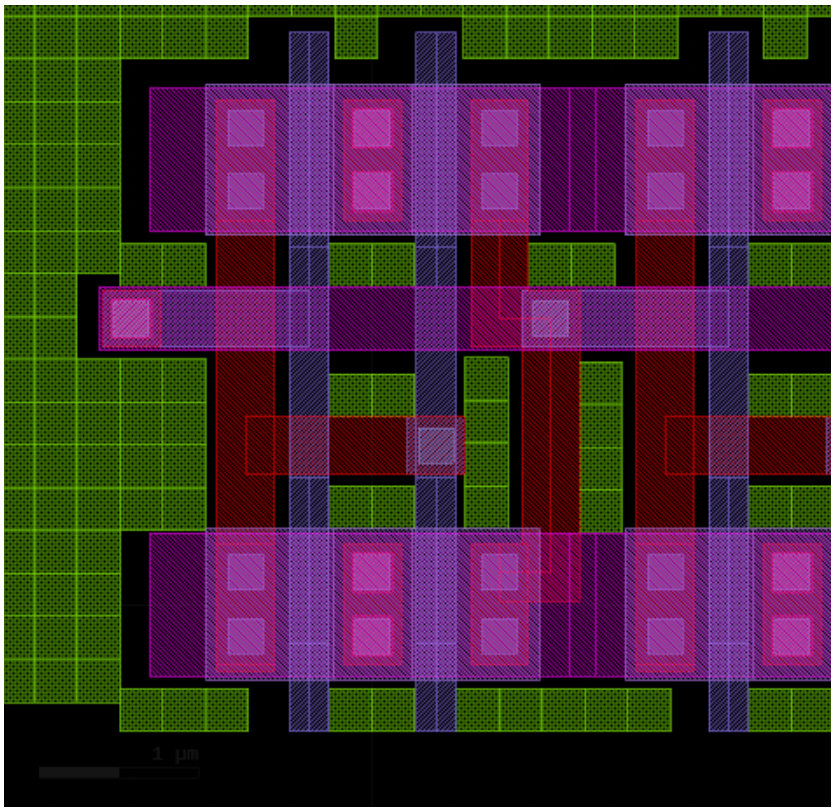
By default, the fill utility operates on a fixed raster. This can lead to a poor fill efficiency in some cases. The fill utility offers a "Enhanced fill" option, where it tries to find a cell arrangement which is not necessarily on a common raster but provides a better fill performance. In addition, second-order fill is supported. In that case, a second - usually smaller - fill cell can be specified which is used to fill the remaining areas of the layout.

The following screenshots show the effect of the different fill modes for some artificial fill problem.

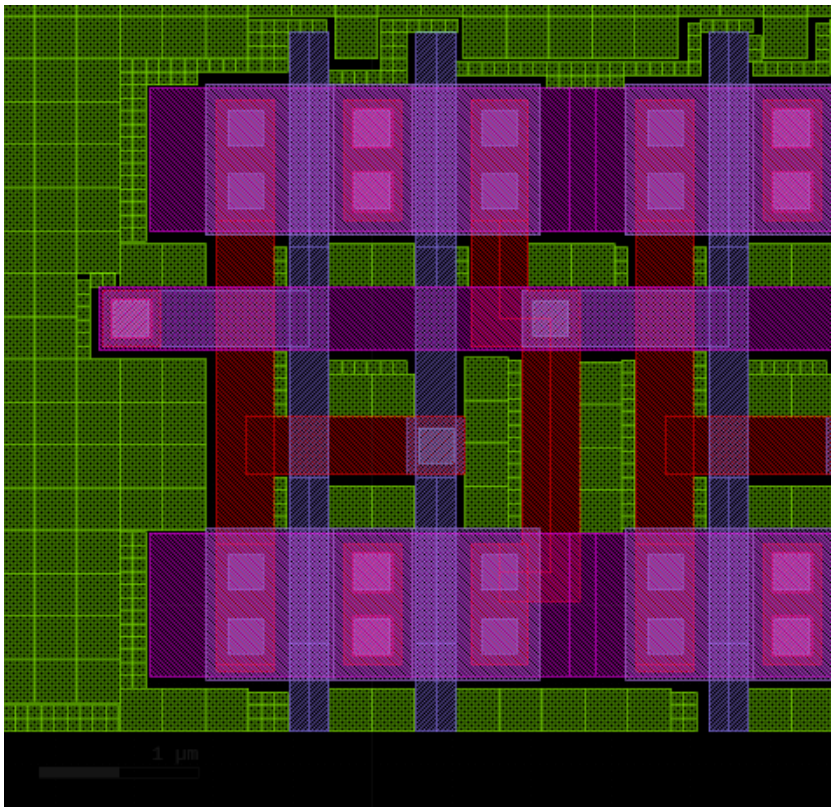
Default:



Enhanced:



Enhanced plus second order:



1.3.4. Import Gerber PCB Files

Gerber PCB import allows creating GDS layout data from Gerber PCB files or to add Gerber files to GDS files as new layers. The import function supports a majority of the RS274X features for artwork files and a couple of different formats for the drill files. The importer will take a set of files and convert them to layout geometry. The importer offers some functionality to adjust the data appropriately, i.e. to define output layers and apply geometrical transformations. Another basic capability is to merge the geometry of a layer to remove overlaps and join paths into larger polygons.

Because of the manifold options, the import specification can become pretty complex. Therefore, it can be saved into a file (suggested suffix is ".pcb") in XML format which contains the importer specifications. Once such a file is created, KLayout can read this file like usual stream files (i.e. it can be specified on the command line) and use it as a recipe to import the associated Gerber files.

The PCB import function is available in the "File" menu ("Import/Gerber PCB"). Different entry points are provided that start a new project, open an existing project or to continue with the last project.

The basic workflow to import PCB data is:

- Specify the directory where the PCB data files are located (the "base" directory).
- Specify the import mode (the destination of the layout data).
- Decide about the layer mapping mode: free layer mapping or metal stack mapping. Free layer mapping allows an arbitrary mapping between PCB layers and GDS layers. This specification is the most flexible one but is tedious to enter. Metal stack mapping is easier to specify but confined to mapping a set of PCB files to a metal/via/metal stack scheme.
- Specify the files, GDS layers and PCB to GDS layer mapping.
- Specify a transformation if desired, either by specifying mapping points or a transformation directly.
- Decide about further options (i.e. merging, database unit, top cell name etc.).

The basic decision is how to specify the layer mapping. In free mode, the specification requires these steps:

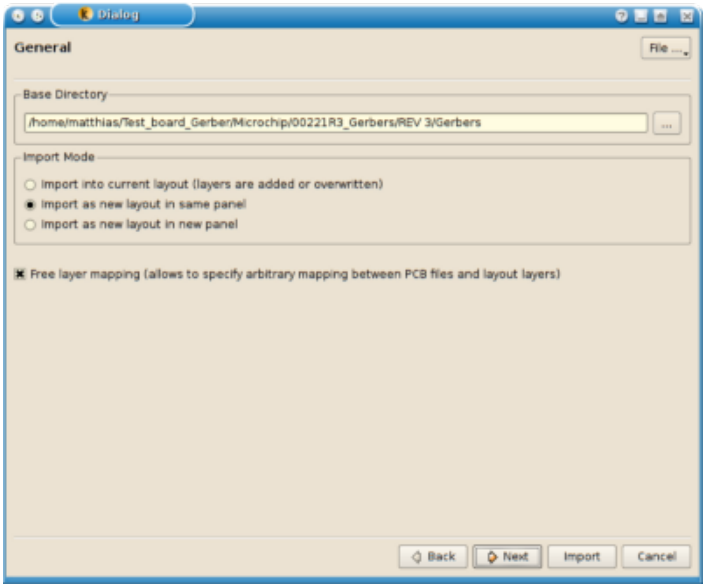
- Specify the files to load (in the dialog on the "Files" page).
- Specify a list of output layers.
- Fill the input to output mapping matrix which assigns one or many output layers to each input file.

In layer stack mode, the specification workflow consists of these steps:

- Specify the GDS layer stack (the complete stack available for mapping PCB data into). The idea is basically to put another set of series of metal/via/metal layers on top of the GDS layer stack. The PCB layer closest to the die surface is placed into the first metal layer which is supposed to be the first above the on-chip layers.
- When the GDS layers are set, specify how many metal and drill hole files the PCB file set contains and whether the chip will be mounted on the top or bottom of the PCB. The latter decides in which order the PCB layers are assigned to GDS layers (remember, the first GDS layer will be the PCB layer closest to the die surface).
- Enter file names for the artwork files corresponding to metal layers.
- Specify file names for the drill files and what metal layers are connected by the (plated) drill holes. Since a drill hole can connect multiple layers in the stack, a connection information is always of the type "from metal, to metal" with the drill holes connecting all metal layers between "from" and "to".

The import dialog

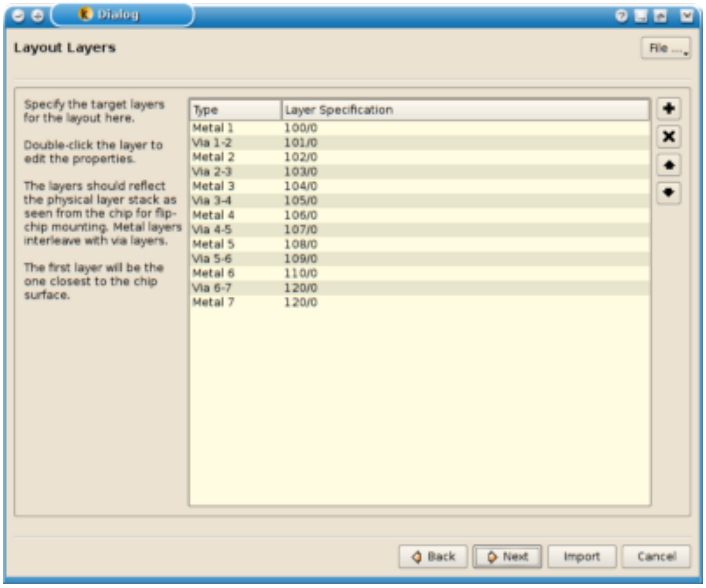
The import dialog is organized in multiple pages that reflect the workflow for the import specification. On every page, the "File" menu button allows saving the current settings as a PCB import project, to open an existing project or to create a new project and to restart from scratch.



The first page offers some basic options:

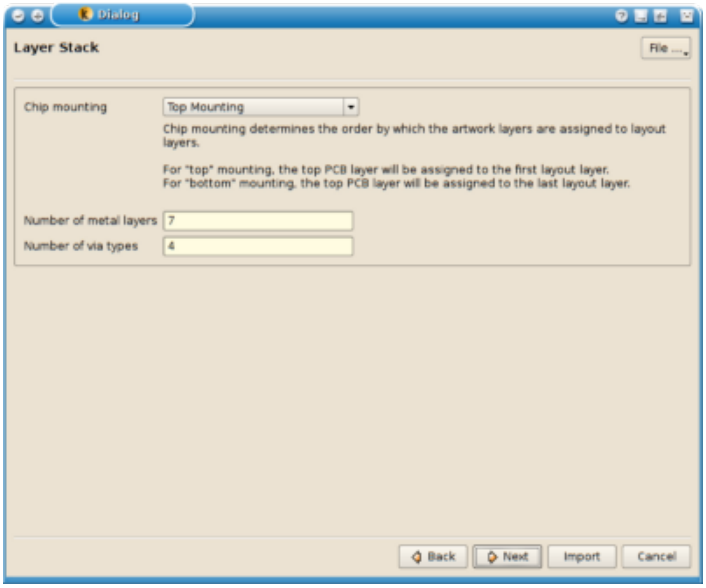
- **Base directory:** this is the directory where all the PCB files are found. Not necessarily all files must be located there but are looked for relative to this directory. If all files are moved, just the base directory must change. The base directory is not stored in a project file. Instead, the base directory is the directory where the project file is stored. Basically this implies, that all data files will be referred to relative to the project file.
- **Import mode:** PCB data can be imported into the current layout (into the current cell). Usually, it this case, layers will be added to the current layout. Alternatively, a layout can be created which will be either placed into a new panel or added to the current panel.
- **Layer mapping mode:** Specify here whether to use free or layer stack mode. Check the box to use free layer mapping mode.

The layer stack flow

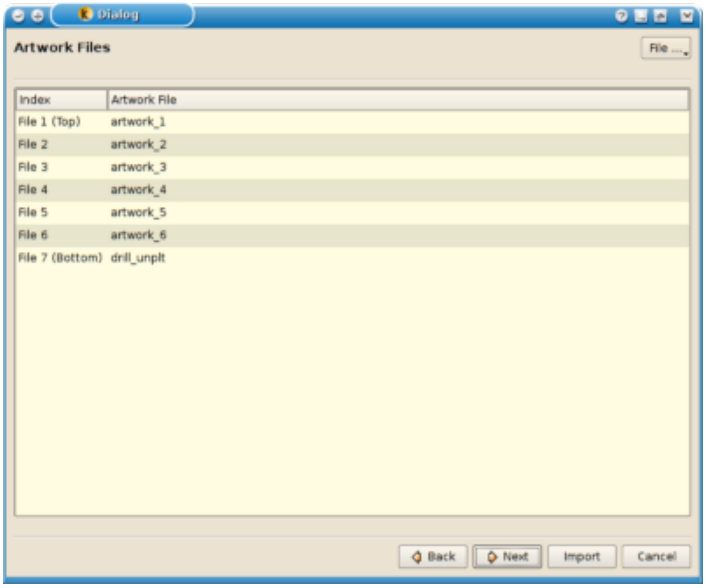


In the layer stack flow, on the first page, a sequence of metal and via layers must be specified. The assignment of metal and via layers is done automatically. The sequence is always a metal layer followed by a via layer. The number of layers must be odd so the last layer is a metal layer again. Via layers will connect the adjacent metal layers only.

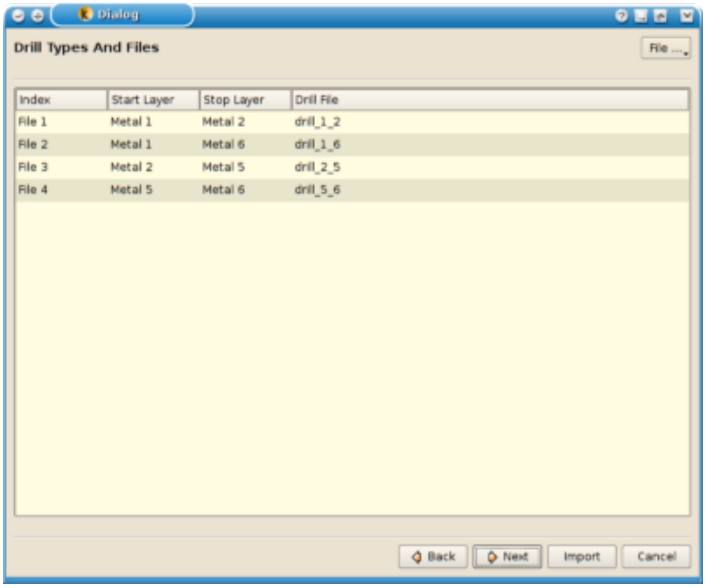
Use the "+" button to add new layers. Move layers by selecting them and moving them up or down with the arrow buttons. Use the "X" button to remove all selected layers.



On the next page, the number of artwork and drill files needs to be specified. Later, the actual files need to be entered and assigned to metal or via layers. In addition the chip mounting position needs to be specified. In "top mounting" mode, it is assumed that the chip is placed surface down on the top (first) PCB layer. Thus the first metal above the chip stack will be the top PCB layer. In "bottom mounting" mode, the last PCB metal layer will be the first metal layer above the chip stack.

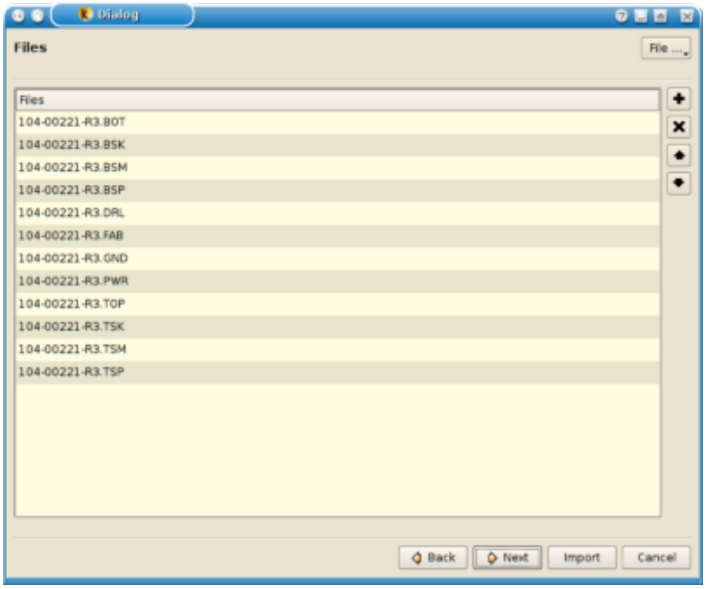


On the "Artwork Files" page, the artfile file names must be entered. They are automatically assigned to the respective metal layers. The assignment order depends on the mounting mode.

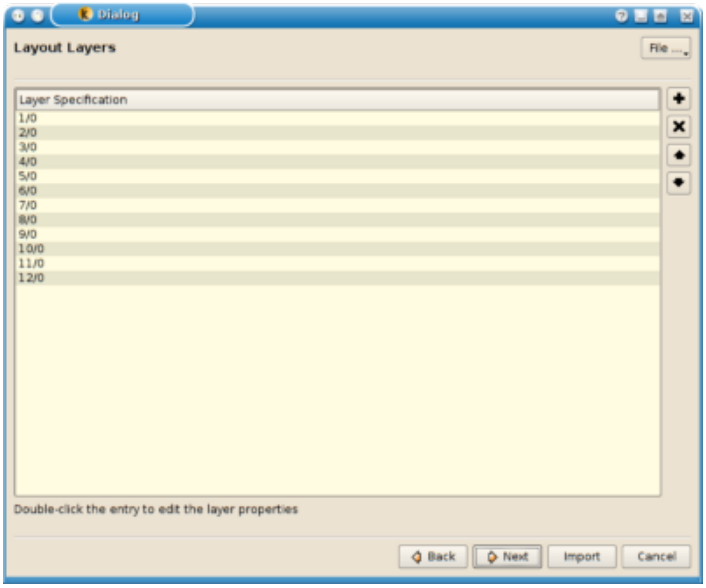


On the "Drill Files" page, the drill file names must be entered. Each drill file describes a certain drill step, which can connect multiple metal layers. On this page, this specification must be made. The first and last metal layer connected by the plated hole must be specified. The corresponding via layers will then be used to create via shapes.

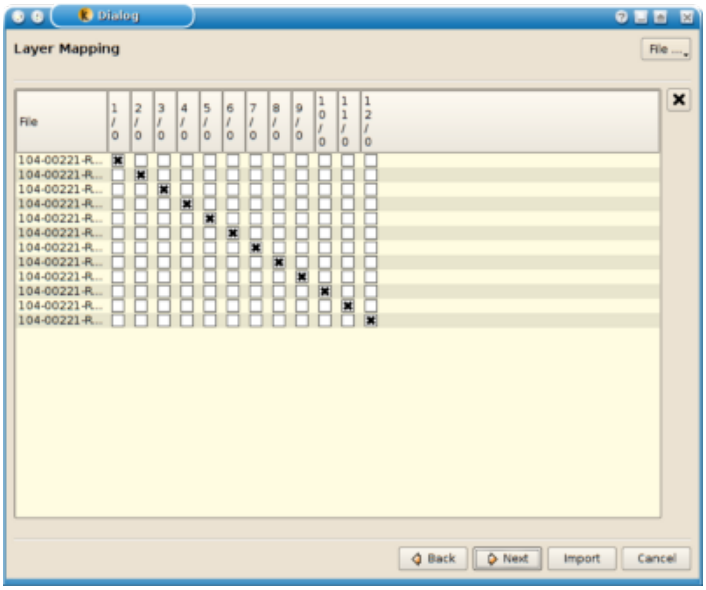
The free layer mapping flow



On the "Files" page, all PCB data files must be specified. This includes artwork and drill files. The order is not important but it is recommended to follow the physical stacking. This simplifies the assignment to GDS layers later. Use the arrow buttons to move the selected entries up or down. Use the "X" button to delete files from the list and use the "+" button to add new files.

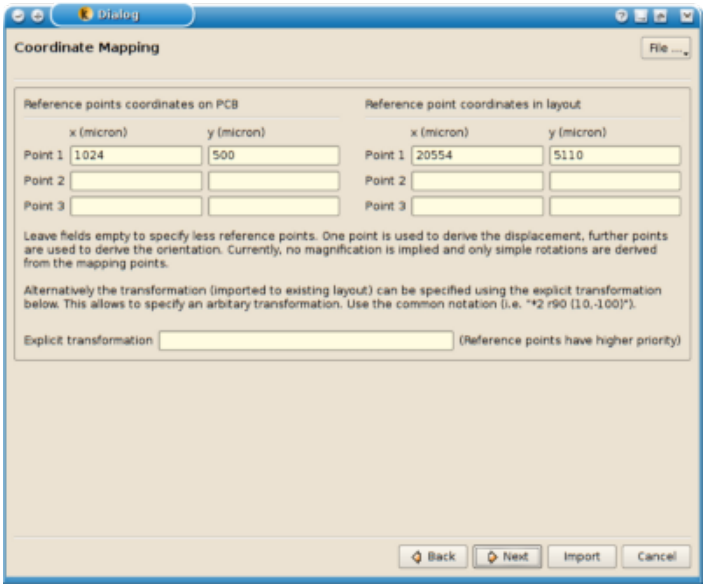


On the "Layout Layers" page all target layers must be specified. Provide a list with all layers that are used as target layers for the import. Again, the order is not important but maintaining a technological order will simplify the assignment in the next step. As on the previous page use the arrow buttons to move selected entries and the "+" and "X" button to add new entries and deleted the selected ones.



On the "Layer Mapping" page, each file can be assigned to one or may GDS layers. The assignment is described in form of a matrix where an "x" means that the file or layer given by the row is imported into the layer given by the column. A file can be imported into multiple layers which basically will duplicate the shapes. Click at the boxes to set or reset the mark. Use the "X" button on the left to reset all marks for the rows selected.

General options



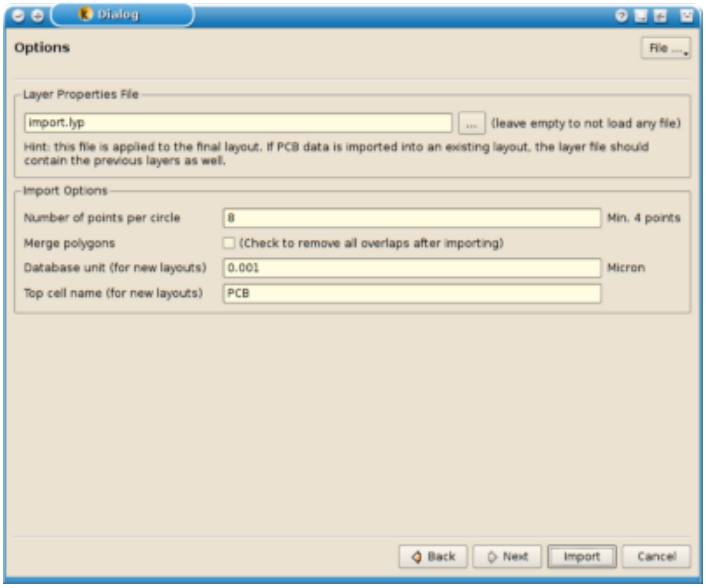
The "Coordinate Mapping" page allows specification of the transformation of the PCB data into the GDS space. Since PCB and GDS rarely share the origin, a transformation can be specified which is applied to the shapes when importing them.

A specification can be made in two ways:

- **By specifying matching points:** The transformation will be computed such that the given PCB coordinates are mapped to the given GDS coordinates. Up to three coordinate pairs can be given. If one coordinate pair is given, a displacement is derived. If two coordinate pairs are given, the rotation is computed as well (only multiples of 90 degree are supported currently). If three coordinate pairs are give, the algorithm can derive mirroring as well.

- **By explicitly specifying the transformation:** The transformation can be specified explicitly in the lower entry field. The format is "x,y" for a simple translation (x, y are given in micron units), "rx" or "mx" for a rotation by the angle "x" or mirroring at the line with angle "x" and "*x" for a magnification of "x". All specifications can be combined, i.e. "r90 170,-5100" specifies a rotation by 90 degree and displacement by 170 micron in horizontal and -5.1 mm in vertical direction.
  For a comprehensive description of that string, see Transformations in KLayout.

Hint: Both specifications can be combined, i.e. one coordinate pair can be given to define the displacement and the rotation can be specified explicitly.



Finally, on the "Options" page, various options can be set:

- **Layer properties file:** If specified, this layer properties file will be loaded after the layers have been imported. The file is specified relative to the base directory.
- **Number of points per circle:** KLayout resolves the circular apertures commonly used in PCB layout into polygons to perform geometrical operations. This options allows choosing how many points will be used for the approximation of a full circle. Less points will mean less accurate representation but smaller polygons hence better performance on boolean operations used to compute clear areas for example.
- **Merge polygons:** If this option is set, all polygons will be joined if they overlap or touch. Note, that merging also happens implicitly if clear layers are used because the boolean operations used to cut out clear regions will implicitly merge the previous layout. This implicit merging cannot be disabled.
- **Database unit and top cell name:** This option allows choosing the database unit and top cell name for new layouts. This applies only, if the import mode implies a new layout.

1.3.5. Import Other Layout Files

This function can merge other layouts into the layout loaded. Merging means that the hierarchy of the specified layout is inserted into the given layout. Different modes are available that control the way how the hierarchy is merged. This function is available in the "File" menu as "Import/Other File Into Current".

The workflow for importing a different layout is this:

- Specify the file to input. At least the file name is required. Additionally, a cell can be specified. In that case, only the cells referred to by the given cell (directly or indirectly) are imported. Reader options can be specified separately for the import. Reader options are applied the same way than the reader options are used for the standard load function.
- Specify the import mode. The modes are described below.
- Specify the layer mapping. Either the shapes are imported on their original layer or an offset can be used that will be added to the layer to form the target layer of the import. An offset of "1000/0" for example specifies to add 1000 to the layer and use the original datatype.
- Specify an optional transformation. The imported layout will be transformed accordingly. The transformation can be specified explicitly or with up to three points which are mapped onto each other.

Four import modes are available that control how the hierarchy of the imported layout is inserted into the existing layout:

- **Merge**: in this mode, the contents of the imported cell will be put into the current cell and the child hierarchy is added below the current cell.
- **Extra**: in this mode, new top level cells containing the hierarchy tree of the imported cell or cells will be created. In this mode, multiple cells can be imported if the imported layout contains multiple top cells. Leave the cell specification empty for this.
- **Instantiate**: the imported cell will be instantiated into the current cell as a separate hierarchy.
- **Merge hierarchy**: The fourth mode is a little bit more complex. Basically it works like "Merge", but identifies corresponding cells and merges the contents for the corresponding imported cells into the original cells. The algorithm identifies corresponding cells by requiring that the flat instances of the imported child cell exactly equal the flat instances of the corresponding original cell (where flat refers to the instances of a cell in the context of the current cell). This is done by selectively thinning out the candidate list and finally employing a name similarity measure to resolve ambiguities.

The import function will create new cell names using the "$x" suffix to avoid name ambiguities.

1.3.6. The Net Tracing Feature

The net tracing function allows tracing of a net by detecting touching shapes that together form a conductive region. It features specification of a stack of metal (or in general "conductive") layers optionally connected through via shapes. The net tracing algorithm will follow connections over the via shapes to form connections to other metal layers. The material footprint can be derived from single layout layers or a boolean combination of several layers. For example, this allows selecting source and drain regions of transistors by subtracting the poly region from the active area region.

Single net tracing

This algorithm is intended for extracting single nets and employs an incremental extraction approach. Therefore extraction of a single small net is comparatively fast while extraction of large nets such as power nets is considerably slower compared to hierarchical LVS tools currently.

The net tracing function can be found in the "Tools" menu. The user interface allows tracing of multiple nets which are stored in a list of nets extracted. If labels are found on the nets, these are used to derive a net name. Beside that, the cells which are traversed in the net extraction are listed, so the cells being connected by this net can be identified.

Before nets can be extracted, a layer stack must be specified. Press "Layer Stack" on the user interface to open the layer stack dialog or use "Edit Layer Stack" in the "Tools" menu. Layers must be specified in the "layer/datatype" notation. The via specification is optional. If no via layer is specified, both metal layer shapes are required to touch in order to form a connection. If a via layer is specified, a via shape must be present to form the connection.

The layer stack (also referred to as "Connectivity") is also a technology component. This means if you select a technology for layout, the technology specific stack is selected. To edit the stack for all technologies, use the Technology Manager ("Tools/Manage Technologies") and use the "Connectivity" section from the technologies.

A connectivity definition can specify multiple stacks, out of which one has to be selected. This is useful, if your technology setup features multiple routing metal schemes for example. You do not need to setup different technologies for each scheme. If you have declared multiple stacks, you can choose one in the "Trace Net" dialog in the drop-down button right of the "Layer Stack" and the "Configuration" button at the bottom left.

Within the stack definition, KLayout allows specification of symbolic layers and to use boolean expressions. That way it is possible to assign meaningful names to layers (i.e. "POLY" or "VIA1") and to use derived layers (i.e. "ACTIVE-POLY" for the source and drain regions of a CMOS transistor). Read more about these features in Connectivity and Symbolic Connectivity Layers.

Once a layer stack has been defined and selected, a net can be traced by pressing the "Trace Net" button and clicking on a point in the layout. Starting from shapes found under this point, the net is extracted and listed in the net list on the left side of the net tracing dialog. If "Lock" is checked, another net can be traced by clicking at another point without having to press the "Trace Net" button again.

Sometimes you encounter large nets (e.g. power nets). When you click on such a net, the tracer will start running and the extraction will take a long time. If you're not interested in the details of such nets, you can limit the depth of the net tracing. This means, after a specified number of shapes is encountered, the tracer will stop and report the shapes collected so far as an incomplete net.

To configure the depth, enter the desired number of shapes in the "Trace depth" box at the bottom of the trace dialog. NOTE: the actual number of shapes in the net may be a litte less than the specified depth due to internal marker shapes which are taken into account, but are not delivered as parts of the net.

The "Trace Path" function works similar but allows specification of two points and let the algorithm find the shortest connection (in terms of shape count, not geometrical length) between those points. If the points are not connected, a message is given which indicates that no path leads from one point to the other.

The display of the nets can be configured in many ways. The configuration dialog is opened when "Configure" is pressed in the trace net dialog. Beside the color and style of the markers used to display the net it can be specified if and how the window is changed to fit the net.

Tracing all nets

This algorithm is borrowed from the LVS feature, where the scenario is extended by device recognition and netlist formation. In the context of the net tracer, nets consist of the connected shapes but don't attach to devices. As LVS extracts all nets in one sweep, using this feature in the net tracer will deliver all nets at once. Although this is a richer information output, the tracing of all nets is typically faster then tracing a single, big net such as power nets. The LVS net extractor also supports hierarchical processing which gives a considerable performance improvement and more compact net representations.

To extract all nets, use "Trace All Nets" from the "Tools" menu. It will start extracting the nets immediately. It will take the connectivity definition from the standard, single-net net tracer. You can edit this layer stack either from the single net tracer UI, from the technology manager or "Edit Layer Stack" from the "Tools" menu.

After the net tracer has finished, the netlist browser dialog opens. In this dialog you can:

- Browser the circuit hierarchy (taken from the cell hierarchy) in the left half of the central view.
- Browse the nets of the circuits in the right half of the view. Clicking on a net will highlight the net.
- Configure the net highlighting behavior. Use the "Configure" button.
- Export all or selected nets to layout, save the netlist (with shapes) to a file, load it back from a file and manage the netlist database. Use the "File" menu button in the right upper corner.
- Search for net names (if labeled) and circuits using the search edit box.
- Navigate through the history using the "back" and "forward" buttons at the top left.

Extracted nets are written and read in a KLayout-specific format called "L2N" ("layout to netlist"). This format contains both the nets and the shapes that make up a net. This way, the traced nets can be saved and retrieved later.

1.4. Design Rule Check (DRC)

The DRC feature of KLayout is described here. The "Basics" section describes the basic concepts and the "Runsets" section the DRC language.

- Design Rule Checks (DRC) Basics
- DRC Runsets

Further information about the DRC features can be found here: DRC Reference.

1.4.1. Design Rule Checks (DRC) Basics

KLayout supports design rule checks beginning with version 0.23. The capabilities of the DRC feature include:

- Basic DRC checks such as checks for minimum width and space.
- Layer-generation methods such as boolean operations and sizing.
- Extended geometrical checks such as overlap, enclosure and inside and outside checks.
- Support for edge objects derived from polygons or as output from other functions. Edge objects are useful to implement edge-related operations, for example selective sizing.
- The capability the work with multiple input layouts.
- Support for text object layers. Text objects are convenient for tagging polygons or labelling nets.
- Cell filtering, local (region-constrained) operation.
- A tiling approach for large layouts which can be configured to make use of multiple CPU cores.
- A hierarchical option.

The DRC functionality is controlled by a DRC script. A DRC script is basically a piece of code which is executed in the context of the DRC engine. The script language is based on KLayout's integrated Ruby interpreter and wraps the underlying object model into a lean and expressive language. Script execution is immediate. That means, that it is possible to embed conditional statements or loops based on the result of a previous operation. It is also possible to code low-level operations on shapes inside the script, although this will be considerably slower than using the functions provided.

Output of the DRC script can be sent to a layout layer or a report database. The report database is visualized in the marker database browser.

Basic scripts

Runset writing is described in detail in DRC Runsets. Here is a simple example for a DRC script:

```
report("A simple script")

active = input(1, 0)
poly = input(6, 0)
gate = active & poly
gate.width(0.3).output("gate_width", "Gate width violations")

metal1 = input(17, 0)
metal1.width(0.7).output("m1_width", "M1 width violations")
metal1.space(0.4).output("m1_space", "M1 spacing violations")
```

This script will compute the gate poly shapes from the active and poly layers using a boolean "AND". The active layer has GDS layer 1, while the poly layer has GDS layer 6. On this computed gate layer, the script will perform a width check for 0.3 micrometer. In addition a width and space check is performed on the first metal layer, which is on GDS layer 17.

Let's take the script apart:

- `report("A simple script")`
  This line will instruct the script to send output to a report database. The report database is shown in the marker database browser. The description text of the report database is given in brackets.
- `active = input(1, 0)`
  This line will create an input layer. "Layers" are basically collections of shapes, edges or edge pairs (edge pairs are objects created as output of check methods). "input" is a function which delivers a layer object. Checks and other functions are performed on those

layer objects in the spirit of object-oriented programming and the underlying Ruby interpreter. "active" will be a variable that holds such an object.
The parameters of the "input" method specify where to take the input from, in that case GDS layer 1 and database 0. In that simple form, the first layout loaded into the current view is used for input.

- `poly = input(6, 0)`
  This line will create another input layer for poly silicon (from GDS layer 6, datatype 0).

- `gate = active & poly`
  This line will compute the boolean "AND" of active and poly layers. The "&" is the operator for the boolean "AND" operation which computes the intersection of active and poly. The result will be sent to a new layer and a new layer object is created and put into the "gate" variable. This layer object is a temporary one and will not appear in the output but can be used in subsequent operations.

- `gate.width(0.3).output("gate_width", "Gate width violations")`
  This line combines two operations into one statement: first is performs a width check against a minimum width of 0.3 micrometer using the width method on the "gate" layer. A "method" is a function performed on a specific object and the notation used in the DRC script is the ".". "gate.width(0.3)" will perform a width check on the gate layer and create a new layer object with "edge pairs" for each violation. "Edge pairs" are marker objects consisting of two edges or partial edges which describe where two edges violate the check condition. In the simple geometrical checks, there are always two edges involved in such a violation - hence such a violation is best described by a pair of edges.
  The result of the check is sent to a report database category using the "output" method. Again this is a method called on an object, in that case the edge pair collection returned by the width check. The parameters of the output method describe a formal name and a readable description of the category.

- `metal1 = input(17, 0)`
  As before, this statement will fetch input from GDS layer 17 and datatype 0 and create a layer object representing that input.

- `metal1.width(0.7).output("m1_width", "M1 width violations")`
  As for the gate, this statement will perform a width check (this time for 0.7 micrometer) and output the violation markers to a report database category.

- `metal1.space(0.4).output("m1_space", "M1 spacing violations")`
  And again a geometrical check: this time a space check for minimum space of 0.4 micrometer.

The script can be written in several alternative forms. Here for example is a very brief version of the gate width check:

```
(input(1, 0)*input(6, 0)).width(0.3).output("gate_width", "Gate width violations")
```

Some aliases are provided for the boolean operation, so if you prefer object-oriented notation, you can use the "and" method:

```
input(1, 0).and(input(6, 0)).width(0.3).output("gate_width", "Gate width violations")
```

or the functional notation:

```
and(input(1, 0), input(6, 0)).width(0.3).output("gate_width", "Gate width violations")
```

Dimensions can be given in different ways:

```
# floating-point (will default to micrometer)
gate.width(0.3).output("gate_width", "Gate width violations")

# floating-point with unit
gate.width(0.3.micron).output("gate_width", "Gate width violations")
gate.width(300.nm).output("gate_width", "Gate width violations")

# integer values will give dimensions in database units!
```

```
gate.width(300).output("gate_width", "Gate width violations")

# as variable
min_width = 300.nm
gate.width(min_width).output("gate_width", "Gate width violations")
```

Installing and running scripts

To create a DRC script, choose "Tools/DRC/New DRC Script". KLayout will open the Macro development IDE and create a new script. The first thing to do is to give the script a proper name. The cursor is already on the name - just enter a new name and press "Enter".

The next step is to give the DRC script some description. Press the "Properties" button in the macro editor's toolbar and enter a description text - this is the text that will appear in the menu entry.

The DRC script will now appear in "Tools/DRC" with the description and selecting that entry will run the script.

To edit the DRC script, choose "Edit DRC Scripts" from "Tools/DRC" or enter the macro editor IDE and select the DRC category (the tab above the macro list).

DRC scripts can be shared or installed globally like normal macros. They can be put into the "macros" folders, but the preferred way is to deploy them in a folder called "drc" beside the "macros" folder. KLayout will scan various places for DRC scripts or macros, including the installation path and the application folder (usually in the home directory). Both places can be used to store DRC scripts.

For the more experienced user, DRC scripts are basically just macros bound to a DRC interpreter instead of the plain Ruby interpreter. You can create and run DRC scripts like ordinary macros. Use "Macros/Macro Development" to enter the macro IDE and create a DRC scripts with the "add macro" function (the "+" button). Choose "DRC scripts" as the template to use (in the "General" section). DRC scripts are by default bound to the DRC menu, but that can be changed in the same way than for any ordinary macro.

See About Macro Development for more details about the macro development facility.

By default, DRC scripts are put into the DRC category of the macro IDE. Macro categories are a way to organize macros, but do not imply a certain runtime behavior. Hence, DRC scripts can be put into any other location beside the "drc" folders selected by the DRC category.

DRC scripts can be executed in the debugger like ordinary macros and breakpoints or single-stepping can be used to debug DRC scripts. Behind the scene, the DRC commands are mapped to Ruby functions, so stepping into such commands will reveal the code behind the DRC functions.

DRC scripts are stored in ".lydrc" files in KLayout's macro format. Those are XML files containing the script code in the text element. KLayout also recognizes plain text files with the extension ".drc", but those files are usually lacking the necessary meta-information that allow KLayout to bind them to a menu entry. Hence such files can only be run from the macro IDE.

Using KLayout as a standalone DRC engine

KLayout can be used as a non-interactive DRC engine using a specific kind of DRC scripts. Since there is no "current layout" in standalong engine mode, those DRC scripts have to specify input explicitly using the "source" function. The same way, output has to be specified explicitly using either "target" to create an output layout or "report" to create an output report database (see DRC Reference: Global Functions for details about these functions).

Here is an example. It reads layer 1, datatype 0 from "input.gds", sizes it by 200 nanometers and writes the output to "out.gds", layer 10, datatype 0:

```
source("input.gds")
target("out.gds")
input(1, 0).sized(200.nm).output(10, 0)
```

Here is another example which saves the results to category "sized" of the report database file "out.lyrdb":

```
source("input.gds")
report("out.lyrdb")
input(1, 0).sized(200.nm).output("sized")
```

To run these DRC scripts, save the scripts to a file with suffix ".drc" and run it like shown below (replace "my.drc" by your file). It is recommended to disable some of the features not used in that case and put KLayout into non-interactive batch mode with "-b":

```
klayout -b -r my.drc
```

"-b" will disable all of the user interface functionality and puts KLayout in engine mode in which no display connection is required on Unix. Implicit loading of macros from the various search locations is disabled (you can still load some with "-rm") and the configuration file is neither read nor written, which causes less I/O and avoids write conflicts between different instances of KLayout.

1.4.2. DRC Runsets

This document will give a detailed introduction into the writing of DRC runsets. See also DRC Reference for a full reference of the DRC functions.

Runset basics

Runsets are basically Ruby scripts running in the context of a DRC runset interpreter. On that level, DRC runsets work with very few classes, specifically:

- Layers ("DRC::DRCLayer" class): layers represent input from the original layout or are created by functions generating information. Layers can be used as input for other methods or methods can be called in layers.
- Sources ("DRC::DRCSource" class): sources represent layout objects from where input is taken from. One default source is always provided - the default layout from where the data is taken from. More layout sources can be created to specify input from other layouts. Sources also carry information how to filter the input - for example cell filters or the working region (a rectangular region from which the input is taken).

Some functions are provided on global level and can be used without any object.

The basic elements of runsets are input and output specifications. Input is specified through "input" method calls. "input" will create a layer object that contains the shapes of specified layer. The results are output by calling the "output" method on a layer object with a specification where the output shall be sent to.

In general, the runset language is rich in alternatives - often there are more than one way to achieve the same result.

The script is executed in immediate mode. That is, each function will immediately be executed and the results of the operations can be used in conditional expressions and loops. Specifically it is possible to query whether a layer is empty and abort a loop or skip some block in that case.

Being Ruby scripts running in KLayout's scripting engine environment, runsets can make use of KLayout's full database access layer. It is possible to manipulate geometrical data on a per-shape basis. For that purpose, methods are provided to interface between the database access layer ("RBA::..." objects) and the DRC objects ("DRC::..." objects). Typically however it is faster and easier to work with the DRC objects and methods.

Including other files

The DRC script language is based on Ruby which delivers many native language features. Basically, inside a script you can include another script through "load". This will read a file and execute the content of this file in the context of the script it is loaded into.

Unfortunately, "load" creates a local context for variables. Hence it's not possible for example to use "load" to read a file that defines variables for further use in the DRC script.

To overcome this problem, KLayout offers a specific extension which embeds another file into the source by employing some kind of preprocessing. This way, a file can be included into another one like it was pasted at this place.

The notation is this:

```
# %include to_include.drc
```

which will include "include.drc". If no absolute path is given, this file is looked up relative to the file it is included in.

The file name can be put in quotes as well. Expression interpolation is supported (for the notation see About Expressions). Hence it is possible to access environment variables for example like this:

```
# %include $(env("HOME"))/to_include.drc
```

Because Ruby does not see the original files, some internals (e.g. introspection) will report wrong file names and line numbers. In most cases - for example when using "__FILE__" or "__LINE__" or when receiving stack traces and errors - the file names and line numbers will correctly refer to the source files before include file processing.

Input and output

Input is specified with the "input" method or global function. "input" is basically a method of a source object. There is always one source object which is the first layout loaded into the current view. Using "input" without and source object is calling that method on that default source object. As source is basically a collection of multiple layers and "input" will select one of them.

"input" will create a layer object representing the shapes of the specified input layer. There are multiple ways to specify the layer from which the input is taken. One of them is by GDS layer and datatype specification:

```
# GDS layer 17, datatype 0
l = input(17)

# GDS layer 17, datatype 10
l = input(17, 10)

# By expression (here: GDS layers 1-10, datatype 0 plus layer 21, datatype 10)
# All shapes are combined into one layer
l = input("1-10/0", "21/10")
```

Input can be obtained from other layouts than the default one. To do so, create a source object using the "layout" global function:

```
# layer 17 from second layout loaded
l = layout("@2").input(17)

# layer 100, datatype 1 and 2 from "other_layout.gds"
other_layout = layout("other_layout.gds")
l1 = other_layout.input(100, 1)
l2 = other_layout.input(100, 2)
```

Output is by default sent to the default layout - the first one loaded into the current view. The output specification includes the layer and datatype or the layer name:

```
# send output to the default layout: layer 17, datatype 0
l.output(17, 0)

# send output to the default layout: layer named "OUT"
l.output("OUT")

# send output to the default layout: layer 17, datatype 0, named "OUT"
l.output(17, 0, "OUT")
```

Output can be sent to other layouts using the target function:

```
# send output to the second layout loaded:
target("@2")

# send output to "out.gds", cell "OUT_TOP"
target("out.gds", "OUT_TOP")
```

Output can also be sent to a report database using the report function:

```
# send output to a report database with description "Output database"
# - after the runset has finished this database will be shown
report("Output database")

# send output to a report database saved to "drc.lyrdb"
```

```
report("Output database", "drc.lyrdb")
```

When output is sent to a report database, the specification must include a formal name and optionally a description. The output method will create a new category inside the report database and use the name and description for that:

```
# specify report database for output
report("The output database")
...
# Send data from layer l to new category "check1"
l.output("check1", "The first check")
```

The report and target specification must appear before the actual output statements. Multiple report and target specifications can be present sending output to various layouts or report databases. Note that each report or target specification will close the previous one. Using the same file name for subsequent reports will not append data to the file but rather overwrite the previous file.

Layers that have been created using "output" can be used for input again, but care should be taken to place the input statement after the output statement. Otherwise the results will be unpredictable.

It is possible to open "side" reports and targets and send layers to these outputs without closing the default output.

To open a "side report", use new_report in the same way you use "report". Instead of switching the output, this function will return a new report object that can be included in the argument list of "output" for the layer that is to be sent to that side report:

```
# opens a new side report
side_report = new_report("Another report")
...
# Send data from layer l to new category "check1" to the side report
l.output(side_report, "check1", "The first check")
```

In the same way, "side targets" can be opened using new_target. Such side targets open a way to write certain layers to other layout files. This is very handy for debugging:

```
# opens a new side target for debugging
debug_out = new_target("debug.gds")
...
# Send data from layer l to the debug output, layer 100/0
l.output(debug_out, 100, 0)
```

Dimension specifications

Dimension specifications are used in many places: for coordinates, for spacing and width values and as length values. In all places, the following rules apply:

- Floating-point numbers are interpreted as micron values by default.
- Integer number are interpreted as database units by default (**Not** integer micron values!).
- To make explicitly clear what dimensions to use, you can add a unit.

Units are added using the unit methods:

- `0.1`: 0.1 micrometer
- `200`: 200 **database units**
- `200.dbu`: 200 database units
- `200.nm`: 200 nm

- `2.um` or `2.micron`: 2 micrometer
- `0.2.mm`: 0.2 millimeter
- `1e-5.m`: 1e-5 meter (10 micrometer)

Area units are usually square micrometers. You can use units as well to indicate an area value in some specific measurement units:

- `0.1.um2` or `0.1.micron2`: 0.1 square micron
- `0.1.mm2`: 0.1 square millimeter

Angles are always given in degree units. You can make clear that you want to use degree by adding the degree unit method:

- `45.degree`: 45 degree

Objects and methods

Runsets are basically scripts written in an object-oriented language. It is possible to write runsets that don't make much use of that fact, but having a notion of the underlying concepts will result in better understanding of the features and how to make full use of the capabilities.

In KLayout's DRC language, a layer is an object that provides a couple of methods. The boolean operations are methods, the DRC functions are methods and so on. Method are called "on" an object using the notation "object.method(arguments)". Many methods produce new layer objects and other methods can be called on those. The following code creates a sized version of the input layer and outputs it. Two method calls are involved: one sized call on the input layer returning a new layer object and one output call on that object.

```
input(1, 0).sized(0.1).output(100, 0)
```

The size method like other methods is available in two flavors: an in-place method and an out-of-place method. "sized" is out-of-place, meaning that the method will return a new object with the new content but not modify the object. The in-place version is "size" which modifies the object. Only the layer object is modified, not the original layer.

The following is the above code written with the in-place version:

```
layer = input(1, 0)
layer.size(0.1)
layout.output(100, 0)
```

Using the in-place versions is slightly more efficient in terms of memory since with the out-of-place version, KLayout will keep the unmodified copy as long as there is a chance it may be required. On the other hand the in-place version may cause strange side effects since because of the definition of the copy operation: a simple copy will just copy a reference to a layer object, not the object itself:

```
layer = input(1, 0)
layer2 = layer
layer.size(0.0)
layer.output(100, 0)
layer2.output(101, 0)
```

This code will produce the same sized output for layer 100 and 101, because the copy operation "layer2 = layer" will not copy the content but just a reference: after sizing "layer", "layer2" will also point to that sized layer.

That problem can be solved by either using the out-of-place version or by creating a deep copy with the "dup" function:

```
# out-of-place size:
layer = input(1, 0)
layer2 = layer
layer = layer.sized(0.0)
layer.output(100, 0)
```

```
layer2.output(101, 0)

# deep copy before size:
layer = input(1, 0)
layer2 = layer.dup
layer.size(0.0)
layer.output(100, 0)
layer2.output(101, 0)
```

Some methods are provided in different flavors including function-style calls. For example the width check can be written in two ways:

```
# method style:
layer.width(0.2).output("width violations")

# function style:
w = width(layer, 0.2)
output(w, "width violations")
```

The function style is intended for users not familiar with the object-oriented style who prefer a function notation.

Here is a brief overview over some of the methods available:

- Source, input and output:
  source, layout, cell, select, clip, input, labels, polygons, output, report, target
- DRC functions:
  width, space, separation (sep), notch, isolated (iso), enclosing (enc), enclosed, overlap
- Universal DRC (see below):
  drc
- Boolean operations:
  & (and), | (or), - (not), ^ (xor), + (join),
- Sizing:
  size, sized
- Merging:
  merge, merged
- Shape selections:
  covering, in, inside, interacting, outside, overlapping
  pull_inside, pull_interacting, pull_overlapping, These methods are available as in-place operations as well:
  select_covering, select_interacting, select_inside, select_outside, select_overlapping
- Filters:
  rectangles, rectilinear, with_area, with_bbox_height, with_bbox_width, with_bbox_max, with_bbox_min, with_perimeter
  with_angle, with_length
  These methods are available as version selecting the opposite:
  non_rectangles, non_rectilinear, without_area, without_bbox_height, without_bbox_width, without_bbox_max, without_bbox_min,
  without_perimeter without_angle, without_length
- Text filters:
  texts, texts_not,
- Transformations:
  moved, rotated, scaled, transformed
  These methods are available as in-place versions as well: move, rotate, scale, transform
- Polygon manipulations:
  extents, hulls, holes

- Edge manipulations:
centers, end_segments, start_segments, extended, extended_in, extended_out
- Information:
length, perimeter, area, polygons?, edges?, edge_pairs?, is_box?, is_clean?, is_empty?, is_merged?, is_raw?
- Layer mode:
raw, clean
- Layer type conversions:
edges, first_edges, second_edges, polygons

Polygon and edge layers

KLayout knows four layer types: polygon, edge, edge pair and text layers. Polygon and edge layers are the basic layer types for geometrical operations.

Polygon layers are created from original layers using input or polygons. "input" will also turn texts into small polygons with a size of 2x2 DBU while "polygons" will skip texts. For handling texts, the labels method is recommended which renders a true text layer. Text layers are described below.

Polygon layers describe objects having an area ("filled objects" in the drawing view). Such objects can be processed with boolean operations, sized, decomposed into holes and hull, filtered by area and perimeter and so on. DRC methods such as width and spacing checks can be applied to polygons in a different way than between different polygons (see space, separation and notch for example).

Polygons can be raw or merged. Merged polygons consist of a hull contour and zero to many hole contours inside the hull. Merging can be ensured by putting a layer into "clean" mode (see clean, clean mode is the default). Raw polygons usually don't have such a representation and consist of a single contour folding inside to form the holes. Raw polygons are formed in "raw" mode (see raw).

Egde layers can be derived from polygon layers and allow the description is individual edges ("sides") of a polygon. Edge layers offer DRC functions similar for polygons but in a slightly different fashion - edges are checked individually, non considering the polygons they belong to. Neither do other parts of the polygons shield interactions, hence the results may be different.

Edges can be filtered by length and angle. extended allows erecting polygons (typically rectangles) on the edges. Edge layers are useful to perform operations on specific parts of polygons, for example width or space checks confined to certain edge lengths.

Edges do not differentiate whether they originate from holes or hulls of the polygon. The direction of edges is always following a certain convention: when looking from the start to the end point of an edge, the "inside" of the polygons from which the edges were derived, is to the right. In other words: the edges run along the hull in clockwise direction and counterclockwise along the holes.

Merged edges are joined, i.e. collinear edges are merged into single edges and degenerate edges (single-point edges are removed). Merged edges are present in "clean" mode (see clean, clean mode is the default).

Polygons can be decomposed into edges with the edges method. Another way to generate edges is to take edges from edge pair objects which are generated by the DRC check functions.

Text collections

Starting with version 0.27, KLayout offers support for text layers. "Texts" are basically locations with a label, i.e. a dot with an arbitrary string attached. "Text collections" are collections of such objects.

Texts can be used to select polygons or as net names in net extractions.

Text collections are kept in "text layers". These are created using the labels methods instead of "input".

These operations are supported for text layers:

- Boolean AND with a polygon layer: will select those texts which are inside or at the border of a polygon. interact is a synonym for this operation.
- Boolean NOT with a polygon layer: will select those texts which are outside of any polygon. not_interact is a synonym for this operation.
- As second layer for region interact: this way, polygons can be selected which are tagged with certain texts.
- Text filtering by string: texts can be filtered either by matching against a fixed text or a glob pattern. The methods provided for this purpose are: texts and texts_not

- flatten will flatten the hierarchy of a text layer.
- Polygon or edge generation around the text's location: polygons and edges

Edge pairs and edge pair collections

Edge pairs are objects consisting of two edges. Edge pairs are handy when discribing a DRC check violation, because a violation occurs between two edges. The edge pair generated for such a violation consists of the parts of both edges violation the condition. For two-layer checks, the edges originate from the original layers - edge 1 is related to input 1 and edge 2 is related to input 2.

Edge pair collections act like normal layers, but very few methods are defined for those. Edge pairs can be decomposed into single edges (see edges, first_edges and second_edges).

Edge pairs can be converted to polygons using polygons. Edge pairs can have a vanishing area, for example if both edges are coincident. In order to handle such edge pairs properly, an enlargement can be applied optionally. With such an enlargement, the polygon will cover a region bigger than the original edge pair by the given enlargement.

Raw and clean layer mode

KLayout's DRC engine supports two basic ways to interpret geometrical information on a layer: in clean mode, polygons or edges are joined if they touch. If regions are drawn in separate pieces they are effectively joined before they are used. In raw mode, every polygon or shape on the input layer is considered a separate part. There are applications for both ways of looking at a set of input shapes, and KLayout supports both ways.

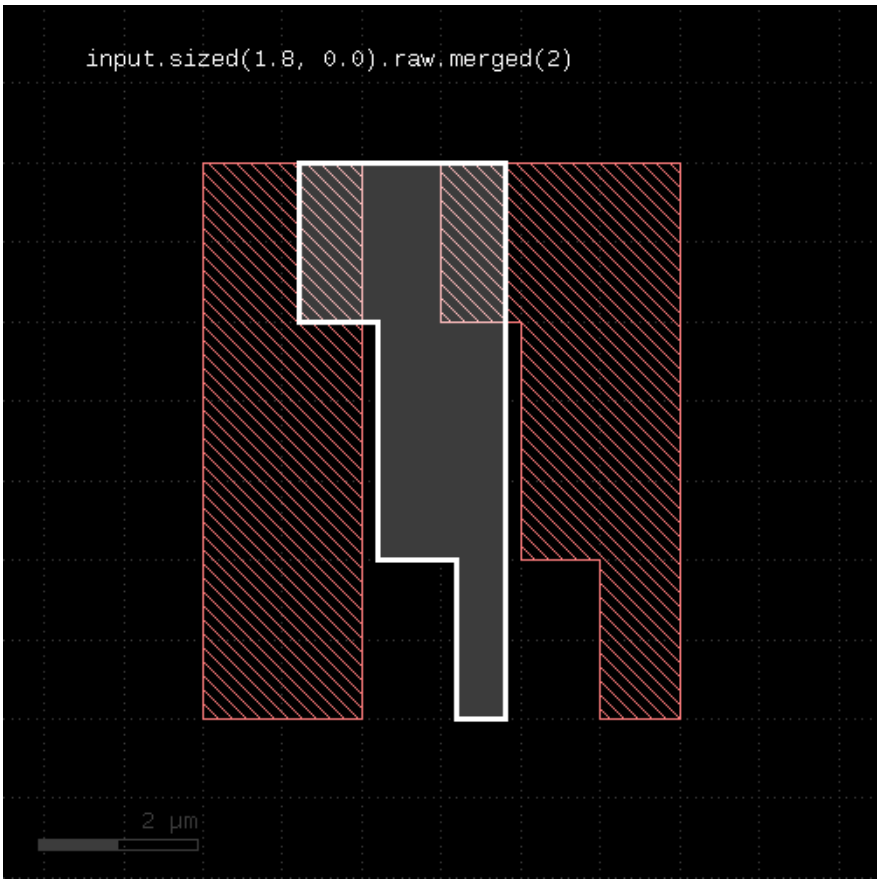
Clean mode is the default - every layer generated or taken from input will be used in clean mode. To switch to raw mode, use the "raw" method. "raw mode" is basically a flag set on the layer object which instructs the engine not the merge polygons prior to use. The raw mode flag can be reset with the "clean" method.

Most functions implicitly merge polygons and edges in clean mode. In the documentation this fact is referred to as "merged semantics": if merged semantics applies for the function, coherent polygons or edges are considered one object in clean mode. In raw mode, every polygon or edge is treated as an individual object.

One application is the detection of overlapping areas after a size step:

```
overlaps = layer.size(0.2).raw.merged(2)
```

That statement has the following effect:



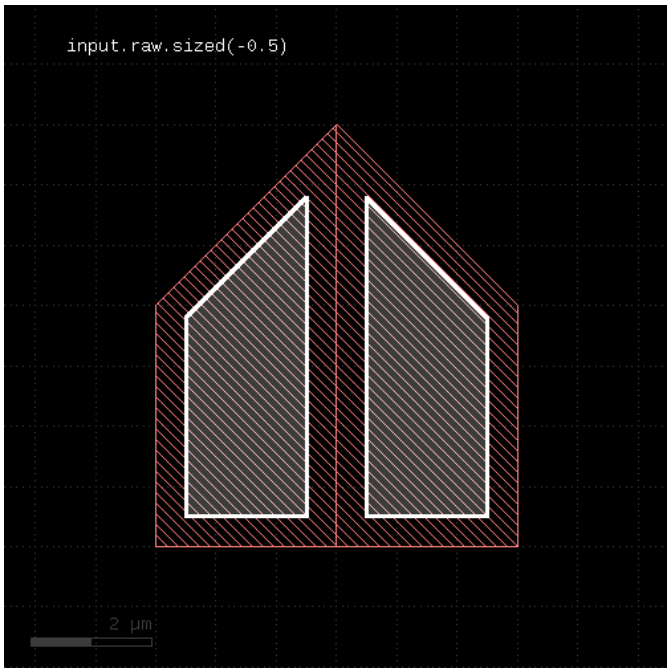
The "merged" method with an argument of 2 will produce output where more than two polygons overlap. The size function by default creates a clean layer, but separate polygons for each input polygon, so by using "raw", the layer is switched into raw mode that makes the individual polygons accessible without merging them into one bigger polygon.

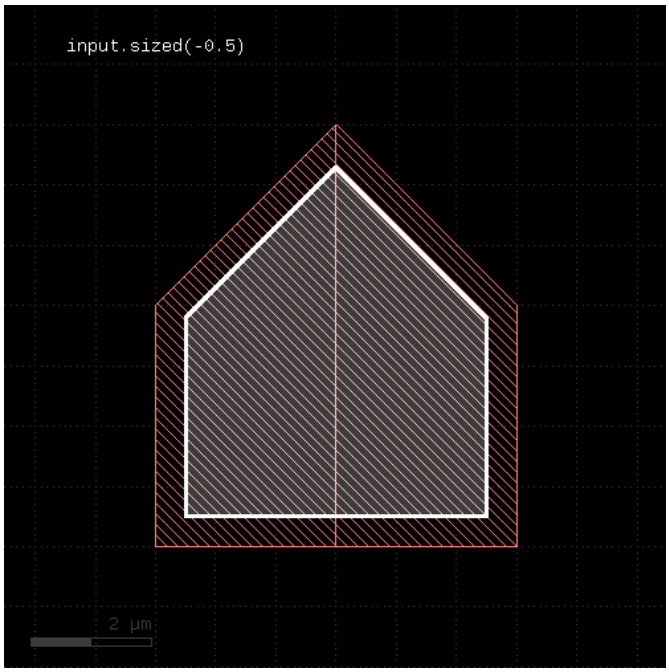
Please note that the raw or clean methods modify the state of a layer so beware of the following pitfall:

```
layer = input(1, 0)
layer.raw.sized(0.1).output(100, 0)

# this check will now be done on a raw layer, since the
# previous raw call was putting the layer into raw mode
layer.width(0.2).ouput(101, 0)
```

The following two images show the effect of raw and clean mode:

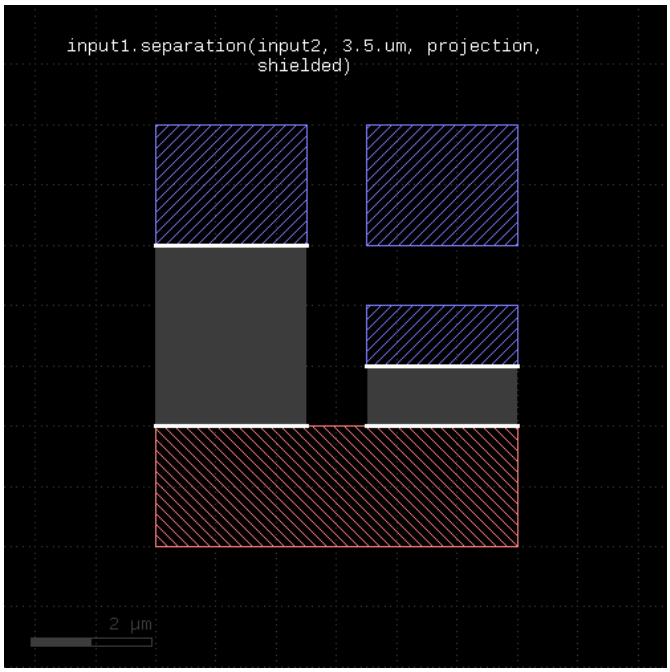


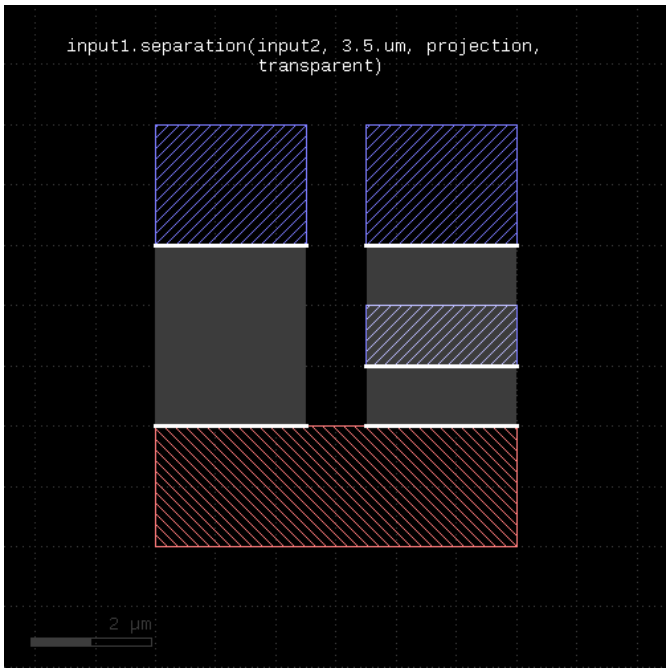


Shielding

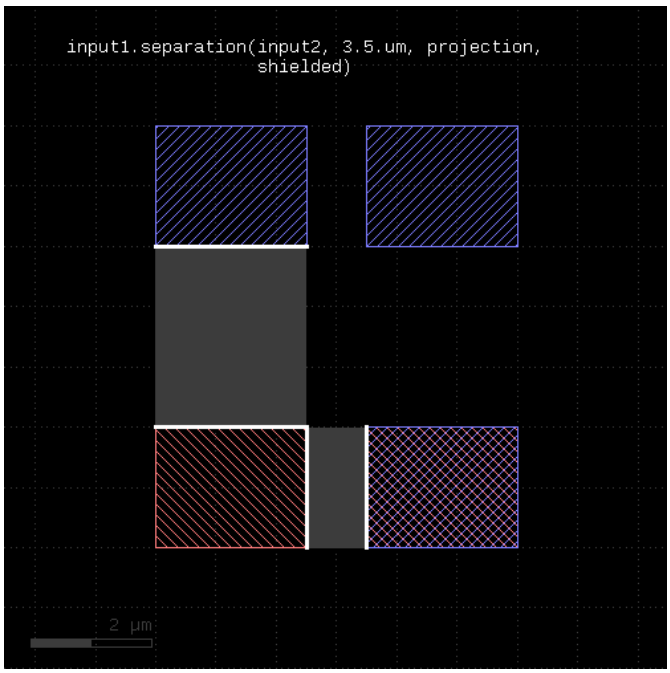
"Shielding" is a concept where DRC measurements do not "look through" layout features. With shielding, a DRC violation is skipped when another feature would (fully) block the violation marker's path. Shielding is available and enabled by default for the (internal or external) distance-based DRC functions: width, space, separation (sep), notch, isolated (iso), enclosing (enc) or enclosed or overlap. Shielding is turned off using the "transparent" option or turned on using "shielded". The latter is only for clarity, but is not required as shielding is enabled by default.

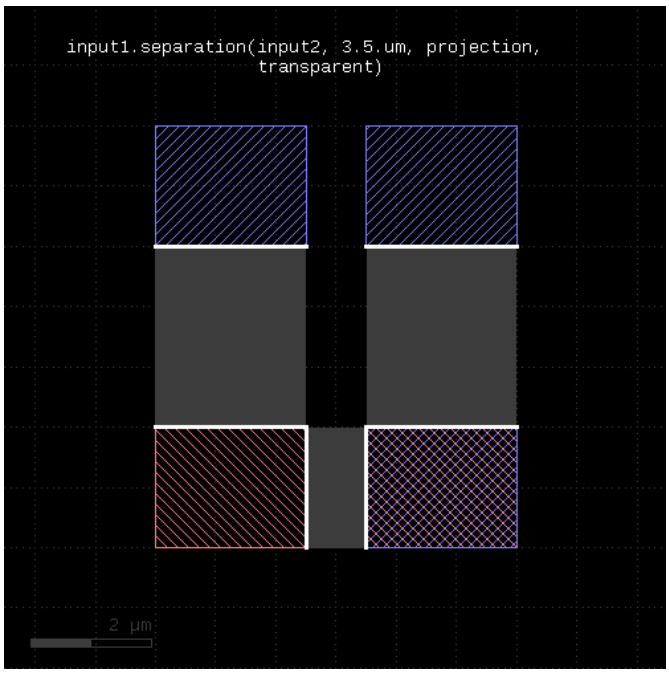
The following examples demonstrate the effect of shielding: in the right example, shielding is turned off. Hence, the violation between the upper box on the right and the lower bar is no longer shielded by the small bar between them and this additional violation is reported too.





Although shielding feels more natural, it can have an adverse effect as it is effective at zero distance already. In the following example, the second layer is a subset of the first. When testing the distance between second and first, the overlapping first layer shapes will block the separation measurement in shielded mode. Hence, only transparent mode will render the actual distance violation. The bottom right blue box is not shielded by the overlaying red box:





Universal DRC

Starting with version 0.27, the DRC language got a new feature which is "universal DRC".

On one hand, this is a more convenient way to write DRC checks because it allows specifications using natural compare operators. For example, the following plain width check

```
...
drc_w = input(1, 0).width(0.2)
...
```

can be written as:

```
...
drc_w = input(1, 0).drc(width < 0.2)
...
```

The drc method is the "universal DRC" method. It takes an operator. In the simple case, this operator is a simple constraint of the form "measurement < value", but it supports a number of different variants:

- `drc( measurement != value )`: renders markers where the dimension is not matching the value
- `drc( measurement == value )`: renders markers where the dimension is matching the given value
- `drc( measurement less_op value )`: ("less_op" is < or <=) renders markers where the dimension is less than or less or equal to the given value
- `drc( measurement greater_op value )`: ("greater_op" is > or >=) renders markers where the dimension is greater than or greater or equal to the given value
- `drc( lower_value less_op measurement greater_op upper_value )`: renders markers where the dimension is between the lower and upper value

"measurement" is "width", "notch", "isolated" ("iso"), "separation" ("sep"), "overlap", "enclosed" or "enclosuring" ("enc"). The last three checks are two-layer checks which require a second layer. The second layer is specified together with the measurement like this:

```
...
l1 = input(1, 0)
l2 = input(2, 0)
drc_sep = l1.drc(separation(l2) <= 0.5)
...
```

Options are also specified together with the measurement and follow the same notation as the plain methods. For example to specify "projection" metrics, use:

```
...
drc_w = input(1, 0).drc(width(projection) < 0.2)
...
```

However, the universal DRC is much more than a convenient way to write checks: it offers a number of options to further process the results. The functionality behind the universal DRC function is basically a kind of loop over all primary shapes (the ones from the layer the "drc" function is called on). The operations in the drc function's brackets is executed on each of the primary shapes where the neighborhood of that single shape is considered. This scheme is more efficient and enables applications beyond the capabilities of the plain layer methods.

For example, the boolean "&" operator implements a "local" boolean AND inside this loop. This allows to efficiently check for both space and width violations:

```
...
drc_ws = input(1, 0).drc((width < 0.2) & (space < 0.3))
```

```
...
```

The boolean AND is computed between the edges on the primary shape and returns the parts where both space and width violations are flagged. The boolean operation is more efficient than the plain alternative:

```
...
drc_ws1 = input(1, 0).width(0.2).edges
drc_ws2 = input(1, 0).space(0.3).edges
drc_ws = drc_ws1 & drc_ws2
...
```

The reason is that performing the boolean computation in the local loop can be shortcut if one inputs is empty. It does not need to store a (potentially big) edge set with edges as produced by the plain-method implementation. Instead it will work with a temporary and local edge set only and free the memory space as soon as it moves on to the next primary shape.

Overall, the universal DRC function is a rich feature and offers filters based on polygons or edge properties, polygon or edge manipulation operators, conditionals and a lot more. For more details see the drc function documentation.

Logging and verbosity

While the runset is executed, a log is written that lists the methods and their execution times. The log is enabled using the verbose function. The log and info functions allows entering additional information into the log. "info" will enter the message if verbose mode is enabled. "log" will enter the message always. silent is equivalent to "verbose(false)".

The log is shown in the log window or - if the log window is not open - on the terminal on Linux-like systems.

The log function is useful to print result counts during processing of the runset:

```
...
drc_w = input(1, 0).width(0.2)
log("Number of width violations: #{drc_w.data.size}")
...
```

The error function can be used to output error messages unconditionally, formatted as an error. The log can be sent to a file instead of the log window or terminal output, using the log_file function:

```
log_file("drc_log.txt")
verbose(true)
info("This message will be sent to the log file")
...
```

The profile function will collect profiling information during the DRC run. At the end of the script, the operations are printed to the log output, sorted by their CPU time and approximate memory footprint. "profile" can be given a numerical argument indicating the number of operations to print. Lower-ranking operations are skipped in that case. By default, all operations are printed.

```
# enables profiling
profile
...
```

The tiling option

Tiling is a method to reduce the memory requirements for an operation. For big layouts, pulling a whole layer into the engine is not a good idea - huge layouts will require a lot of memory. The tiling method cuts the layout into tiles with a given width and height and processes them individually. The tiling implementation of KLayout can make use of multiple CPU cores by distributing the jobs on different cores.

Tiling does not come for free: some operations have a potentially infinite range. For example, selecting edges by their length in clean mode basically requires to collect all pieces of the edge before the full length can be computed. An edge running over a long length however may cross multiple tiles, so that the pieces within one tile don't sum up to the correct length.

Fortunately, many operations don't have an infinite range, so that tiling can be applied successfully. These are the boolean operations, sizing and DRC functions. For those operations, a border is added to the tile which extends the region inside which the shapes are collected. That way, all shapes potentially participating in an operation are collected. After performing the operation, polygons and edges extending beyond the tile's original boundary are clipped. Edge pairs are retained if they touch or overlap the original tile's border. That preserves the outline of the edge pairs, but may render redundant markers in the tile's border region.

For non-local operations such as the edge length example, a finite range can be deduced in some cases. For example, if small edges are supposed to be selected, the range of the operation is limited: longer edges don't contribute to the output, so it does not matter whether to take into account potential extensions of the edge in neighboring tiles. Hence, the range is limited and a tile border can be given.

To enable tiling use the tiles function. The threads function specifies the number of CPU cores to use in tiling mode. flat will disable tiling mode:

```
# Use a tile size of 1mm
tiles(1.mm)
# Use 4 CPU cores
threads(4)

... tiled operations ...

# Disable tiling
flat

... non-tiled operations ...
```

Some operations implicitly specify a tile border. If the tile border is known (see length example above), explicit borders can be set with the tile_borders function. no_borders will reset the borders (the implicit borders will still be in place):

```
# Use a tile border of 10 micron:
tile_borders(10.um)

... tile operations with a 10 micron border ...

# Disable the border
no_borders
```

A word about the tile size: typically tile dimensions in the order of millimeters is sufficient. Leading-edge technologies may require smaller tiles. The tile border should not be bigger than a few percent of the tile's dimension to reduce the redundant tile overlap region. In general using tiles is a compromise between safe function and performance. Very small tiles imply some performance overhead do to shape collection and potentially clipping. In addition, the clipping at the tile's borders may introduce artificial polygon nodes and related snapping to the database unit grid. That may not be desired in some applications requiring a high structure fidelity. Hence, small tiles should be avoided in that sense too.

Hierarchical mode

Alternatively to the tiling option, hierarchical mode is available. In hierarchical mode, the DRC functions operate on subcells if their configuration allows this. The algorithm will automatically detect whether an operation can be performed in a subcell. For example, a sizing operation can be done inside a subcell, if the cell's content is not connected to anything outside the cell.

To enable hierarchical operations, use the "deep" statement:

```
report("deep 2")

# enable deep (hierarchical) operations
deep

poly = input(3)
```

```
spc = poly.space(0.5)
spc.output("poly space >0.5")
```

"deep" is not compatible with tiling. "tiles" will disable "deep" and vice versa. To disable deep mode, use "flat".

Deep processing is a layer property. After "deep" has been specified, layers derived with "input" are declared to be deep - i.e. hierarchical operations are enabled on them. Operations on deep layers will usually render other deep layers. This is also true for edge and edge pair layers. For example, the "space" operation above will render a hierarchical edge pair layer.

In binary operations such as boolean operations, the operation is performed hierarchically, if both involved layers are deep. A layer can be explicitly converted to a flat layer using "flatten".

To check whether a layer is deep, use "is_deep?".

```
report("deep 2")

# enable deep (hierarchical) operations
deep

poly = input(3)
puts poly.is_deep?   # -> true
poly.flatten
puts poly.is_deep?   # -> false
```

Most operations are hierarchy enabled, with a few exceptions. Some operations - specifically the transformation operations such as "move", "rotate" and the anisotropic sizing or the grid snap operations will generate cell variants. Such variants reflect different configurations of cells with respect to the requested operation. For example, with anisotropy (x != y), rotated cells need to be treated differently from non-rotated ones. In the "snap" feature, cell variants are created if the cell's instances are not all on-grid. Most functions need to create variants only when the same cell is instantiated with different magnification factors.

When writing back a layout with cell variants, new versions of cells will appear.

When sending the output of hierarchical operations to a report database, the markers will be listed under the cell name they appear. A sample cell instance is provided within the marker database to allow visualizing the marker in at least one context.

Limitations

Functions which require merged polygons utilize the net clustering algorithm to form the merged polygons. All connected shapes are collected and merged into a bigger polygon. This happens in the lowest possible level on the hierarchy where the shape clusters are complete. In some cases - when the shapes come from big coherent regions - this may happen on the top cell level and the resulting polygon will be very big. This will lead to poor performance.

The DRC's hierarchical mode will - except for cell variants in the cases mentioned - not modify the cell hierarchy. This hierarchy-preserving nature is good for certain applications, but leads to a compromise in terms of resolving hierarchically different configurations. As the algorithm is not allowed to create variants in most cases, the only remaining option is to propagate results from such cases into the parent cells. In the worst case this will lead to flattening of the layout and loss of hierarchy.

DRC and user properties

The DRC feature has some support for user properties. User properties are sets of key/value pairs attached to shapes. This is a standard feature of KLayout and GDS/OASIS. The GDS format supports numerical (positive integer) keys and string values while OASIS supports more types of keys and values - specifically string keys.

For DRC, the property set attached to a shape is regarded as a whole. The DRC can act on these properties in specific ways:

- **Ignore properties**: this is the default mode
- **Use properties**: configure operations such as checks and some boolean operations to only consider shapes with the same or different properties
- **Map/filter**: change property keys/sets or remove them
- **Transfer properties**: through operations, e.g. "size" or "with_..." selectors

Specifically, DRC functions can also **generate** properties. Currently there is only the "nets" method which attaches net identity information to shapes involved in a "connect" statement. This feature opens a path to implementing "connected" or "unconnected" mode boolean operations and DRC checks.

As of this writing, user property support is somewhat experimental. User properties support has a huge potential, so there is more to come.

Currently, the following operations can be conditioned to act on shapes with same or different properties:

- Polygon boolean operations: "and", "not" and "andnot"
- Polygon-mode DRC checks such as "separation", "space", "isolated" etc.

A variety of operations can transfer properties, i.e. edge-pair-to-polygon, edge-pair-to-edges, polygon-to-edges, edge-to-polygon, some filters, the "size" function. It is planned to enable most features to transfer properties where applicable.

Property generation is supported currently by:

- Reading properties from input layouts
- Using the "nets" feature to generate net identity properties.

Property manipulation is supported in a very basic way: properties can be removed entirely from a layer or certain property keys can be selected and optionally mapped to a different key. Property values cannot be manipulated currently.

In general, once a layer has properties, shapes with different properties are regarded as non-interacting. When shapes are merged, only groups of shapes with the same properties are merged into bigger chunks. This applies to polygons and edges. This can have the strange consequence that after merge, still polygons may overlap. Note that this only applies to the case with properties. The normal behavior is not changed.

Reading user properties

By default, user properties are not read into the shape containers. You need to enable them explicitly:

```
l1 = input(1, 0, enable_props)
```

At this point you can select certain keys from the set of properties. For example to select only values with key 17 and 18 (numerical), use:

```
l1 = input(1, 0, select_props(17, 18))
```

You can also select and map keys to other keys, like this:

```
l1 = input(1, 0, map_props({ 17 => 1, 18 => 18 }))
```

This will map values with key 17 to 1 and read those from 18 while maintaining the key. Values with other keys are ignored. See input function documentation for more details.

Manipulating properties

Once you have a layer with properties, you can remove them:

```
layer_without_properties = layer.remove_props
```

You can also apply select_props or map_props to filter values with certain keys or map keys:

```
reduced_layer = layer.select_props(17, 18)
reduced_layer = layer.map_props({ 17 => 1, 18 => 18 })
```

Generating properties as net identities

The most important application is to use the nets method to generate net identity properties:

```
connect(metal1, via1)
connect(via1, metal2)

metal1_nets = metal1.nets
```

By default, a unique net identifier (a tuple of circuit and net name) is generated on property key 0. You can specify the key as well:

```
metal1_nets = metal1.nets(prop(17))
```

The "nets" function has a number of options, specifically you can filter certain nets (by name or circuit + name). This makes the "nets" function useful for other purposes too. If you do not need properties then, specify "nil" as the property key:

```
metal1_vdd_net = metal1.nets(prop(nil), "VDD")
```

Using properties in checks and boolean operations

The main purpose of properties is to use them in operations. To confine a boolean operation to shapes with different properties, use the props_ne keyword. To confine a boolean operation to shapes with the same properties, use props_eq:

```
connect(metal1, via1)
connect(via1, metal2)

metal1_nets = metal1.nets
metal2_nets = metal2.nets

metal1_over_metal2_connected = metal1_nets.and(metal2_nets, props_eq)
metal1_over_metal2_unconnected = metal1_nets.and(metal2_nets, props_ne)
```

You can also instruct this operation to emit the original properties on the output with props_copy:

```
result_with_props = metal1_nets.and(metal2_nets, props_eq + props_copy)
```

Similarly, properties can participate in checks:

```
connect(metal1, via1)
connect(via1, metal2)

metal1_nets = metal1.nets
metal2_nets = metal2.nets

metal1_space_connected = metal1_nets.space(0.4.um, props_eq)
metal1_space_unconnected = metal1_nets.space(1.um, props_ne)
```

"props_eq", "props_ne" and "props_copy" are also available on the generic DRC function (drc), which opens new options, e.g. detecting potential short locations ("critical area") between unconnected nets:

```
connect(metal1, via1)
connect(via1, metal2)

metal1_nets = metal1.nets
metal2_nets = metal2.nets

critical_area = l1_nets.drc(primary.sized(0.2.um) & foreign.sized(0.2.um), props_ne)
```

1.5. Layout vs. Schematic (LVS)

LVS is a verification step which checks whether a layout matches the circuit from the schematic. The LVS feature is described in the following topic chapters:

- Layout vs. Schematic (LVS) Overview
- LVS Introduction
- LVS Devices
- LVS Device Classes
- LVS Device Extractors
- LVS Input/Output
- LVS Connectivity
- LVS Compare
- LVS Netlist Tweaks

A reference for the functions and objects available for LVS scripts can be found here: LVS Reference.

1.5.1. Layout vs. Schematic (LVS) Overview

Basic usage of LVS scripts

Starting with version 0.26, KLayout supports LVS as a built-in feature. LVS is an important step in the verification of a layout: it ensures the drawn circuit matches the desired schematic.

The basic functionality is simply to analyze the input layout and derive a netlist from this. Then compare this netlist against a reference netlist (schematic). If both netlist are equivalent, the circuit is likely to work in the intended fashion.

Beside the layout, a LVS script will also need a schematic netlist. Currently, KLayout can read SPICE-format netlists. The reader can be configured to some extent, so the hope is that a useful range of SPICE netlists can be digested.

While the basic idea is simple, the details become pretty complex. This documentation tries to cover the solutions KLayout offers to implement LVS as well as the constraints imposed by this process.

KLayout's LVS is integrated into the Macro Development IDE the same way as DRC scripts. In fact, LVS is an add-on to DRC scripts. All DRC functions are available within LVS scripts. Netlist extraction is performed in the DRC framework which was given the ability to recognize devices and connections and turn them into a netlist. Although DRC does not really benefit from these extensions, they are still useful for implementing Antenna checks for example. As it happens, the majority of features required for LVS is documented in the DRC Reference, while the few add-ons required specifically for LVS are documented in LVS Reference.

LVS scripts are created, edited and debugged in the Macro Editor IDE. They are managed in the "LVS" tab. For more details about the IDE, see About Macro Development. For an introduction about how to work with DRC scripts see Design Rule Checks (DRC) Basics.

LVS scripts carry the ".lylvs" extension for the XML form (in analogy to ".lydrc" for DRC) and ".lvs" for the plain text form (same as ".drc"). Like DRC scripts, LVS scripts can be executed standalone in batch mode like DRC scripts. See "Using KLayout as a standalone DRC engine" in Design Rule Checks (DRC) Basics.

KLayout's LVS implementation

The LVS implementation inside KLayout is designed to be highly flexible in terms of connectivity, device recognition and input/output channels. Here are some highlights:

- **Agnostic approach:** KLayout tries to make as few assumptions as possible. It does not require labels (although they are helpful), a specific hierarchy, specific cell names or specific geometries. Netlist extraction is done purely from the polygons of the layout. Labels and the cell hierarchy add merely useful hints which simplify debugging and pin assignment, but no strict requirement.

- **Hierarchical analysis:** KLayout got a hierarchical layout processing engine to support hierarchical LVS. Hierarchical processing means that boolean operations happen inside the local cell environment as far as possible. As a consequence, devices are recognized inside their layout cell and layout cells are turned into respective subcircuits in the netlist. The netlist compare will benefit as it is able follow the circuit hierarchy. This is more efficient and gives better debugging information in case of mismatches. As a positive side effect of hierarchical layout processing the runtimes for some boolean and other operations is significantly reduced in most cases.

- **Hierarchically stable:** KLayout won't modify the layout's hierarchy nor will it introduce variants - at least for boolean and some other operations. This way, matching between layout and schematic hierarchy is maintained even after hierarchical DRC operations. Variants are introduced only for some anisotropic operations, the grid snap method and some other features which require differentiation of cells in terms of location and orientation.

- **Flexible engine:** The netlist formation engine is highly flexible with respect to device recognition and connectivity extraction. First, almost all DRC features can be used to derive intermediate layers for device formation and connectivity extraction. Second, the device recognition can be scripted to implement custom device extractors. Five built-in device extractors are available for MOS and bipolar transistors, resistors, capacitors and diodes.

- **Flexible I/O:** Netlists are KLayout object trees and their components (nets, devices, circuits, subcircuits ...) are fully mapped to script objects (for the main class see Netlist in the API documentation). Netlists can therefore be analyzed and manipulated within LVS scripts or in other contexts. It should be possible to fully script readers and writers for custom formats. Netlists plus the corresponding layout elements (sometimes called "annotated layout") can be persisted in a KLayout-specific, yet open format. SPICE format is available to read and write pure netlist information. The SPICE reader and writer is customizable through delegate classes which allow tailoring of the way devices are read and written.

- **User interface integration:** KLayout offers a browser for the netlist extraction results and LVS reports (cross-reference, errors).

Terminology

KLayout employs a specific terminology which is explained here:

- **Circuit:** A graph of connected elements as there are: devices, pins and subcircuits. The nodes of the graph are the nets connecting at least two elements. If derived from a layout, a circuit corresponds to a specific layout cell.
- **Abstract circuits:** Abstract circuits are circuits which are cleared from their inner structure. Such circuits don't have nets and define pins only. Abstract circuits are basically "black boxes" and LVS is required to consider their inner structure as "don't care". Abstract circuits are useful to reduce the netlist complexity by taking out big IP blocks verified separately (e.g. RAM blocks).
- **Pin:** A point at which a circuit makes a connection to the outside. Circuits can embed other circuits as "subcircuits". Nets connecting to the pins of these subcircuits will propagate into the subcircuit and connect further elements there. Pins are usually attached to one net - in some cases, pins can be unattached (circuits abstracts). Pins can be named. Upon extraction, the pin name is derived from the name of the net attached to the pin.
- **Subcircuit:** A circuit embedded into another circuit. One circuit can be used multiple times, hence many subcircuits can reference the same circuit. If derived from a layout, a subcircuit corresponds to a specific cell instance.
- **Device:** A device is a n-terminal entity describing an atomic functional unit. Devices are passive devices (resistors, capacitors) or active devices such as transistors.
- **Device class:** A device class is a type of device. Device classes are of a certain kind and there can be multiple classes per type. For example for MOS transistors, the kind is "MOS4" (a four-terminal MOS transistor) and there is usually "NMOS" and "PMOS" classes at least in a CMOS process. A device class typically corresponds to a model in SPICE.
- **Device extraction:** Device extraction is the process of detecting devices and forming links between conductive areas and the device bodies. These links will eventually form the device terminals.
- **Device combination:** Device combination is the process of forming single devices from combinations of multiple devices of the same class. For example, serial resistors can be combined into one. More importantly, parallel MOS transistors ("fingered" transistors) are combined into a single device. Device combination is a step explicitly requested in the LVS script.
- **Terminal:** A "terminal" is a pin of a device. Terminals are typically named after their function (e.g. "G" for the gate of a MOS transistor).
- **Connectivity:** The connectivity is a description of conductive regions in the technology stack. A layer has intra-layer and inter-layer connectivity: "Intra-layer connectivity" means that polygons on the same layer touching other polygons form a connected - i.e. conductive - region. "Inter-layer connectivity" means that two layers form a connection where their polygons overlap. The sum of these rules forms the "connectivity graph".
- **Netlist:** A hierarchical structure of circuits and subcircuits. A netlist typically has a top circuit from which other circuits are called through subcircuits.
- **Extracted netlist:** The extracted netlist is the netlist derived from the layout. Sometimes, "extracted netlist" describes the netlist enriched with parasitic elements such as resistors and capacitors derived from the wire geometries. In the context of KLayout's LVS, "extracted netlist" is the pure connectivity without parasitic elements.
- **Schematic:** The "schematic" is a netlist taken as reference for LVS. The "schematic" is thought of the "drawn" netlist that is turned into a layout by the physical implementation process. In LVS, the layout is turned back into the "extracted netlist" which is compared to the schematic.
- **Annotated layout, Net geometry:** The collection of polygons belonging to the individual nets. Each net inside a circuit is represented by a bunch of polygons representing the original wire geometry and the device terminals. As nets can propagate to subcircuits through pins, nets and therefore annotated layout carries a per-net hierarchy. The per-net hierarchy consists of the subcircuits attached to one net and the nets within these subcircuits that connect to the outer net. Subcircuits can instantiate other subcircuits, so the hierarchy may extend over many levels.

- **Layout to netlist database (L2N DB):** This is a data structure combining the information from the extracted netlist and the annotated layout into a single entity. The L2N database can be used to visualize nets, probe nets from known locations and perform other analysis and manipulation steps. An API for handling L2N databases is available.
- **Cross reference:** The cross reference is a list of matching objects from the two netlists involved in a LVS netlist compare ("pairing"). The cross-reference also lists non-matching items and inexact pairs. "Inexact pairs" are pairs of objects which do not match precisely, but still are likely to be paired. The cross reference also keeps track of the compare status - i.e. whether the netlists match and if not, where a mismatch originates from.
- **LVS database:** The "LVS database" is the combination of L2N database, the schematic netlist and the cross-reference. It's a complete image of the LVS results. An API is available to access the elements of the LVS database.
- **Labels:** "Labels" are text objects drawn in a layout to mark certain locations on certain layers with a text. Typically, labels are used to assign net names - if included in the connectivity, nets formed from such labels get a name according to the text string of the label.

1.5.2. LVS Introduction

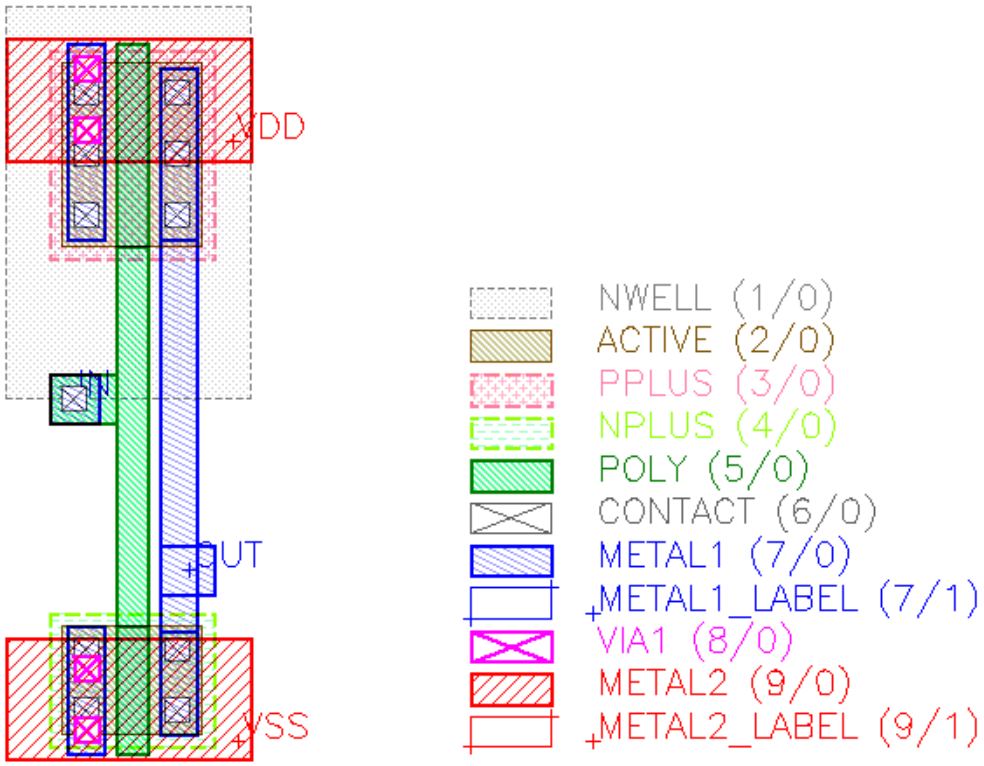
LVS introduction

For introducing the LVS feature we consider the most simple CMOS structure there is: the two-transistor inverter.

Layout

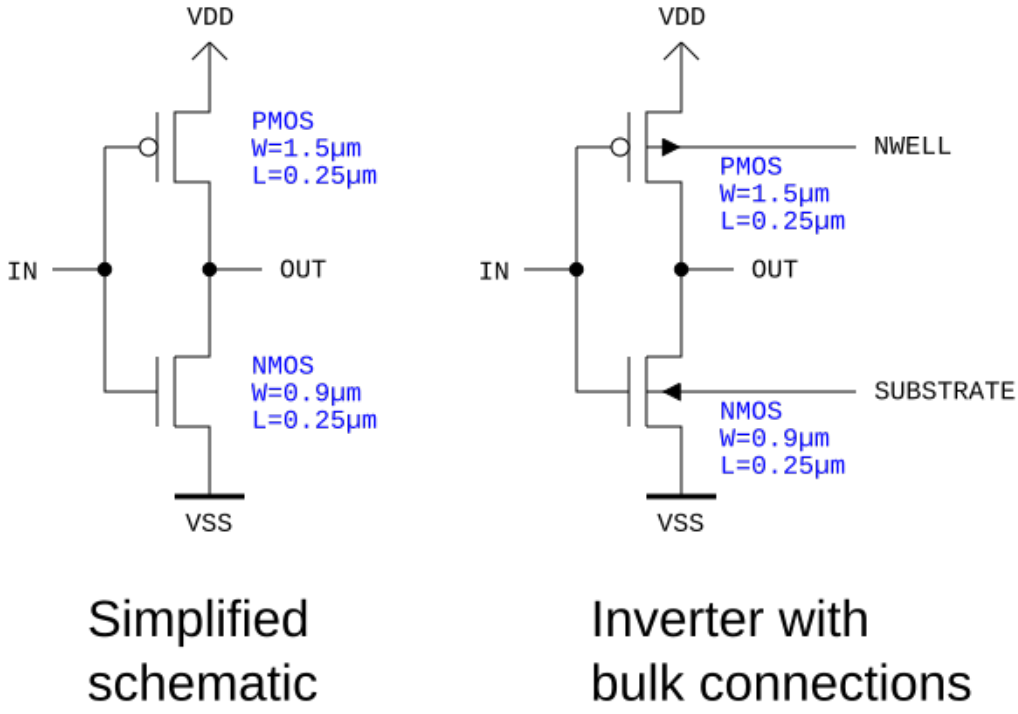
The inverter consists of two MOS transistors. A single transistor is made from an active region (a rectangle on the ACTIVE layer) and a gate (POLY layer) crossing the active region. The gate forms the channel from source to drain regions (left and right of gate). Contacts (CONTACT) provide connections from the first metal layer (METAL1) to the gate polysilicon (POLY) and to source/drain regions (where over ACTIVE). Via holes (VIA1) provide connections from the first (METAL1) to the second metal (METAL2). Finally, specific devices are formed by the source/drain implants which is n+ (NPLUS marker) for NMOS and p+ (PPLUS marker) for PMOS devices. PMOS devices sit in a n implant region (n-well) which forms the p-channel region. NMOS devices are built over substrate which is p doped to supply the n-channel region.

The actual layout is made as a standard cell. Multiple standard cells can be arrayed horizontally in a row. The power rails are formed in the second metal for VDD at the top and VSS at the bottom. The n-well extends over the top of the cell and is supposed to connect to neighbor well regions:



Schematic

For the inverter we can draw a schematic in a simplified form (left) and in a more realistic form (right) which also includes the bulk potentials of the transistors. It is important to keep the bulk of of the transistors at a defined potential to avoid latch-up. Hence we need pins for these terminals too. This makes a total of six pins: for input (IN) and output (OUT), for the power (VDD, VSS) and the two bulk potentials (NWELL, SUBSTRATE):



For LVS we first need a reference schematic. This is the SPICE netlist corresponding to the schematic with the bulk connections:

```
* Simple CMOS inverer circuit (inv.cir)
.SUBCKT INVERTER VSS IN OUT NWELL SUBSTRATE VDD
Mp VDD IN OUT NWELL     PMOS W=1.5U L=0.25U
Mn OUT IN VSS SUBSTRATE NMOS W=0.9U L=0.25U
.ENDS
```

The circuit we are going to analyze is a cell which is embedded in bigger circuits. Hence it makes sense to describe the inverter as a subcircuit. If the netlist consists of a subcircuit only, KLayout will consider this circuit. Otherwise it will consider the global definitions as the main circuit. In the latter case, pins cannot be defined while with subcircuits pins can be listed as given names too.

Sample LVS script

The LVS script to compare the layout above and the schematic now is this (for more details see LVS Reference):

```
# LVS script (demo technology, KLayout manual)

# Preamble:

deep

# Reports generated:

report_lvs     # LVS report window

# Drawing layers:

nwell       = input(1, 0)
```

```
active      = input(2, 0)
pplus       = input(3, 0)
nplus       = input(4, 0)
poly        = input(5, 0)
contact     = input(6, 0)
metal1      = input(7, 0)
metal1_lbl  = labels(7, 1)
via1        = input(8, 0)
metal2      = input(9, 0)
metal2_lbl  = labels(9, 1)

# Bulk layer for terminal provisioning:

bulk        = polygon_layer

# Computed layers:

active_in_nwell       = active & nwell
pactive               = active_in_nwell & pplus
pgate                 = pactive & poly
psd                   = pactive - pgate

active_outside_nwell  = active - nwell
nactive               = active_outside_nwell & nplus
ngate                 = nactive & poly
nsd                   = nactive - ngate

# Device extraction

# PMOS transistor device extraction
extract_devices(mos4("PMOS"), { "SD" => psd, "G" => pgate, "W" => nwell,
                                "tS" => psd, "tD" => psd, "tG" => poly, "tW" => nwell })

# NMOS transistor device extraction
extract_devices(mos4("NMOS"), { "SD" => nsd, "G" => ngate, "W" => bulk,
                                "tS" => nsd, "tD" => nsd, "tG" => poly, "tW" => bulk })

# Define connectivity for netlist extraction

# Inter-layer
connect(psd,        contact)
connect(nsd,        contact)
connect(poly,       contact)
connect(contact,    metal1)
connect(metal1,     metal1_lbl)   # attaches labels
connect(metal1,     via1)
connect(via1,       metal2)
connect(metal2,     metal2_lbl)   # attaches labels

# Global
connect_global(bulk,  "SUBSTRATE")
connect_global(nwell, "NWELL")

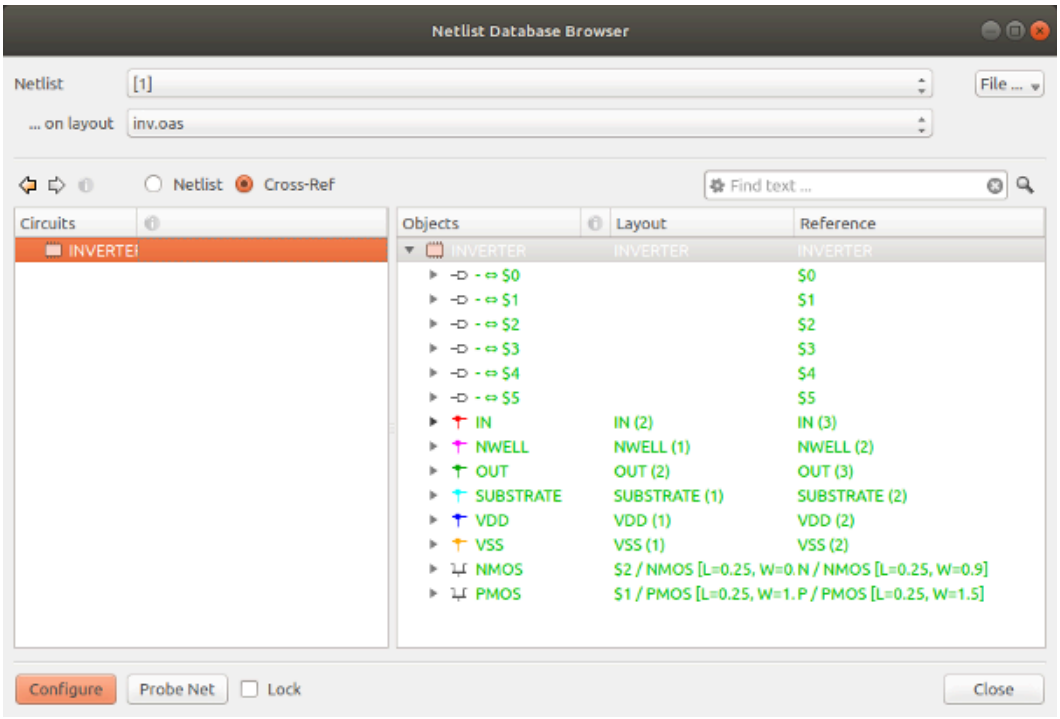
# Compare section

schematic("inv.cir")

align              # flattens unpaired circuits
netlist.simplify   # removes floating nets, combines devices

compare
```

For trying this script, load the inverter layout from "testdata/lvs/inv.oas" (KLayout sources) and open the Macro Editor IDE (Tools/Macro Development). Create a new script in the LVS tab and paste the text from above. Then run the script. The LVS report browser will open and show everything in green. This indicates the compare was successful:



Anatomy of the LVS script

The first and important statement of a LVS script should be the "deep" switch which enables hierarchical mode. Without hierarchical mode, the netlist is produced without subcircuits. Such flat netlist are inefficient to compare and hard to debug. Hence we switch to hierarchical mode with the "deep" statement (see deep):

```
deep
```

We also instruct LVS to create a report and open it in the report browser once LVS has finished:

```
report_lvs
```

We can also write the report to a file if we want (see report_lvs):

```
report_lvs("inv.lvsdb")
```

The next step is the declaration of the input layers:

```
nwell       = input(1, 0)
active      = input(2, 0)
pplus       = input(3, 0)
nplus       = input(4, 0)
poly        = input(5, 0)
contact     = input(6, 0)
metal1      = input(7, 0)
metal1_lbl  = labels(7, 1)
via1        = input(8, 0)
metal2      = input(9, 0)
metal2_lbl  = labels(9, 1)
```

"input" and "labels" are functions which pull layout layers from the layout source (the layout source is - as in DRC - usually the current layout). While "input" pulls all kind of shapes, "labels" will only pull texts. We use "labels" to pull labels for first metal from GDS layer 7, datatype 1 and labels for second metal from GDS layer 9, datatype 1. For details see input and labels.

In addition, we create an empty layer which we will need to represent the "substrate". This layer does not constitute a closed region but rather a heap of shapes which will all connect to the same (global) net later:

```
bulk = polygon_layer
```

The names we give to the layers are actually variables which represent a layout layer. As in DRC, we can use these to compute some derived layers:

```
active_in_nwell       = active & nwell
pactive               = active_in_nwell & pplus
pgate                 = pactive & poly
psd                   = pactive - pgate

active_outside_nwell  = active - nwell
nactive               = active_outside_nwell & nplus
ngate                 = nactive & poly
nsd                   = nactive - ngate
```

These formulas are all boolean operations. "&" is the boolean AND operation and "-" is the boolean NOT. Hence "active_in_nwell" is the part of "ACTIVE" which is inside "NWELL" while "active_outside_nwell" is the part of "ACTIVE" outside it. The main purpose of these formulas is to separate source and drain regions but cutting away the gate area from the "ACTIVE" area. This renders "psd" and "nsd" (PMOS and NMOS source/drain). The boolean operations are part of the DRC feature set. For more functions and detailed descriptions see DRC Reference: Layer Object.

We also separate gate regions for PMOS (pgate) and NMOS transistors (ngate) and with these ingredients we are ready to move to device extraction:

```
extract_devices(mos4("PMOS"), { "SD" => psd, "G" => pgate, "W" => nwell,
                                "tS" => psd, "tD" => psd, "tG" => poly, "tW" => nwell })
```

The first argument of "extract_devices" (see extract_devices) is the device extractor. The device extractor is an object responsible for the actual extraction of a certain device type. In our case the template is "MOS4" and we want to produce a new class of devices called "PMOS". `mos4("PMOS")` will create a new device extractor which produces devices of "MOS4" kind with class name "PMOS".

The second argument is a hash of layer symbols and layers. Each device extractor type defines a specific set of layer symbols. For all devices, two sets of the layers are required: the input layers which the extractor employs to recognize the device and the terminal connection layers which the extractor uses to place "magic" terminal shapes on. These polygons will create connections to the devices produced by the extractor.

The input layers are designated by upper-case letters, while the terminal output layers are designated with a lower-case "t" followed by the terminal name. The specification above is complete, but because "tW" defaults to "W" and "tS" and "tD" default to "SD", it can be written shorter as:

```
extract_devices(mos4("PMOS"), { "SD" => psd, "G" => pgate, "W" => nwell, "tG" => poly })
```

We also need an extractor for the "NMOS" class. It's built exactly the same way than the PMOS extractor:

```
extract_devices(mos4("NMOS"), { "SD" => nsd, "G" => ngate, "W" => bulk,
                                "tS" => nsd, "tD" => nsd, "tG" => poly, "tW" => bulk })
```

Having the devices is already half the work. We now need to supply the connectivity (see connect):

```
connect(psd,        contact)
connect(nsd,        contact)
connect(poly,       contact)
connect(contact,    metal1)
connect(metal1,     metal1_lbl)   # attaches labels
```

```
connect(metal1,     via1)
connect(via1,       metal2)
connect(metal2,     metal2_lbl)   # attaches labels
```

These statements will connect PMOS source/drain regions (psd) with CONTACT regions (contact), NMOS source/drain regions (nsd) also with CONTACT. POLY will also connect to CONTACT. Remember that we specified psd, nsd and poly as terminal outputs "tS", "TD" and "tG" in the device extraction. By including these layers into the connectivity, we establish device terminal connections to the nets formed by these layers.

The metal stack is trivial (CONTACT to METAL1, METAL1 to METAL2 via VIA1). The labels are attached to nets simply by including the label layers into the connectivity. The net extractor will pull the text strings from these connected text objects and assign them to the nets as net names.

Furthermore, two special connections need to be made (see connect_global):

```
connect_global(bulk,  "SUBSTRATE")
connect_global(nwell, "NWELL")
```

Global connections basically say that all shapes on a certain layer belong to the same net - even if they do not touch - and this net is always shared between circuits and subcircuits. This is certainly true for the bulk layer, but not necessarily for the NWELL layer. Isolated NWELL patches do not connect together. We will correct this small error later when it comes to extraction with tie-down diodes.

We have now provided all the essential inputs for the netlist formation. We now have to specify the reference netlist:

```
schematic("inv.cir")
```

Two optional, but recommended steps are hierarchy alignment and extracted netlist simplification:

```
align              # flattens unpaired circuits
netlist.simplify   # removes floating nets, combines devices
```

"align" will remove circuits which are not present in the other netlist by integrating their content into the parent cell. This will remove auxiliary cells which are usually present in a layout but don't map to a schematic cell (e.g. device PCells). "netlist.simplify" reduces the netlist by floating nets, performs device combination (e.g. fingered transistors). This method will also create pins from labeled nets in the top level circuit.

The order should be "align", then "netlist.simplify". Both have to happen before "compare" to be effective. "align" is described in LVS Compare, "netlist.simplify" in LVS Netlist Tweaks.

Finally after having set this up, we can trigger the compare step:

```
compare
```

If we insert a netlist write statement (see target_netlist) at the beginning of the script, we can obtain a SPICE version of the extracted netlist:

```
# SPICE output statement (insert at beginning of script):
target_netlist("inv_extracted.cir", write_spice, "Extracted by KLayout")
```

Since we have a LVS match, the extracted netlist is pretty much the same than the reference netlist, but enhanced by some geometrical parameters such as source and drain area and perimeter:

```
* Extracted by KLayout

* cell INVERTER
.SUBCKT INVERTER
* net 1 IN
* net 2 VSS
* net 3 VDD
* net 4 OUT
```

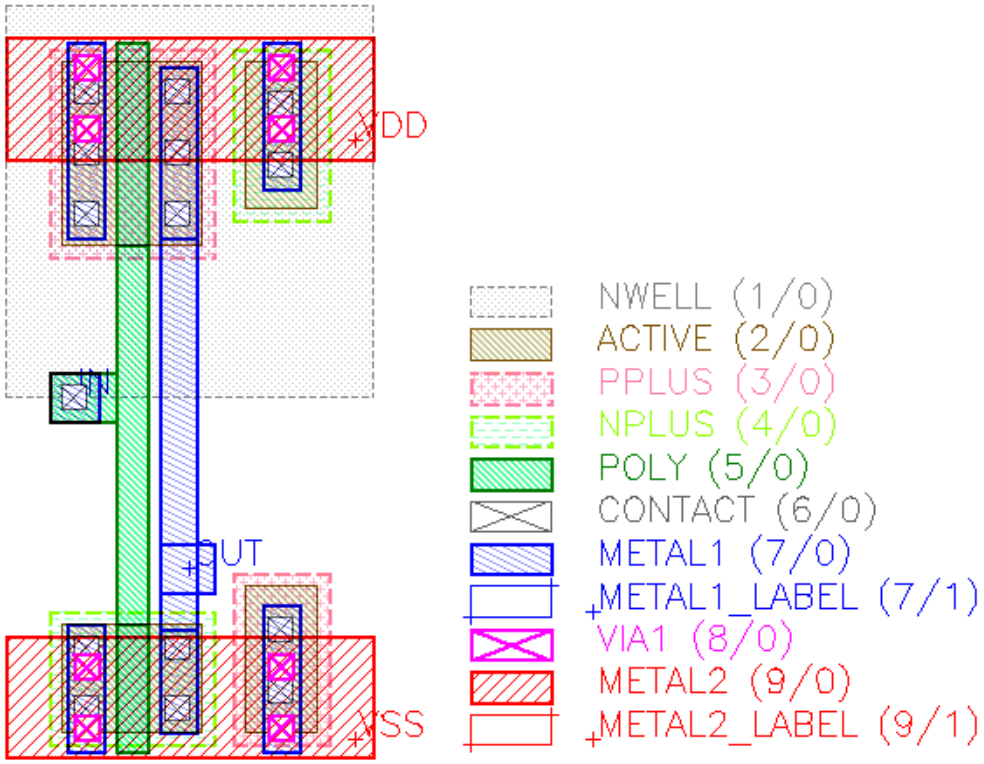
```
* net 5 NWELL
* net 6 SUBSTRATE
* device instance $1 r0 *1 1.025,4.95 PMOS
M$1 3 1 4 5 PMOS L=0.25U W=1.5U AS=0.675P AD=0.675P PS=3.9U PD=3.9U
* device instance $2 r0 *1 1.025,0.65 NMOS
M$2 2 1 4 6 NMOS L=0.25U W=0.9U AS=0.405P AD=0.405P PS=2.7U PD=2.7U
.ENDS INVERTER
```

Inverter with tie-down diodes

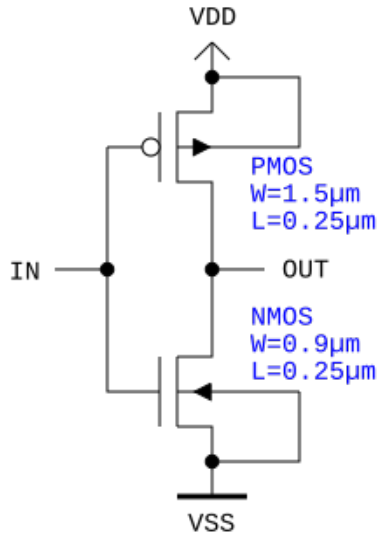
The inverter cell above is not useful by itself as it lacks features to tie the n well and the substrate to a defined potential. This is achieved with tie-down diodes.

Tie-down diodes are contacts over active regions. The active regions are implanted p+ on the substrate and n+ within the n well (the opposite implant type of transistors). With this doping profile, the metal contact won't form a Schottky barrier to the Silicon bulk and behave like an ohmic contact. So in fact, the "diode" isn't a real diode in the sense of a rectifier.

The modified layout is this one:



The corresponding schematic is this:



Inverter with
tie-down diodes

With this circuit, the n well is always at VDD potential and the substrate is tied at VSS:

```
* Simple CMOS inverer circuit
.SUBCKT INVERTER_WITH_DIODES VSS IN OUT VDD
Mp VDD IN OUT VDD PMOS W=1.5U L=0.25U
Mn OUT IN VSS VSS NMOS W=0.9U L=0.25U
.ENDS
```

The LVS script is slightly longer when extraction of tie-down diodes is included:

```
# LVS script (demo technology, KLayout manual)

# Preamble:

deep

# Reports generated:

report_lvs     # LVS report window

# Drawing layers:

nwell       = input(1, 0)
active      = input(2, 0)
pplus       = input(3, 0)
nplus       = input(4, 0)
poly        = input(5, 0)
contact     = input(6, 0)
metal1      = input(7, 0)
metal1_lbl  = labels(7, 1)
```

```
via1        = input(8, 0)
metal2      = input(9, 0)
metal2_lbl  = labels(9, 1)

# Bulk layer for terminal provisioning

bulk        = polygon_layer

# Computed layers

active_in_nwell       = active & nwell
pactive               = active_in_nwell & pplus
pgate                 = pactive & poly
psd                   = pactive - pgate
ntie                  = active_in_nwell & nplus

active_outside_nwell  = active - nwell
nactive               = active_outside_nwell & nplus
ngate                 = nactive & poly
nsd                   = nactive - ngate
ptie                  = active_outside_nwell & pplus

# Device extraction

# PMOS transistor device extraction
extract_devices(mos4("PMOS"), { "SD" => psd, "G" => pgate, "W" => nwell,
                                "tS" => psd, "tD" => psd, "tG" => poly, "tW" => nwell })

# NMOS transistor device extraction
extract_devices(mos4("NMOS"), { "SD" => nsd, "G" => ngate, "W" => bulk,
                                "tS" => nsd, "tD" => nsd, "tG" => poly, "tW" => bulk })

# Define connectivity for netlist extraction

# Inter-layer
connect(psd,        contact)
connect(nsd,        contact)
connect(poly,       contact)
connect(ntie,       contact)
connect(nwell,      ntie)
connect(ptie,       contact)
connect(contact,    metal1)
connect(metal1,     metal1_lbl)   # attaches labels
connect(metal1,     via1)
connect(via1,       metal2)
connect(metal2,     metal2_lbl)   # attaches labels

# Global
connect_global(bulk, "SUBSTRATE")
connect_global(ptie, "SUBSTRATE")

# Compare section

schematic("inv2.cir")

align
netlist.simplify

compare
```

The main difference is the computation of the regions for n tie-down (inside n well) and p tie-down. This is pretty straightforward:

```
ntie                  = active_in_nwell & nplus
ptie                  = active_outside_nwell & pplus
```

Device extraction does not change, but we need to include the tie-down regions into the connectivity:

```
connect(ntie,       contact)
connect(nwell,      ntie)
connect(ptie,       contact)
```

By connecting ntie to contact and nwell, we readily establish a connection to n well which behaves then like a conductive layer (although the resistance will be very high). Remember the the device extractors for PMOS will put the bulk terminals on nwell too, so the transistor is automatically connected to the nwell net.

ptie cannot be simply connected as there are no polygons for "substrate". But we can include ptie in the global connections:

```
connect_global(bulk, "SUBSTRATE")
connect_global(ptie, "SUBSTRATE")
```

nwell is no longer included in the global connections, hence we do no longer and incorrectly consider all nwell regions to be connected.

The extracted netlist shows the bulk terminals of NMOS and PMOS connected to source (drain and source are equivalent):

```
* Extracted by KLayout

* cell INVERTER_WITH_DIODES
.SUBCKT INVERTER_WITH_DIODES
* net 1 IN
* net 2 VDD
* net 3 OUT
* net 4 VSS

M$1 2 1 3 2 PMOS L=0.25U W=1.5U AS=0.675P AD=0.675P PS=3.9U PD=3.9U
* device instance $2 r0 *1 1.025,0.65 NMOS
M$2 4 1 3 4 NMOS L=0.25U W=0.9U AS=0.405P AD=0.405P PS=2.7U PD=2.7U
.ENDS INVERTER_WITH_DIODES
```

1.5.3. LVS Devices

Device extractors and device classes

KLayout provides two concepts for handling device variety:

Device classes are device categories. There are general categories such as resistors or MOS transistors. Specific categories can be created to represent specific incarnations - e.g. NMOS and PMOS devices. Device classes also determine how devices combine.

Device classes are documented here: LVS Device Classes.

Device extractors are the actual worker objects that analyze layout and produce devices. As for device classes, there are general device extractors. Each device extractor produces devices from a specific class.

Device extractors are documented here: LVS Device Extractors.

1.5.4. LVS Device Classes

KLayout implements a variety of standard device classes. These device classes are the basis for forming particular incarnations of device classes. For example, the MOS4 class is the basis for the specific device classes for NMOS and PMOS transistors.

Resistor

DeviceClassResistor

The plain resistor has two terminals, A and B. It features the following parameters:

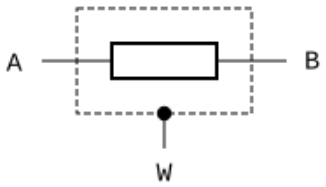
- **R** : The resistance value in Ohm
- **L** : The length in µm
- **W** : The width in µm
- **A** : The area of the resistor area in µm²
- **P** : The perimeter of the resistor area in µm

Resistors can combine in parallel or serial fashion.

In SPICE, plain resistors are represented by the "R" element. The API class is DeviceClassResistor.

Resistor with bulk terminal

```
DeviceClassResistorWithBulk
```



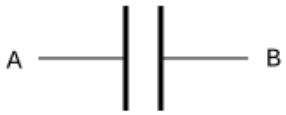
The resistor with bulk terminal is an extension of the plain resistor. If has the same parameters, but one additional terminal (W) which connects to the area the resistor sits in (e.g. well or substrate).

Resistors with bulk can combine in parallel or serial fashion if their bulk terminals are connected to the same net.

The API class of the resistor with bulk is DeviceClassResistorWithBulk.

Capacitor

```
DeviceClassCapacitor
```



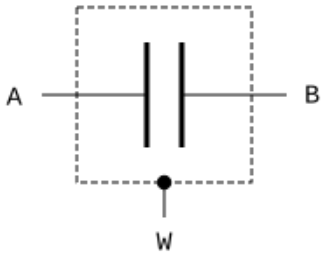
The plain capacitor has two terminals, A and B. It features the following parameters:

- **C** : The capacitance value in Farad
- **A** : The area of the capacitor area in µm²
- **P** : The perimeter of the capacitor area in µm

In SPICE, plain capacitors are represented by the "C" element. The API class is DeviceClassCapacitor.

Capacitor with bulk terminal

DeviceClassCapacitorWithBulk



The capacitor with bulk terminal is an extension of the plain capacitor. If has the same parameters, but one additional terminal (W) which connects to the area the capacitor sits in (e.g. well or substrate).

Capacitors with bulk can combine in parallel or serial fashion if their bulk terminals are connected to the same net.

The API class of the capacitor with bulk is DeviceClassCapacitorWithBulk.

Diode

DeviceClassDiode

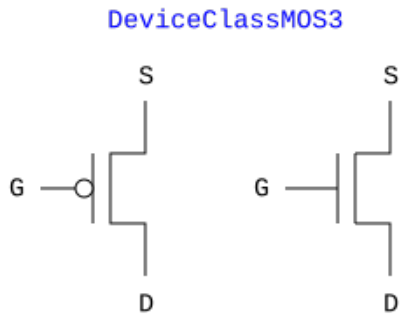
Diodes have two terminals, A and C for anode and cathode. Diodes feature the following parameters:

- **A** : The area of the diode in µm²
- **P** : The perimeter of the diode in µm

Diodes combine in parallel (A to A and C to C). In this case their areas and perimeters will add.

In SPICE, diodes are represented by the "D" element using the device class name as the model name. The API class is DeviceClassDiode.

MOS transistor



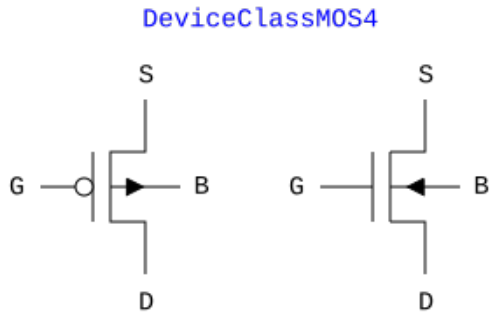
Three-terminal MOS transistors have terminals S, G and D for source, gate and drain. S and D are commutable. They feature the following parameters:

- **W** : The gate width in µm
- **L** : The gate (channel) length in µm
- **AS** : The source area in µm²
- **PS** : The source perimeter in µm
- **AD** : The drain area in µm²
- **PD** : The drain perimeter in µm

MOS3 transistors combine in parallel when the source/drains and gates are connected and their gate lengths are identical. In this case their widths, areas and perimeters will add.

MOS transistor with bulk

The API class of the three-terminal MOS transistor is DeviceClassMOS3Transistor.

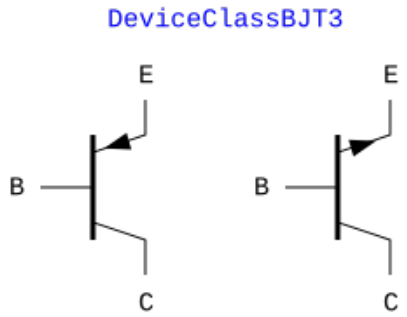


The four-terminal transistor is an extension of the three-terminal one and offers an additional bulk terminal (B). It is probably the most prominent transistor device as the four-terminal version is compatible with the SPICE "M" element.

MOS transistors with bulk can combine in parallel the same way the three-terminal versions do if their bulk terminals are connected to the same net.

In SPICE, MOS4 devices are represented by the "M" element with the device class name as the model name. The API class is DeviceClassDiode.

Bipolar transistor



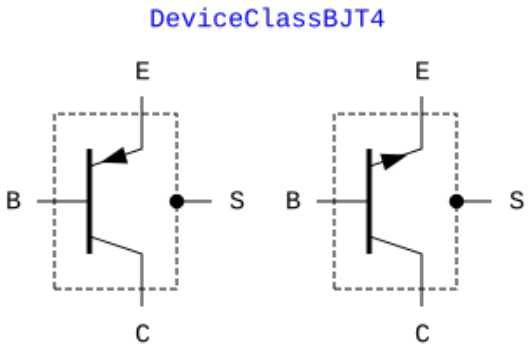
The three-terminal bipolar transistor can be either NPN or PNP type. In KLayout, this device type can represent both lateral and vertical types. The parameters are:

- **AE** : The emitter area in µm²
- **PE** : The emitter perimeter in µm
- **NE** : The emitter count (initially 1)
- **AB** : The base area in µm²
- **PB** : The base perimeter in µm
- **AC** : The collector area in µm²
- **PC** : The collector perimeter in µm

Upon extraction, multi-emitter versions are extracted as multiple devices - one for each emitter area - and NE = 1. Bipolar transistors combine when in parallel. In this case, their emitter parameters AE, PE and NE are added.

In SPICE, BJT3 devices are represented by the "Q" element with the device class name as the model name. The API class is DeviceClassBJT3Transistor.

Bipolar transistor with substrate



The four-terminal transistor is an extension of the three-terminal one and offers an additional bulk terminal (S).

Bipolar transistors with bulk can combine in parallel the same way the three-terminal versions do if their bulk terminals are connected to the same net.

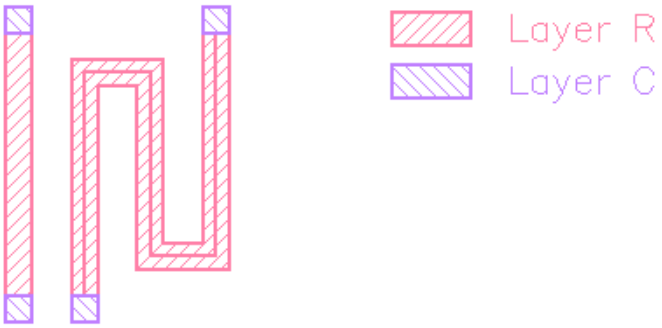
In SPICE, BJT4 devices are represented by the "Q" element with four nodes and the device class name as the model name. The API class is DeviceClassBJT4Transistor.

1.5.5. LVS Device Extractors

Device extractors and the actual "workers" of the device extraction process. KLayout comes with a variety of pre-built device extractors. It's possible to implement custom device extractors in the framework of LVS scripts (speaking Ruby).

Resistor extractors (resistor and resistor_with_bulk)

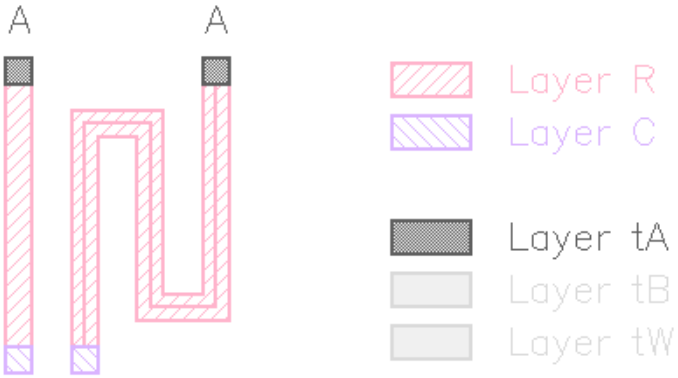
The resistor extractor assumes a layout which consists of a resistor "wire" and two caps (contacts). The wire is specified with the layer symbol "R", the caps are specified with the layer symbol "C":

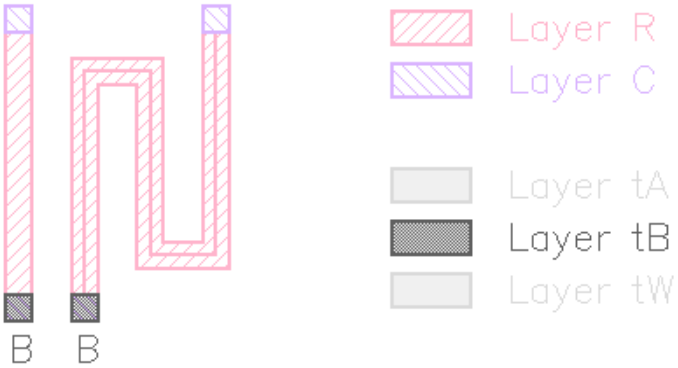


The extractor will compute the resistance from the number of squares and the sheet resistance. The sheet resistance needs to be given when creating the extractor:

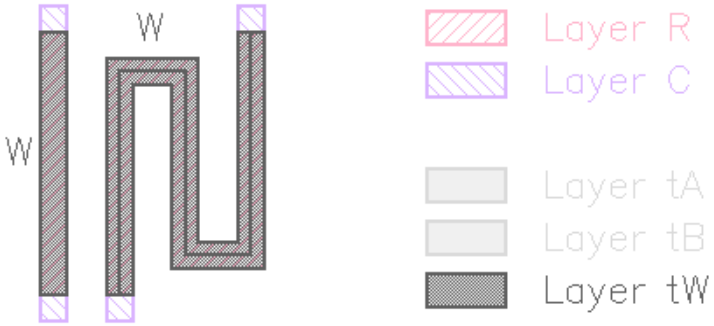
```
sheet_rho = 0.5
model_name = "RES"
extract_devices(resistor(model_name, sheet_rho), { "R" => res_layer, "C" => contact_layer })
```

The plain resistor offers two terminals which it outputs on "tA" and "tB" terminal layers. If "tA" or "tB" is not specified, "A" or "B" terminals will be written on the "C" layer. respectively.





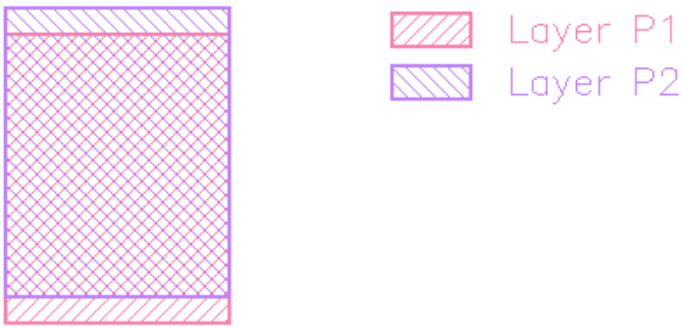
For the resistor with bulk, the wire area is output on the "tW" terminal layer as the "W" terminal:



Note: The resistance computation is based on a simple approximation. It computes the number of squares by tracing the perimeter of the "R" polygon. The perimeter length is separated in parts where the perimeter touches the "C" layer and parts where it does not. The number of squares is computed from the non-touching length divided by the touching length.

Capacitor extractors (capacitor and capacitor_with_bulk)

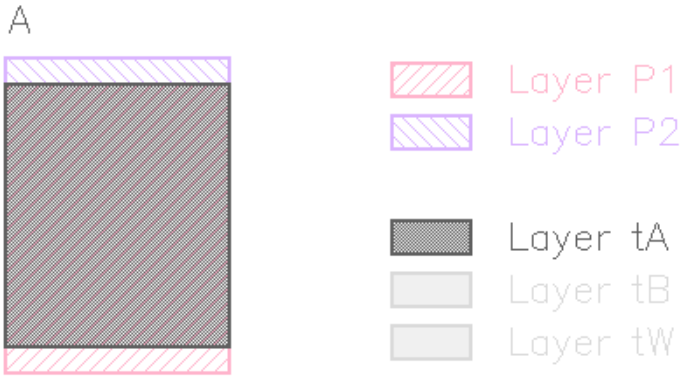
Capacitors are assumed to consist of two "plates" (vertical capacitors). The plates are on layers P1 and P2. The capacitor is extracted from the area where these two layers overlap.

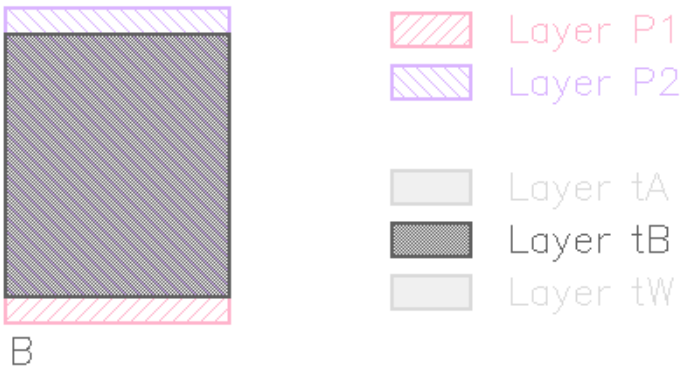


The extractor will compute the capacitance from the area of the overlap and the capacitance per area (F/µm²) value.

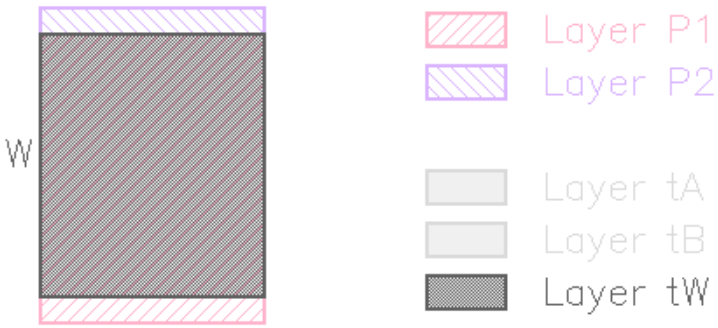
```
area_cap = 1.5e-15
model_name = "CAP"
extract_devices(capacitor(model_name, area_cap), { "P1" => metal1, "P2" => metal2 })
```

The plain capacitor offers two terminals which it outputs on "tA" and "tB" terminal layers. If "tA" or "tB" is not specified, "A" or "B" terminals will be written on the "P1" and "P2" layers respectively.



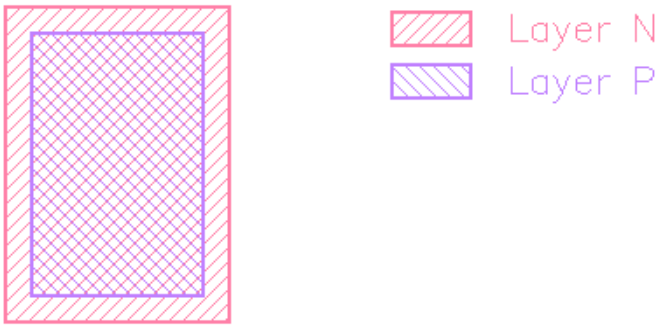


For the capacitor with bulk, the capacitor area is output on the "tW" terminal layer as the "W" terminal:



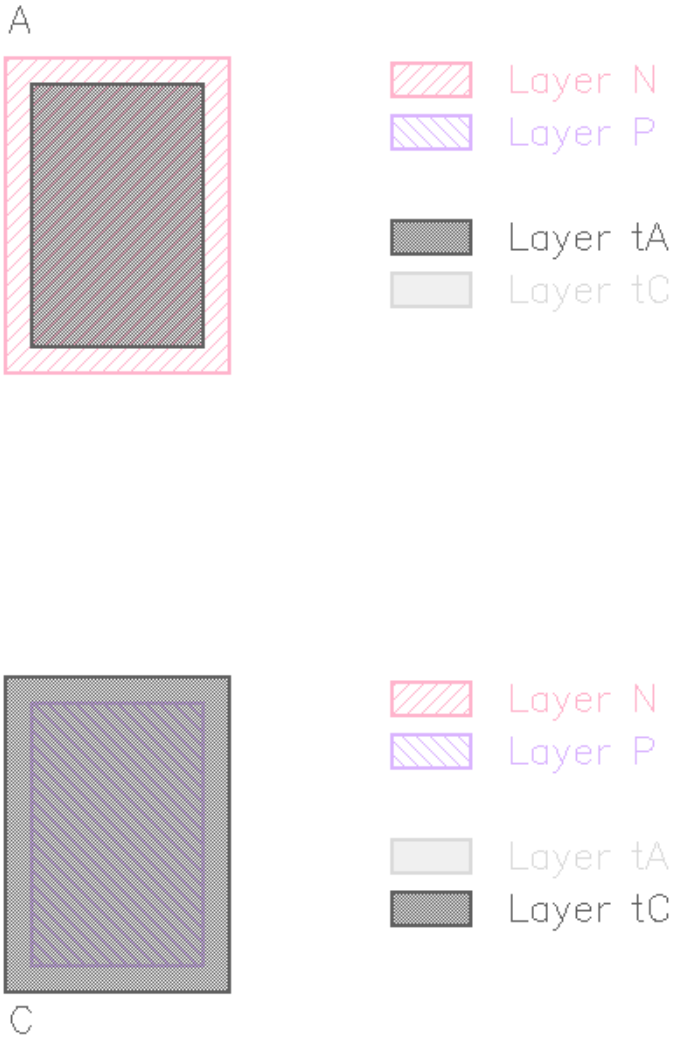
Diode extractor (diode)

Diodes are assumed to consist of two vertical implant regions (wells, diffusion). One of the regions is p type ("P" layer) and the other "n" type ("N" layer). These layers also form the anode (p) and cathode (n) of the diode.



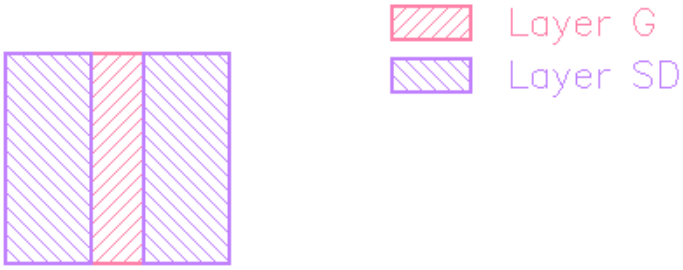
```
model_name = "DIODE"
extract_devices(diode(model_name), { "P" => pplus, "N" => nwell })
```

The diode offers two terminals which it outputs on "tA" and "tC" terminal layers. If "tA" is not specified, "A" terminals will be written on the "P" layer. If "tC" is not specified, "C" terminals will be written on the "N" layer.



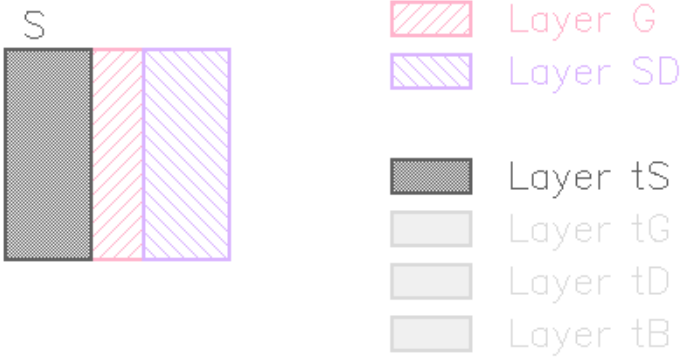
MOS transistor extractor (mos3 and mos4)

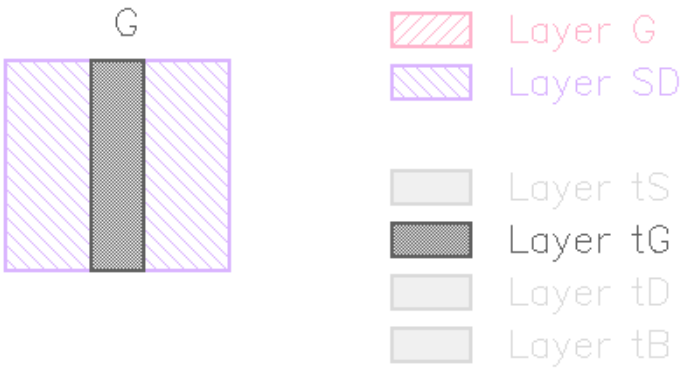
MOS transistors are recognized by their gate ("G" input) and source/drain ("SD" input) regions. Source and drain needs to be separated from the gate shape. The touching edges of gate and source/drain regions define the width of the device, the perpendicular dimension the gate length. Because the separation of source/drain, the computation of gates and the separation of these for NMOS and PMOS devices, the "G" and "SD" layers are usually derived layers. As these usually won't participate in the connectivity, it's important to specify the "tS", "tD", "tG" and "tB" (for MOS4) layers explicitly and redirect the terminal shapes to layers that really participate in connections.

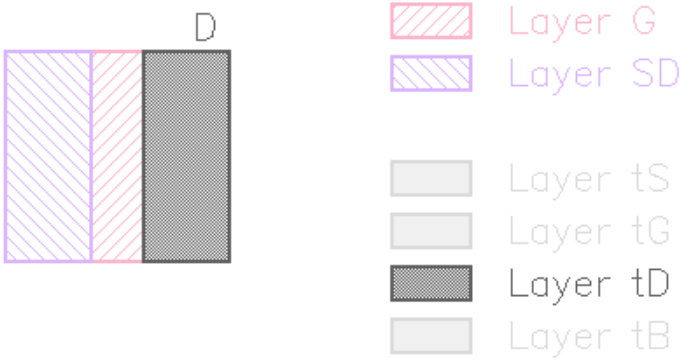


```
model_name = "PMOS"
extract_devices(mos4(model_name), { "SD" => (active - poly) & pplus, "G" => (active & poly), "W" => nwell,
                                    "tS" => active, "tD" => active, "tG" => poly, "tB" => nwell })
```

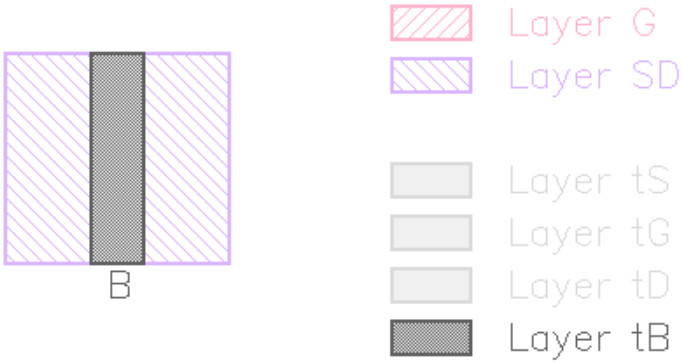
The MOS3 device produces three terminals which it outputs on "tS", "tG" and "tD" terminal layers (source, gate and drain respectively):







The MOS4 device offers one more terminal (bulk) which it writes on "tB".



Diffusion MOS transistor extractor (dmos3 and dmos4)

DMOS devices are basically identical to MOS devices, but for those source and drain are separated. This is often the case for diffusion MOS transistory, hence this name.

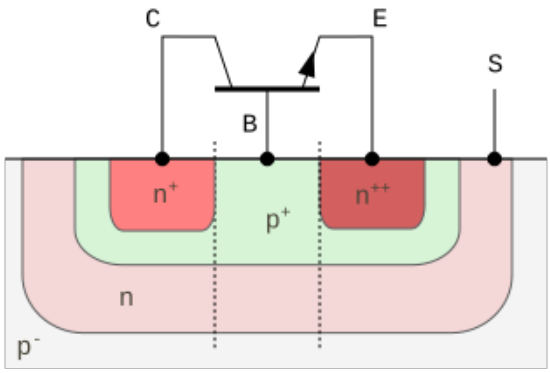
DMOS and MOS devices share the same device class. DMOS devices are configured such that source and drain cannot be swapped. The netlist compare will report source/drain swapping as errors for such devices.

DMOS transistors are recognized by their gate ("G" input), source ("S" input) and drain ("D" input) regions. Source and drain needs to be separated from the gate shape. The touching edges of gate and source/drain regions define the width of the device, the perpendicular dimension the gate length. The terminal output layers for DMOS devices are the same than for MOS devices: "tS" for source, "tD" for drain, "tG" for gate, "tB" for bulk (4-terminal version).

Bipolar transistor extractor (bjt3 and bjt4)

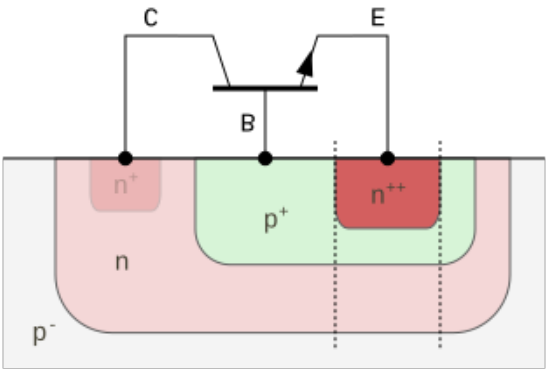
There are basically two kind of bipolar transistors: vertical and lateral ones.

Lateral transistors are formed by implant or diffusion wells creating a intermittent n/p structure on the wafer. The basic recognition region is the base region. The collector and emitter regions are inside or overlapping the base region and use the opposite doping than base: if the base region is n doped, then collector and emitter regions have to be p doped. The structure then forms a PNP transistor. KLayout recognizes lateral transistors when the base is **partially** covered by the collector region. For lateral transistors, the emitter is defined by the emitter region inside base. The collector region is defined by collector inside base and outside emitter.



(lateral NPN transistor)

Vertical transistors are formed by a stack of n/p wells. Sometimes vertical transistors are formed as parasitic devices in standard CMOS processes. A PNP transistor can be formed by taking the collector as the substrate, nwell for the base and pplus implant for the emitter. KLayout recognizes a vertical bipolar transistor when the base is covered **entirely** by the collector or has **no collector at all** - this means the collector region can be empty (e.g. bulk).

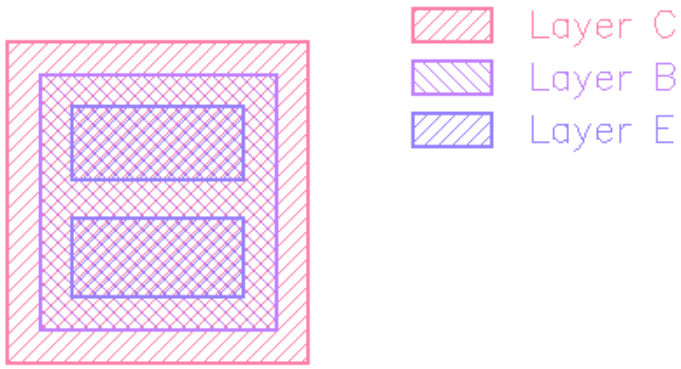


(vertical NPN transistor)

In both cases, there can be multiple emitter regions inside a base island. In this case, one transistor is extracted for each emitter region.

Vertical bipolar transistors

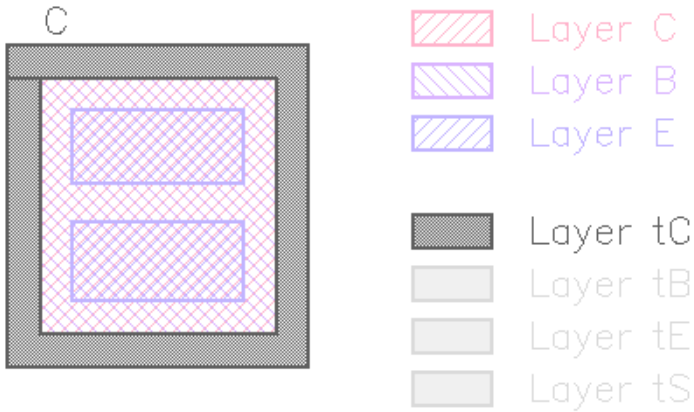
Vertical bipolar transistors take their inputs from "B" (base), "C" (collector) and "E" (emitter). "C" is optional:



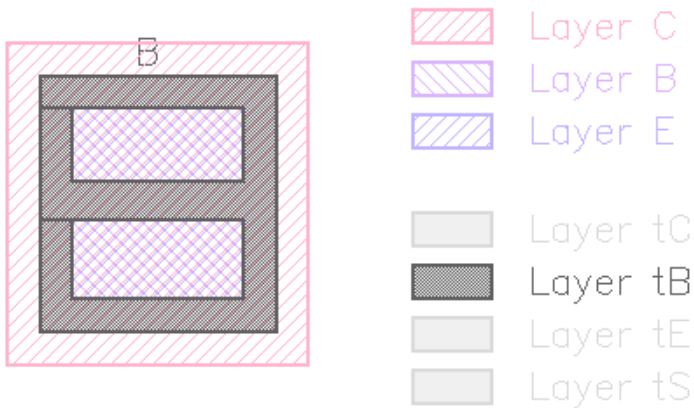
Especially for bipolar devices it's important to device useful terminal output layers. Typically, the wells and diffusion areas will be connected through "contact", (not considering the Schottky diodes for now). So it's a good idea to send the terminals to the contact layer:

```
model_name = "PNP"
extract_devices(bjt3(model_name), { "C" => collector, "B" => base, "E" => emitter,
                                    "tC" => contact, "tB" => contact, "tE" => contact })
```

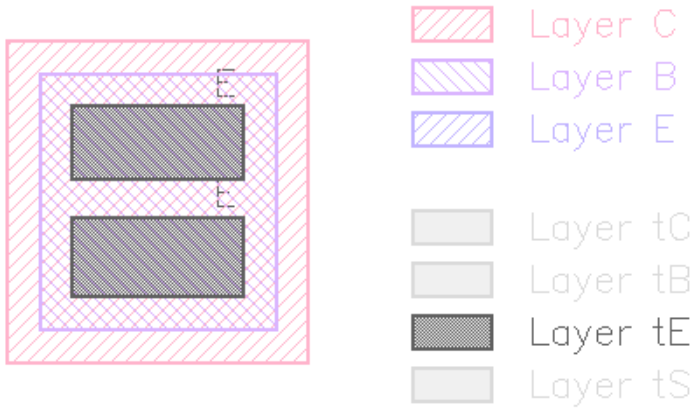
The BJT3 device produces three terminals which it outputs on "tC", "tB" and "tE" terminal layers (collector, base and emitter respectively):



C
Layer C
Layer B
Layer E
Layer tC
Layer tB
Layer tE
Layer tS

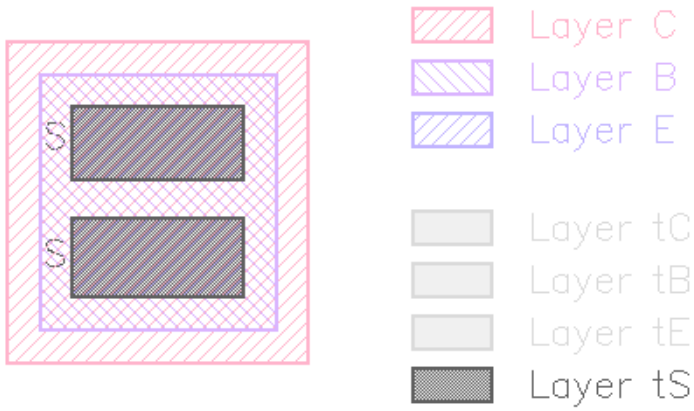


B
Layer C
Layer B
Layer E
Layer tC
Layer tB
Layer tE
Layer tS



If the collector region is empty (e.g. p substrate), the base shape is copied to the "tC" output layer for the collector terminal.

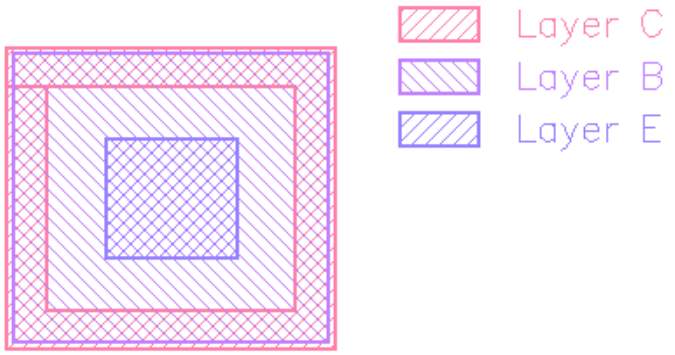
The BJT4 device offers one more terminal (substrate) which it writes on "tS". "tS" is a copy of the emitter shape but connected to the substrate terminal:



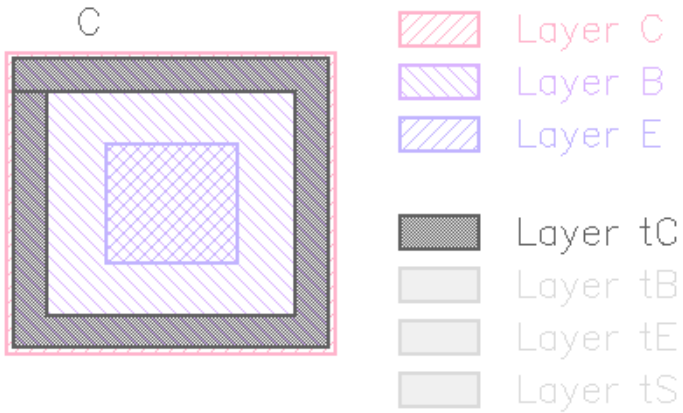
Lateral bipolar transistors

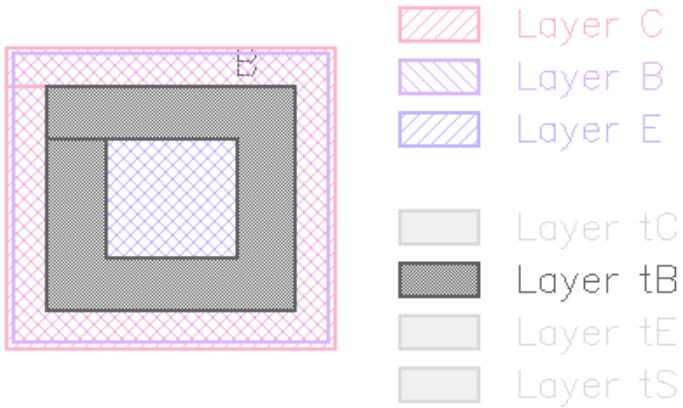
Lateral bipolar transistors also take their inputs from "B" (base), "C" (collector) and "E" (emitter). For lateral transistors, "C" is not optional and must not fully cover the base region. Apart from this, the use model for BJT3 and BJT4 extractors is identical for vertical and lateral transistors.

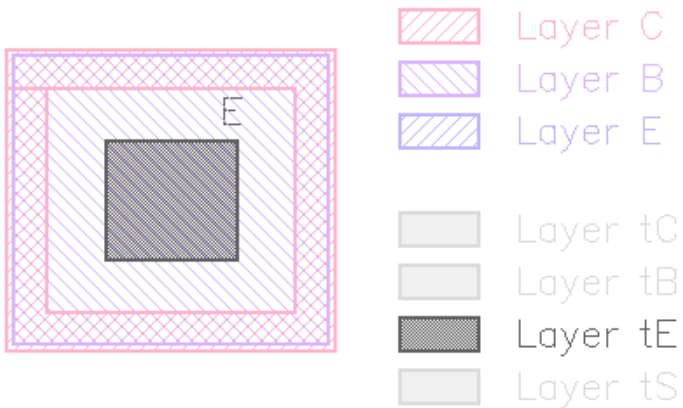
A typical lateral transistor is formed by a collector ring and emitter island inside the base region:



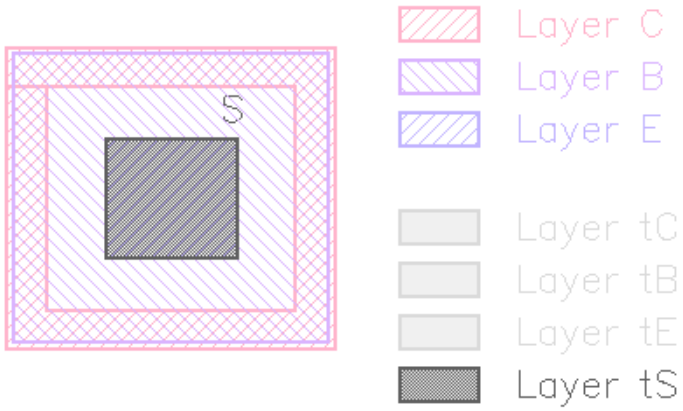
The terminals produced by the bipolar transistor extractor in the lateral case are the same than for the vertical case, but with a different geometry:







Again, for BJT4, "tS" is a copy of the emitter shape but connected to the substrate terminal:



Device extractors and device classes

"extract_devices" will return the DeviceClass object of the devices generated. This object can be useful to apply some basic modifications. The most important of them is enabling or disabling certain parameters.

Most device extractors extract more parameters than they give you by default. For example, the resistor extractor will not just extract the resistance, but also the length (L) and width (W) of the resistor stripe and its area (A) and perimeter (P). By default these additional parameters are declared "secondary" - i.e. they will not participate in the device compare and will not be netlisted.

Parameters can be fully enabled by using enable_parameter or disabled using disable_parameter. tolerance can be used to enable a parameter for compare and to specify a compare tolerance. ignore_parameter can be used to ignore a parameter in the compare step.

Another way of customizing the built-in device extractors is to supply a custom device class. The following code creates a new resistor class which changes the preconfigured device parameter definitions to enable "W" and "L".

```
class MyResistor < RBA::DeviceClassResistor
  def initialize
    super
    enable_parameter("W", true)
    enable_parameter("L", true)
  end
end

...

extract_devices(resistor("RES", 1, MyResistor), ...)
```

Using a custom device class opens the option to supply additional parameters for example or to implement some entirely new device while using the extraction mechanics of the resistor extractor. The only requirement is compatibility of the parameter and terminal definitions.

1.5.6. LVS Input/Output

LVS (and also DRC as far as netlist extraction is concerned) provides interfaces to write and read netlists/schematics, annotated layout and LVS results. There are three major categories of I/O:

- **Netlist**: this is the plain circuit information. With subcircuit this forms a hierarchical netlist. Currently, the format available to import and export netlists is a certain SPICE netlist flavor. It's possible to customize the reading and writing process to achieve some flexibility.
- **Layout-to-netlist database (L2N DB)**: also called extracted netlist or annotated layout. This is the netlist taken from the original layout together with the corresponding shapes. This database allows reconstructing a net geometrically as far as non-device shapes are involved. Devices are abstracted by their terminal geometries.
- **LVS result database (LVS DB)**: this is the L2N database plus the reference netlist and a "cross reference": a list of paired circuits, nets, devices, pins and subcircuits and status information. The cross-reference is both a lookup table and a debugging aid.

Writing netlists

You can write a netlist file to supply netlists for (functional) simulators for example. Within LVS scripts, the global "target_netlist" statement triggers writing of a netlist (see target_netlist for details).

```
target_netlist("output.cir", write_spice, "Created by KLayout")
```

This statement can basically appear anywhere in the LVS script. The netlist will written after the script has executed successfully. The first argument is the file's path (by default relative to the original layout file). The second argument is the "writer". "write_spice" creates a netlist writer writing SPICE format with a limited degree of flexbility. See below for customizing the writer. The third argument finally is an (optional) comment which will be written into the netlist as a header.

The "write_spice" configuration function has two options:

```
write_spice(use_net_names, with_comments)
```

Both options are boolean values. If true and present, the first option will make the writer use the real net's names instead of numerical IDs. If true and present, "with_comments" will embed debug comments into the netlist showing instance locations, pin names etc.

Further customization can be achieved by providing an explicit SPICE writer with a delegate (see NetlistSpiceWriterDelegate). For doing so, subclass NetlistSpiceWriterDelegate and reimplement one or several of the methods provided for reimplementation. Those are NetlistSpiceWriterDelegate#write_device, NetlistSpiceWriterDelegate#write_device_intro and NetlistSpiceWriterDelegate#write_header.

Here is an example that supplied subcircuit models rather than device elements:

```
# Write extracted netlist to extracted.cir using a special
# writer delegate

# This delegate makes the writer emit subcicuit calls instead of
# standard elements for the devices
class SubcircuitModels < RBA::NetlistSpiceWriterDelegate

  def write_header
    emit_line(".INCLUDE 'models.cir'")
  end

  def write_device(device)
    str = "X" + device.expanded_name
    device_class = device.device_class
    device_class.terminal_definitions.each do |td|
      str += " " + net_to_string(device.net_for_terminal(td.id))
    end
    str += " " + device_class.name
    str += " PARAMS:"
    device_class.parameter_definitions.each do |pd|
      str += " " + pd.name + ("=%.12g" % device.parameter(pd.id))
```

```
    end
    emit_line(str)
  end

end

# Prepare a writer using the new delegate
custom_spice_writer = RBA::NetlistSpiceWriter::new(SubcircuitModels::new)
custom_spice_writer.use_net_names= true
custom_spice_writer.with_comments = false

# The declaration of netlist production using the new custom writer
target_netlist("extracted.cir", custom_spice_writer, "Extracted by KLayout")
```

This script will produce the following netlist for the simple inverter from the LVS introduction. Instead of printing "M" elements - which is the default - subcircuit calls are produced. This allows putting more elaborate models into subcircuits. The device class name addresses these model subcircuits:

```
* Extracted by KLayout
.INCLUDE 'models.cir'

.SUBCKT INVERTER
X$1 VDD IN OUT NWELL PMOS PARAMS: L=0.25 W=1.5 AS=0.675 AD=0.675 PS=3.9 PD=3.9
X$2 VSS IN OUT SUBSTRATE NMOS PARAMS: L=0.25 W=0.9 AS=0.405 AD=0.405 PS=2.7
+ PD=2.7
.ENDS INVERTER
```

Netlists can be written directly from the netlist object. Within the script, the netlist object can be obtained with the netlist function. This function will first trigger a netlist extraction unless this was done already and return a Netlist object. Use Netlist#write to write this netlist object then. Unlike "target_netlist", this method is executed immediately and this way, a single netlist can be written to multiple files in different flavours.

Reading netlists

The main use case for reading netlists is for comparison in LVS. Reference netlists are read with the "schematic" function (see schematic):

```
schematic("inverter.cir")
```

Currently SPICE is understood with some limitations: Only a subset of elements is implemented by default. These are "M" (gives "MOS4" device classes), "Q" (gives BJT3 or BJT4 device classes), "R" (gives Resistor device classes), "C" (gives Capacitor device classes) and "D" (gives diode device classes).

As for the SPICE reader, a delegate can be provided to customize the reader. For doing so, subclass the NetlistSpiceReaderDelegate class and reimplement the methods provided. These are: NetlistSpiceReaderDelegate#wants_subcircuit, NetlistSpiceReaderDelegate#element, NetlistSpiceReaderDelegate#finish and NetlistSpiceReaderDelegate#start

This example customizes a reader to pull MOS devices from subcircuit models rather than from "M" elements. Basically this customization does the opposite part of the writer customization before (only for MOS devices).

```
# Provides a SPICE netlist reader delegate which turns
# some subcircuit models (for subcircuits NMOS and PMOS)
# into devices

class SubcircuitModelsReader < RBA::NetlistSpiceReaderDelegate

  # implements the delegate interface:
  # says we want to catch these subcircuits as devices
  def wants_subcircuit(name)
    name == "NMOS" || name == "PMOS"
  end

  # implements the delegate interface:
  # take and translate the element
  def element(circuit, el, name, model, value, nets, params)
```

```
    if el != "X"
      # all other elements are left to the standard implementation
      return super
    end

    if nets.size != 4
      error("Subcircuit #{model} needs four nodes")
    end

    # provide a device class
    cls = circuit.netlist.device_class_by_name(model)
    if ! cls
      cls = RBA::DeviceClassMOS4Transistor::new
      cls.name = model
      circuit.netlist.add(cls)
    end

    # create a device
    device = circuit.create_device(cls, name)

    # and configure the device
    [ "S", "G", "D", "B" ].each_with_index do |t,index|
      device.connect_terminal(t, nets[index])
    end

    # parameters in the model are given in micrometer units, so
    # we need to translate the parameter values from SI to um values:
    device.set_parameter("W", (params["W"] || 0.0) * 1e6)
    device.set_parameter("L", (params["L"] || 0.0) * 1e6)

    return true

  end

end

# Instantiate a reader using the new delegate
reader = RBA::NetlistSpiceReader::new(SubcircuitModelsReader::new)

# Import the schematic with this reader
schematic("inv_xmodels.cir", reader)
```

Layout-to-Netlist database/report

The layout-to-netlist database (L2N DB) is written using the global report_netlist function. This function can be put anywhere in the script. Writing will happen after the script executed successfully:

```
report_netlist("extracted.l2n")
```

Without the filename, only the netlist browser will be opened but no file will be written. The layout-to-netlist database is a KLayout-specific format. It contains the netlist information plus the shape and instance information from the layout. L2N databases can be read into the netlist browser for example. Hence exchange of extracted netlists is possible.

Layout-vs-Schematic database/report

The Layout-vs-schematic database (LVS DB) is written using the global report_lvs function. This function can be put anywhere in the script. Writing will happen after the script executed successfully:

```
report_lvs("extracted.lvsdb")
```

Without the filename, only the netlist browser will be opened but no file will be written. The LVS database is a KLayout-specific format. It contains the extracted netlist information, the reference netlist and the cross-reference table. LVS databases can be read into the netlist browser for example. Hence exchange of LVS reports is possible.

1.5.7. LVS Connectivity

Intra- and inter-layer connections

The connectivity setup of a LVS script determines how the connections are made. Connections are usually made through conductive materials such as Aluminium or Copper. The polygons representing such a material form a connection. Connections can be made across multiple polygons - touching polygons form connected islands of conductive material. This "intra-layer" connectivity is implicit: in LVS scripts connections are always made between polygons on the same layer.

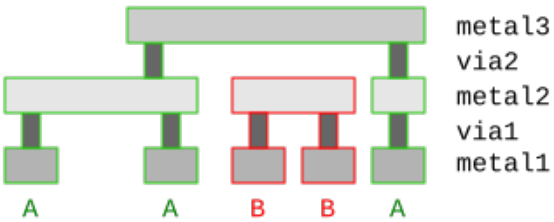
Connections often cross layers. A via for example is a hole in the insulator sheet which connects two metal layers. This connection is modelled using a "connect" statement (see connect):

```
connect(layer1, layer2)
```

A connect statement will specify an electrical connection when the polygons from layer1 and layer2 overlap. layer1 and layer2 are original or derived layers. "connect" statements should appear in the script before the netlist is required - i.e. before "compare" or any other netlist-related statement inside the LVS script. The order of the connect statements is not relevant. Neigther is the order of the arguments in "connect": connections are always bidirectional.

This is an example for a vertical cross section through a simple 3-metal layer stack with the corresponding "connect" statements:

```
connect(metal1, via1)
connect(via1, metal2)
connect(metal2, via2)
connect(via2, metal3)
```



Labels can be included in the connectivity too. Typically labels are placed on metal layers. If the labels are drawn on the same layer than the metal shapes they are automatically included when using "input" to read the layer. If only labels shall be read from a layer, use "labels" (see labels).

To attach labels to metal layers, simply connect the label and metal layers:

```
metal1_labels = labels(10, 0)
metal1        = input(11, 0)
via1          = input(12, 0)
metal2_labels = labels(13, 0)
metal2        = input(14, 0)

connect(metal1, metal1_labels)
connect(metal1, via1)
connect(via1, metal2)
connect(metal2, metal2_labels)
```

If labels are connected to metal layers, their text strings will be used to assign net names to the resulting nets. Ideally, one net is labeled with a single text or with texts with the same text string. In this case, the net name will be non-ambiguous. If multiple labels with different strings are present on a net, the net name will be made from a combination of these names.

Global connections

KLayout supports implicit connections made across all polygons on a layer, regardless whether they connect or not. A typical case for such a connection is the substrate (aka "bulk"). This connection represents the (lightly conductive) substrate material. There is no polygon representing the wafer. Instead, a layer is defined which makes a global connection with "connect_global" (see connect_global):

```
connect_global(bulk, "VSS")
```

The arguments to "connect_global" is the globally connected layer and the name of the global net to create. The function will make all shapes on "bulk" being connected to a single net "VSS". Every circuit will at least have the "VSS" net. In addition, each circuit will be given a pin called "VSS" which propagates this net to parent circuits.

Implicit connections

Implicit connections can be useful to supply preliminary connections which are supposed to be created higher up in the hierarchy: Imagine a circuit with a big power net for example. When the layout is made, the power net may not be completely connected yet, because the plan is to connect all parts of this power net later when the cell is integrated. In this situation, the subcircuit cell itself won't be LVS clean, because the power net is a single net schematic-wise, but exist as multiple nets layout-wise. This prevents bottom-up verification - a very useful technique to achieve LVS clean layouts. It also prevents matching in general, as the layout cell will have two pins while the schematic subcircuit has only one. In this case, the cell and subcircuit will never match.

To allow verification of such a cell, "implicit connections" can be made by giving the net parts the same name through labels and assuming these parts are connected: for example to specify implicit connections between all parts of a "VDD" net, place a label "VDD" on each part and include the following statement in the script:

```
connect_implicit("VDD")
```

"connect_implicit" (see connect_implicit) can be present multiple times to make many of such connections. Implicit connections are accepted on top level, but a warning is issued, indicating that the connection needs to be made further up in the hierarchy. In a subcircuit, implicit connections are required to be connected on the next level of hierarchy - either physically or by another implicit connection. This way, a missing physical connection does not escape and at least a warning is issued if the connection is still not made on top level.

You can declare the layout as being a top level one. This turns the warning about missing physical connections into an error:

```
top_level(true)
```

The "connect_implicit" feature is also called "must connect" nets in other systems.

You can include labels of a certain class in a "connect_implicit" statement using glob-style pattern:

```
connect_implicit("VDD*")
```

This will connect all nets labelled with "VDD1" for example or those labelled with "VDD_5V". However, this statement will only connect "VDD1" with "VDD1", **not** nets with different labels. I.e. it will not connect "VDD1" with "VDD2" labels. To make connections between differently named nets, use "explicit connections" (see below).

"connect_implicit" can be present multiple times. Each statement extends the choice of labels which will be connected.

The above examples of "connect_implicit" apply to all cells. The statement can be made cell specific, by giving a cell name glob pattern for the first argument, followed by the net name pattern.

The following statement will connect all nets labelled with "VDD" from the "MEMCELL" subcell:

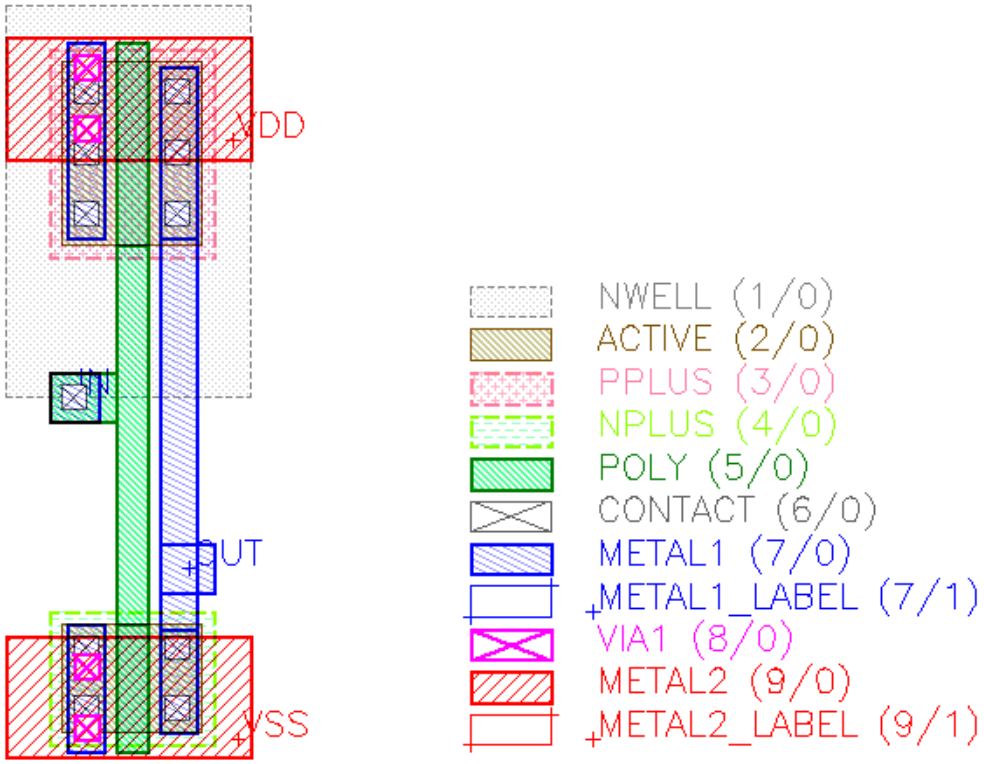
```
connect_implicit("MEMCELL", "VDD")
```

The rule is applied to all cells matching the glob pattern in the first argument. Again, the "connect_implicit" rule may be given multiple times. In this case, all matching occurrences act together.

The "connect_implicit" statements must be given before the netlist is extracted. Typically this happens before or shortly after "connect" statements.

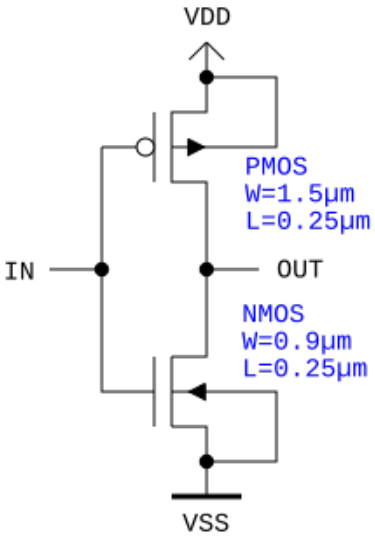
Explicit connections

Explicit connections can be useful to enforce a connection in the layout which is made in the schematic, but not physically on the level of the cell. For example consider the following layout for an inverter:

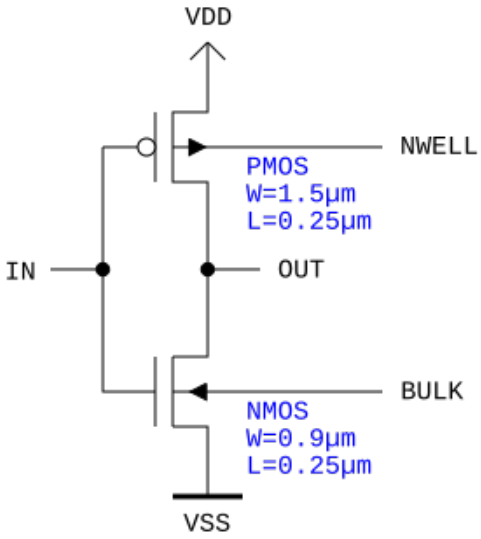


In the layout there are no tie-down diodes, hence there is no physical connection to the n-well region and no physical connection to the bulk substrate. This saves space, but these diodes need to be added by other ways. Usually this is done when the standard cells are combined into macros. Filler cells will be added which include these substrate and well contacts.

On the inverter level however, there is no such connection. Therefore the inverter has separate bulk and n-well pins. The schematic sometimes is a simplified version which does not offer these pins. Hence there is an intrinsic mismatch between layout and schematic.



Inverter schematic



Inverter layout

To align layout and schematic, bulk and VSS pins can be connected explicitly. Same for n-well and VDD. This scheme is similar to the "connect_implicit" scheme explained above, but can connect differently named nets.

To establish an explicit connection in the above example, make sure that n-well and bulk have proper names. For the n-well this can be done by creating labels on the n-well islands giving them a proper name - e.g. "NWELL". The bulk isn't a real layout layer with polygons on it. Using "connect_global" will both connect everything on this layer and give it a name.

The following code will connect the bulk net with "VSS" inside the cell "INV":

```
connect_global(bulk, "BULK")
...
connect_explicit("INV", [ "BULK", "VSS" ])
```

Note that this rule will form a new net called "BULK,VSS" combining both subnets.

The cell name can be a pattern. For example "INV*" will apply this rule on all cells starting with "INV". The cell pattern is not mandatory: if it is omitted, the rule is applied to all cells.

Like implicit connections, explicit connections are checked for being made on the next level of hierarchy, either physically or by another explicit or implicit connection.

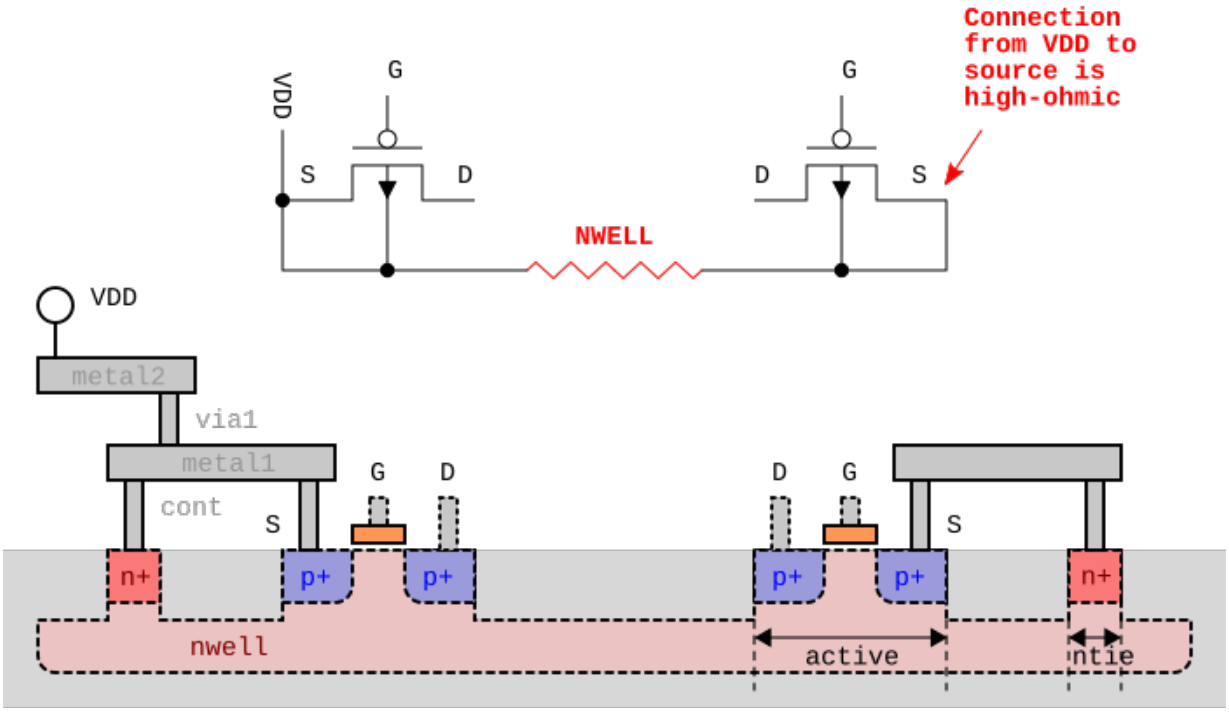
An explicit connection will also imply implicit connections on the nets listed in the net names. So in the example above, different pieces of "VSS" are connected even if they are not physically connected. Again, it is checked that these connections are made later up in the hierarchy.

Again, the "connect_explicit" statements must be given before the netlist is extracted. Typically this happens before or shortly after "connect" statements.

Soft connections

Soft connections are a way to find wiring issues where signals or even power is routed over high-ohmic paths. High-ohmic paths can be established through connections via poly silicon, implant, well or substrate areas. Such areas can easily show resistance values which are a hundred times higher than that of metal connections. We have to make sure that for routing power or critical signals, connections are not made through such areas, but primarily through metal connections.

Here is an example:



In this case, we have a standard textbook planar CMOS technology with two PMOS devices sitting in a n-well. These could be the two PMOS of two inverter pairs for example. Both PMOS need to be connected to VDD at their sources. In addition, the n-well area also needs to be tied to VDD in order to provide reverse bias for the p+ drain areas and the body potential for the transistors, forming the opposite electrode of the gate capacity.

Such a technology stack can be described by the following connectivity:

```
# Input layers

nwell = ...
active = ...
pplus = ...
nplus = ...
poly = ...
contact = ...
metal1 = ...
via1 = ...
metal2 = ...

# computed layers
```

```
(nactive, pactive) = active.and_not(nwell)

# PMOS and NMOS source/drain regions
psd  = (nactive & pplus) - poly
nsd  = (pactive & nplus) - poly

# n tie and p tie (nwell and substrate contact)
ntie = nactive & nplus
ptie = pactive & pplus

# connections

# nwell connections
connect(ntie, nwell)
connect(contact, ntie)

# substrate connections
connect_global(ptie, "BULK")
connect(contact, ptie)

# device connections
connect(contact, psd)
connect(contact, nsd)
connect(contact, poly)

# metal connections
connect(metal1, contact)
connect(via1, metal1)
connect(metal2, via1)
```

However, there is an issue: As shown in the picture, the left PMOS source is properly connected to VDD. The right one however lacks the metal connection to VDD. From the perspective of pure connectivity, this transistor's source is connected to VDD, but only through a weak n-well connection. Such a device will not work - or at least, badly.

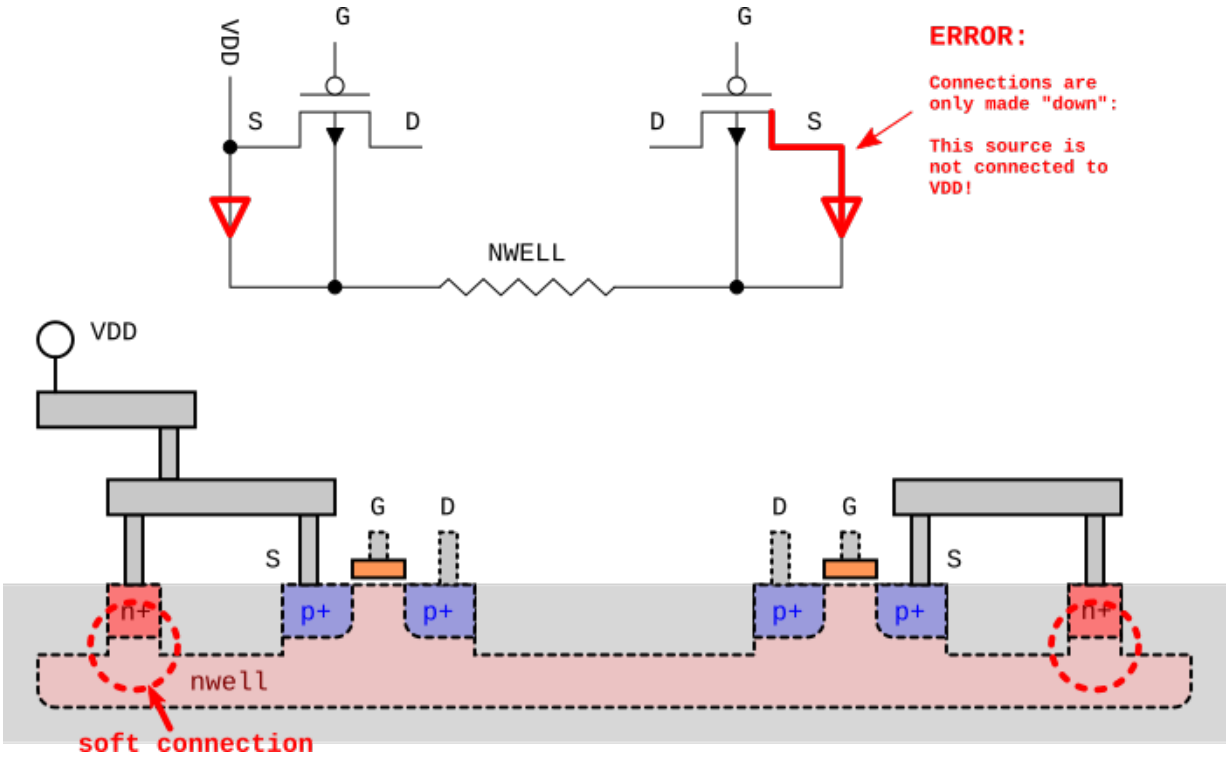
The solution is to introduce soft connections. Soft connections are made by replacing "connect" with "soft_connect" and "connect_global" with "soft_connect_global" (see soft_connect and soft_connect_global). The first layer is the "upper" layer while the second layer is the "lower" layer. The lower layer is the high-ohmic one. In global connections, the global net is always the high-ohmic one.

Soft connections can be visualized as directional connections: current can only flow from the upper to the lower layer, but not the other way. So, a real connection is only made, if both upper terminals of the soft connections are connected to the same physical net.

To solve the n-well issue we have to substitute the n-tie to n-well connection statement by a "soft_connect" statement:

```
soft_connect(ntie, nwell)
```

The above picture now looks like this:



With this definition, the netlist extractor is able to detect the fault and raise a warning or an error (in top level mode). The warning is shown on the log tab and indicates incomplete wiring plus details about the subnets, separated by the soft connections.

The complete the setup we also need to include other soft connections, such as connections via substrate (a global soft connect to the BULK net), via source/drain implants, via the tie implants and via poly:

```
# Input layers

nwell = ...
active = ...
pplus = ...
nplus = ...
poly = ...
contact = ...
metal1 = ...
via1 = ...
metal2 = ...

# computed layers

(nactive, pactive) = active.and_not(nwell)

# PMOS and NMOS source/drain regions
psd  = (nactive & pplus) - poly
nsd  = (pactive & nplus) - poly

# n tie and p tie (nwell and substrate contact)
ntie = nactive & nplus
ptie = pactive & pplus

# connections

# nwell connections
soft_connect(ntie, nwell)
soft_connect(contact, ntie)
```

```
# substrate connections
soft_connect_global(ptie, "BULK")
soft_connect(contact, ptie)

# device connections
soft_connect(contact, psd)
soft_connect(contact, nsd)
soft_connect(contact, poly)

# metal connections
connect(metal1, contact)
connect(via1, metal1)
connect(metal2, via1)
```

As this code demonstrates, multiple soft connections can be specified. From the perspective of the check, all soft connections are of the same kind.

Note, that two opposite soft connections cancel, so this would eventually make a hard connection:

```
soft_connect(a, b)
soft_connect(b, a)
```

NOTE: It is therefore important to observe the direction of soft connections: upper and high-conductive / low-ohmic layer first, and lower and low-conductive / high-ohmic layer second.

Soft connections and "must connect" nets

Soft connections and must connect nets (aka "connect_explicit" and "connect_implicit") serve the same purpose - to detect incomplete wiring. Typically they are used together, such as doing "connect_implicit" on VDD nets and "connect_explicit" on VDD and NWELL nets if the schematic circuits do not feature an explicit NWELL pin.

Soft connections are checked before connect_explicit and connect_implicit are executed. This means, that soft connection errors cannot be masked by declaring them "must connect". On the other hand, that is not a real issue as both checks would raise an warning or error (in the top-level case). It would only be a different kind of warning.

1.5.8. LVS Compare

The actual compare step is rather simple. Provided you have set up the extraction (extract_devices), the connectivity (connect, connect_global, connect_implicit) and provided a reference netlist (schematic), this function will perform the actual compare:

```
compare
```

This method (compare will extract the netlist (if not already done) and compare it against the schematic. It returns true on success and false otherwise, in case you like to take specific actions on success or failure.

The compare step can configured by providing hints.

Net equivalence hint

It can be useful to declare two nets as identical, at least for debugging. The compare algorithm will then be able to deduce the real causes for mismatches. It is helpful for example to provide equivalence for the power nets, because netlist compare fails will often cause the power nets no to be mapped. This in turn prevents matching of other, good parts of the circuit. To supply a power net equivalence for "VDD" within a circuit (e.g. "LOGIC"), use this statement:

```
same_nets("LOGIC", "VDD", "VDD:P")
```

In this example it is assumed that the power net is labeled "VDD" in the layout and called "VDD:P" in the schematic. Don't leave this statement in the script for final verification as it may mask real errors.

"same_nets" can also be used to require a matching between specific nets. This is useful on top level to check for matching nets assigned to specific pads. This allows checking correct pad assignment. For example to check whether the same net is attached to the "VDD" pad, label the net "VDD" in the layout and specify:

```
same_nets!("CHIP", "VDD", "VDD")
```

The exclamation-mark version will report a net mismatch if either there is no "VDD" net in either layout or schematic or if these nets to not match. The above specification can be abbreviated as layout and schematic net name are identical:

```
same_nets!("CHIP", "VDD")
```

It's also possible to specify pattern for circuit names or net names. This example requires all nets starting with "PAD" to have a counterpart in layout and schematic for circuit "TOP" and each of these pairs has to match:

```
same_nets!("TOP", "PAD*")
```

So it is an error if there is a PAD1 net in layout but none in the schematic. It is also an error if a net called PAD2 is there is layout and schematic but they do not match.

"same_nets" and "same_nets!" can appear anywhere in the LVS script.

For more information about "same_nets" see same_nets and same_nets!.

Circuit equivalence hint

By default, circuits with the same name are considered equivalent. If this is not the case, equivalence can be established using the same_circuit function:

```
same_circuits("CIRCUIT_IN_LAYOUT", "CIRCUIT_IN_SCHEMATIC")
```

Declaring circuits as 'same' means they will still be compared. The function is just a hint where to look for the compare target.

Device class equivalence hint

By default, device classes with the same name are considered equivalent. If this is not the case, equivalence can be established using the same_device_classes function:

```
same_device_classes("PMOS_IN_LAYOUT", "PMOS_IN_SCHEMATIC")
same_device_classes("NMOS_IN_LAYOUT", "NMOS_IN_SCHEMATIC")
```

This method can be used also multiple times to establish a many-to-many equivalence:

```
same_device_classes("POLYRES", "RES")
same_device_classes("WELLRES", "RES")
```

If one target is "nil", the corresponding devices are basically ignored:

```
# ignores "POLYRES" devices:
same_device_classes("POLYRES", nil)
```

Tolerances

When comparing device parameters, by default strict equivalence is required. However, when drawing a device like a resistor, it's usually difficult to match the exact value unless the resistor calibration is consistent with drawing grids and the resistor geometry is not confined by design rule constraints. So sometimes the target value or a device parameter can only be approximated in the layout. This will by default lead to a mismatch.

The solution is to specify parameter tolerances. Tolerances can be specified in an absolute or relative fashion. If an absolute tolerance is given, the layout parameter may deviate from the target value by this tolerance either to lower or higher values. So the unit of the tolerance is the same than the unit of the parameter.

If a relative tolerance is given, the deviation is computed from the target value times the tolerance. So the relative tolerance is a factor and a value of 0.05 for example specifies an allowed deviation of plus or minus 5%. Relative tolerances are unit-less.

It's also possible to specify both an absolute and a relative tolerance. In this case, both tolerances add and the allowed deviation becomes larger.

To specify an absolute tolerance, use the tolerance function:

```
tolerance("NMOS", "L", 0.05)
```

The two arguments are the name of the device class and the name of the parameter for which the tolerance will be applied. In the case above, a tolerance of 50nm (the unit of L is micrometer) is applied to the length parameter of "NMOS" devices.

A relative tolerance is specified as an additional forth parameter. You can set the absolute tolerance to zero to specify only relative tolerances. This will specify 1% tolerance for the "L" parameter of "NMOS" devices:

```
tolerance("NMOS", "L", 0.0, 0.01)
```

There is also a more explicit notation for the tolerance:

```
tolerance("NMOS", "L", :absolute => 0.05)
```

or

```
tolerance("NMOS", "L", :relative => 0.01)
```

An absolute plus relative tolerance can be specified by giving both. The following calls will give you 50nm absolute and 1% relative tolerance for the "L" parameter of "NMOS" devices:

```
tolerance("NMOS", "L", 0.05, 0.01)
tolerance("NMOS", "L", :absolute => 0.05, :relative => 0.01)
```

Ignoring parameters

It is possible to ignore certain parameters from certain devices in the netlist compare. For example, if you don't want to compare the "L" parameter of the "NMOS" devices, use this statement:

```
ignore_parameter("NMOS", "L")
```

This statement can be put into the script anywhere before the "compare" statement.

By default, only "primary" parameters are compared. For a resistor for example, "R" is a primary parameter, the other ones like "L", "W", "A" and "P" are not. Using "tolerance" will implicitly enable a parameter - even if it is not a primary one - while "ignore_parameter" will disable a parameter for compare - even if it is a primary one.

Enabling and disabling parameters

As mentioned before, some device parameters are primary while other are not. For example, for the resistor device, "R" (the resistance value) is a primary parameter while the device length ("L") is not. You can make the "L" parameter primary for a device class called "RES" by using:

```
enable_parameter("RES", "L")
```

This has two effects: first, the "L" parameter is written into the Spice output netlist and in addition it is compared against the schematic "L" parameter.

Correspondingly, a primary parameter can be disabled using:

```
disable_parameter("RES", "R")
```

This behavior is overridden by a "tolerance" or "ignore_parameter" specification for that parameter or if a custom device comparer is installed. Netlisting is affected only for the elementary devices (R, C and L) and any Spice writer delegate can choose to ignore the primary flag. A custom device comparer may also ignore this flag. So after all, enabling or disabling a parameter is not a strong concept but rather a hint.

Pin swapping

Pin swapping can be useful in cases, where a logic element has logically equivalent, but physically different inputs. This is the case for example for a CMOS NAND gate where the logic inputs are equivalent in function, but not in the circuit and physical implementation. For such circuits, the compare function needs to be given a degree of freedom and be allowed to swap the inputs. This is achieved with the equivalent_pins function:

```
equivalent_pins("NAND_GATE", "A", "B")
```

The first argument is the name of the circuit in the layout netlist. You can only specify equivalence in layout, not in the reference schematic. Multiple pins can be listed after the circuit name. All of them will be considered equivalent.

Capacitor and resistor elimination

This feature allows eliminating "open" resistors and capacitors. Serial resistors cannot be elimiated currently (shorted).

To eliminate all resistors with a resistance value above a certain threshold, use the max_res function. This will eliminate all resistors with a value >= 1kOhm:

```
max_res(1000)
```

To eliminate all capacitors with a capacitance value below a certain threshold, use the min_caps function. This will eliminate all capacitances with a value <= 0.1fF:

```
min_caps(1e-16)
```

Compare and netlist hierarchy

Good layouts are built hierarchically and the netlist compare can make use of hierarchy. "Hierarchically" means that a circuit is built from cells which itself map to subcircuits of the schematic netlist. The netlist extractor tries hard to maintain the hierarchy and the netlist compare will utilize the hierarchy to provide more meaningful reports and enable a bottom-up design approach.

Given a hierarchical layout and schematic netlist, the compare algorithm will work bottom-up: it will first compare the leaf circuits (circuits without subcircuit calls) and if those match, it will continue with the calling circuits. This approach is more efficient and fosters a clean relationship between layout and schematic netlist.

To enable hierarchical extraction, you must use "deep" mode (deep). If the deep mode statement is missing, the layout netlist will be flat (i.e. without subcircuits).

The second useful feature is "align" (align). This statement will remove circuits from the layout or schematic netlist which are unknown in the other netlist. Often, layouts contain helper cells which are not corresponding to a circuit (e.g. via cells). These are removed in this step. Eventually, this step will also flatten the schematic netlist if the layout has been extracted in a flat way.

In general, it's a good idea to include "align" before "netlist.simplify" or similar netlist manipulation and the "compare" step.

A very useful side effect of "align" is this: it will remove circuits above the top level circuit of either side. So it will eventually render a sub-tree from the circuit tree and use that for compare. This enables **subcell verification**: by selecting a subcell in the layout hierarchy, an "align"-enabled LVS script will compare this cell against the corresponding subcircuit in the schematic netlist. It will ignore the parent hierarchy of this subcircuit. This way, you can work yourself upwards in the hierarchy and fix LVS errors cell by cell with the same schematic netlist.

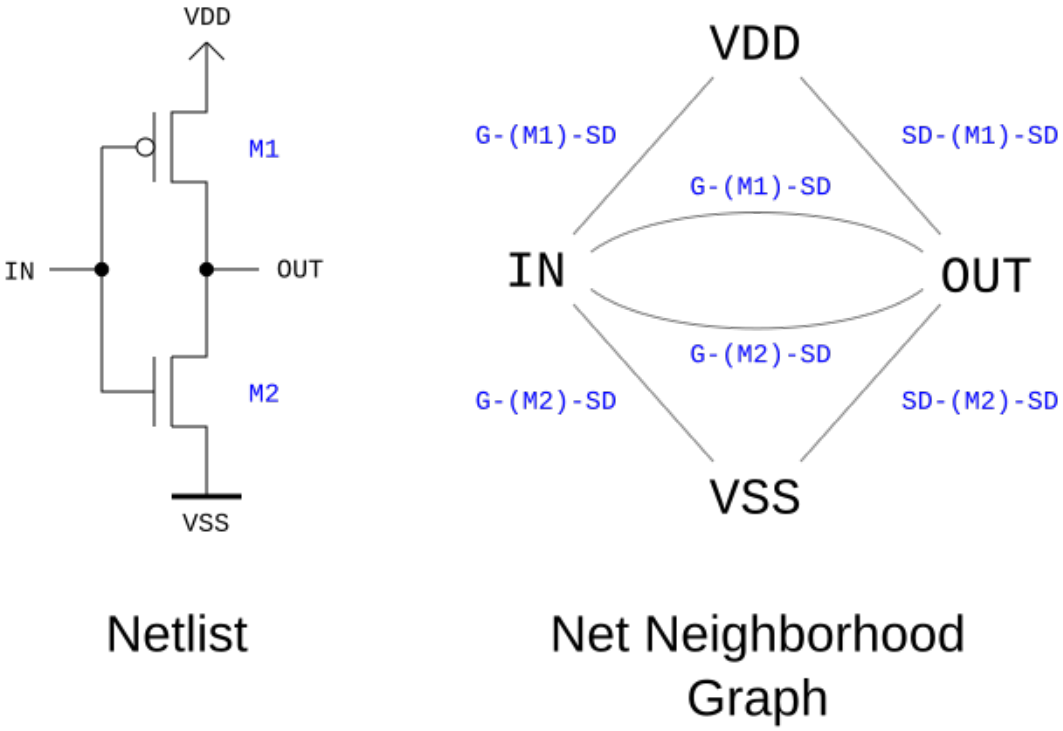
How the compare algorithm works

The coarse flow of the netlist compare algorithm is this:

```
foreach circuit bottom up:
  if matching circuit found in reference netlist:
    if all subcircuits have been matched and pin matching has been established for them:
      compare net graph locally from this circuit
    else:
      skip circuit with warning
  else:
    issue a circuit mismatch error
```

A consequence of this flow is that the compare will stop treating parent circuits when one circuit's pins can't be matched to pins from the corresponding reference circuit or the corresponding circuit can't be found in the reference netlist. This behaviour fosters a bottom-up debugging approach: first fix the issues in subcircuits, then proceed to the parent circuits.

The local net graph compare algorithm is a backtracking algorithm with hinting through topological net classification. Topological net classification is based on nearest-net neighborhood. The following image illustrates this:



Here the IN net's neighborhood is VDD via a traversal of gate to source/drain over M1, to OUT via a twofold traversal of gate to source/drain over M1 and M2 and to VSS via another single traversal of gate to source/drain over M2. This uniquely identifies IN in this simple circuit. In effect, OUT, VDD and VSS can be identified uniquely because their transitions from the IN net are unambigously identifying them. The topological neighborhood is a simple metrics which allows identifying matching nets from two netlists and deducing further relations.

In big netlists, the algorithm will first try to match nets unambigously according to their neighborhood metrics and register them as paired nets. Such pairs often allow deducing further matching pairs. This deduction is continued until all non-ambiguous pairing options are exhausted. For resolving ambiguities, backtracking is employed: the algorithm proposes a match and tentatively proceeds with this assumption. If this execution path leads to a mismatch or logical contradiction, the algorith will go back to the beginning and restart with a new proposal. Backtracking is usually required mainly to match networks with a high symmetry such as clock trees.

1.5.9. LVS Netlist Tweaks

Netlist tweaking is important to standardize netlists. Without tweaking, the extracted netlist may contain elements that are redundant or don't match anything found in the schematic.

Netlist tweaks are applied on the extracted Netlist object. This can be obtained with the netlist function. This function will extract the netlist if not done already.

Netlist tweaks can also be applied to the schematic netlist. For example to flatten away a model subcircuit called "NMOS", use this Netlist#flatten_circuit:

```
schematic.flatten_circuit("NMOS")
```

Top level pin generation

Circuits extracted don't have pins on the top hierarchy level as the extractor cannot figure out where to connect to this circuit. The compare function does not try to match pins in this case. But to gain a useful extracted netlists, pins are required. Without pins, a circuit can't be embedded in a testbench for example.

KLayout offers a function to create top-level pins using a simple heuristics: for every named (i.e. labeled) net in the top level circuit a pin will be created (Netlist#make_top_level_pins):

```
netlist.make_top_level_pins
```

Device combination

Combining devices is important for devices which are not represented as coherent entities in the layout. Examples are:

- **Fingered MOS transistors:** MOS transistors with a large width are often split into multiple pieces to reduce the parasitic gate and diffusion resistances and capacitances. In the layout this is equivalent to multiple parallel transistors.
- **Serial resistors:** Large resistors are often separated into stripes which are then connected in a meander structure. From the device perspective such resistors consist of several resistors connected in series.
- **Array capacitors:** Large capacitors are often split into smaller ones which are arranged in an array and connected in parallel. This helps controlling the parasitic series resistances and inductances and avoids manufacturing issues.

In all these cases, the schematic usually summarizes these devices into a single one with lumped parameter values (total resistance, capacitance, transistor width). This creates a discrepancy which "device combination" avoids. "Device combination" is a step in which devices are identified which can be combined into single devices (such as serial or parallel resistors and capacitors). To run device combination, use Netlist#combine_devices:

```
netlist.combine_devices
```

The combination of serial devices might leave floating nets (the net connecting the devices originally. These nets can be removed with Netlist#purge_nets. See also Netlist#simplify, which is wrapper for several methods related to netlist normalization.

It's recommended to run "make_toplevel_pins" and "purge" before this step (see below).

Circuit flattening (elimination)

It's often required to flatten circuits that do not represent a specific level of organisation but act as a wrapper to something else. In layouts, devices are often implemented as PCells and appear as specific cells for no other reason than being implemented in a subcell. The same might happen for schematic subcircuits which wrap a device. "Flattening" means that a circuit is removed and its contents are integrated into the calling circuits.

To flatten a circuit from the extracted netlist use Netlist#flatten_circuit:

```
netlist.flatten_circuit("CIRCUIT_NAME")
```

The argument to "flatten_circuit" is a glob pattern (shell-like). For example, "NMOS*" will flatten all circuits starting with "NMOS".

Automatic circuit flattening (netlist alignment)

Instead of flattening circuits explicitly, automatic flattening is provided through the align method.

The "align" step is optional, hence useful: it will identify cells in the layout without a corresponding schematic circuit and flatten them. "Flatten" means their content is replicated inside their parent circuits and finally the cell's corresponding circuit is removed. This is useful when the layout contains structural cells: such cells are inserted not because the schematic requires them as circuit building blocks, but because layout is easier to create with these cells. Such cells can be PCells for devices or replication cells which avoid duplicate layout work.

The "align" method will also flatten schematic circuits for which there is no layout cell:

```
align
```

Black boxing (circuit abstraction)

Circuit abstraction is a technique to reduce the verification overhead. At an early stage it might be useful to replace a cell by a simplified version or by a raw pin frame. The circuits extracted from such cells is basically empty or are intentionally simplified. But as long as there is something inside the cell which the parent circuit connects to, pins will be generated. These pins then can be thought of as the circuit's abstraction.

A useful method in this context is the "blank_circuit" method. It clears a circuit's innards from a netlist. After this, the compare algorithm will identify both circuits as identical, provided they feature the same number of pins. Named pins are required to match exactly unless declared equivalent. Unnamed pins are treated as equivalent. To name pins use labels on the pin's nets inside the circuit's layout.

To wipe out the innards of a circuit, use the Netlist#blank_circuit method:

```
netlist.blank_circuit("CIRCUIT_NAME")
schematic.blank_circuit("CIRCUIT_NAME")
```

NOTE: In this version, use "blank_circuit" before "purge" or "simplify" (see below). "blank_circuit" sets a flag (Circuit#dont_purge) which prevents purging of abstract circuits.

There is a short form for this too (blank_circuit). In contrast to netlist-based "blank_circuit", this method can be used anywhere in the LVS script:

```
blank_circuit("CIRCUIT_NAME")
```

The argument to "blank_circuit" in both cases is a glob pattern (shell-like). For example, "MEMORY*" will blank out all circuits starting with the word "MEMORY".

Joining of symmetric nodes

Sometimes it is possible to omit connections in the layout because these will not carry any current. This might simplify the layout and allow denser packing, but finally there is a mismatch between schematic and layout. In general, connections can be omitted if they would connect symmetric nodes. When symmetric nodes are swapped, the circuit will not change. Hence they will always carry the same potential (at least in theory) and a connection between them will not carry any current. So it can be omitted.

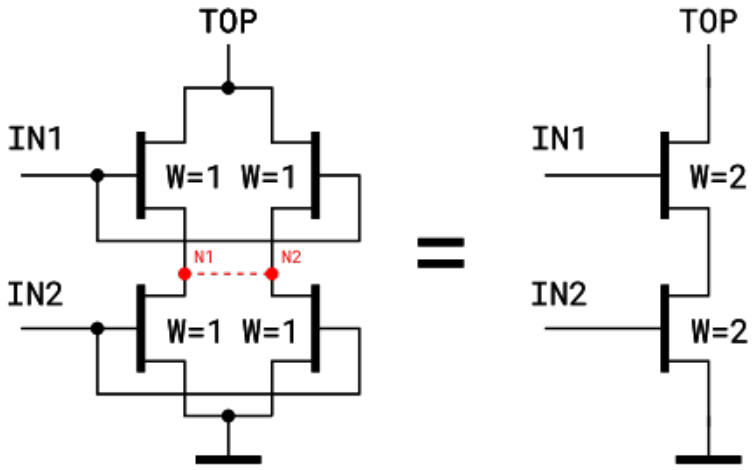
This feature can be used to solve the "split_gates" problem (see "split_gates" below). The internal source/drain nodes are symmetric in the configuration shown there, so "join_symmetric_nets" can be used to solve make the required connections, e.g.:

```
join_symmetric_nets("NAND2")
```

However, there is a more specific feature available ("split_gates") which covers more cases, but is specialized on MOS devices.

Split gates

The following picture describes such a situation known as "split gate configuration". In this case, the N1 and N2 are identical: swapping them will not change the circuit's topology. Hence, they will carry the same potential and the red connection is not required physically. But without such a connection, the parallel transistors (top pair and bottom pair) will not be recognized as parallel and the pairs will not be joined into one each:



KLayout provides a feature (split_gates) which will add such connections after extraction of the netlist:

```
split_gates("NMOS")
```

This function will analyze all circuits in the extracted netlist with respect to "NMOS" devices and connect all split gates relevant source/drain nodes inside. If this function is called before "combine_devices" (e.g. through "netlist.simplify"), this connection is already present then and parallel devices will be recognized and combined.

The device name must denote a MOS3, MOS4, DMOS3 or DMOS4 device. The gate lengths of all involved devices must be identical. For MOS4 and DMOS4, all devices on one gate net must share the same bulk net.

In addition to the device name, a glob-style circuit pattern can be supplied. In this case, the analysis is restricted to the circuits matching this pattern.

"split_gates" can be used anywhere in the LVS script.

Purging (elimination of redundancy)

Extracted netlists often contain elements without a functional aspect: via cells for example generate subcircuits with a single pin and no device. Isolated metal islands (letters, logos, fill/planarisation patches) will create floating nets etc. Two methods are available to purge those elements.

Netlist#purge will remove all floating nets, all circuits without devices or subcircuits. Netlist#purge_nets will only purge floating nets. Floating nets are nets which don't connect to any device or subcircuit.

```
netlist.purge
netlist.purge_nets
```

Normalization wrapper (simplification)

Netlist#simplify is a wrapper for "make_top_level_pins", "purge", "combine_devices" and "purge_nets" in this recommended order:

```
netlist.simplify
```

As a technical detail, "make_top_level_pins" is included in this sequence as with pins, nets are not considered floating. So "purge_nets" will maintain pins for labeled nets even if these nets are not connected to devices. This allows adding optional pins while maintaining the top level circuit's interface.

2. Various Topics

This category covers various special topics and provides additional information for certain features in KLayout. The following topics are available:

2.1. Layer Mapping Tables

Layer mapping tables are used to specify the behavior of the layout reader. Specifically, they define what actions are taken when a shape on a certain layer is encountered. They can be used to

- Filter layers
- Supply layer names for GDS layer and datatype combinations
- Map layers to different ones
- Combine different layers into the same layer

A layer mapping table consists of two specifications: a match expression and an optional target expression. If a shape is encountered, the reader looks up the shape's layer in the mapping table. If an entry is found whose match expression matches the layer of the shape, the shape is assigned a new layer given by the target expression if present. By assigning different match expressions the same target expressions, multiple input layers can be combined into a single one.

If no matching entry is found, the reader can be configured to either store the shape under the original layer or discard it. This option can be found in the reader options dialog as the "Read all layers" option. If that box is checked, the shapes are stored under their original layer and discarded if not.

A target expression can be used also to add information, specifically a layer name. In GDS there is no layer name but just a layer and datatype number. In OASIS, there is a layer name in addition. Other formats just use named layers and don't have the concept of layer number or datatype number. When the target expression specifies a layer name that name is used. That allows adding of OASIS layer names to GDS files for example. Layers with names are usually more useful than layers that just have a number.

The layer mapping table consists of lines, each specifying the match expression and optional target expression. The match and target expressions are separated by a colon. Each expression has the form "layer" (numeric), "layer/datatype" (both numberic), "name" (a string) or "name(layer)" or "name(layer/datatype)" (all specifications). When name and layer/datatype are specified in a match string, KLayout will first look for a matching layer/datatype and then for a matching layer name. The name match is case sensitive. For the numerical specifications, ranges are allowed using a hyphen for an interval and the comma for enumerations (see second example below).

Here are some examples:

1/0 or **1**	Matching layer 1, datatype 0
17/1-5,10	Matching layer 17, datatypes 1 to 5 and 10
1/0:22	Matching Layer 1, datatype 0. Shapes are shifted to layer 22, datatype 0
1/0:A	Matching layer 1, datatype 0. The name "A" is added to that layer
1/0:A(2/0)	Matching Layer 1, datatype 0 mapped. Shapes are shifted to layer 2, datatype 0 and name "A"
A	Matching named layer "A"
A:1/0	Matching named layer "A". Shapes are shifted to layer 1, datatype 0

When the layer mapping is read from a file, each line corresponds to one entry. Blanks are ignored as are empty lines. Comments can be inserted using the "#" character in front of the comment.

Wildcards

Source layers can be specified using wildcards. A wildcard is a "*" character matching "any layer". Examples for such expressions are:

10-*/0	Matching layer 10 and above, datatype 0
***/10**	Matching datatype 10 of every layer
0-5,10-*/*	Matching layer 0 to 5 (inclusive) and above 10, all datatypes.

When ranges or wildcards are used as match expressions, the specified layers will be lumped together into a single layer. This layer will have the least permitted layer and datatype number. For example, with a match expression of "1-10/*", all these layers will be mapped to "1/0". This behavior can be modified using a target layer specification with wildcards.

Wildcard expansion and relative layer mapping

If the match expression includes a numerical range or wildcards for the layer or datatype number, by default all these layers will be combined into a single one, where its layer or datatype number is derived from the least permitted number.

This behavior can be modified using wildcard expansion. This is a target layer which includes a "*" wildcard. This wildcard is substituted by the actual layer or datatype number:

10-*/0 : */10	Maintain layers for layer 10 and above and map datatype to 10
10-*/0 : */*	Select layers 10 and above, datatype 0 and maintain these as individual layers
1/* : 2/*	Map layer number 1 to 2, maintain all datatypes

Relative layer mapping allows adding an offset to the layer or datatype numbers. This offset can be negative with undefined behavior when the resulting number goes below zero:

10-20/*: *+1000/*	Selects all layers between 10 and 20, all datatypes. These layers will be read into the original layers plus 1000 for the layer number.
10/10-*: */*-10	Selects layer 10, datatypes 10 plus. The resulting datatypes will be 10 less starting from 0.

Multi-mapping and unmapping

Layer mapping table support an advanced feature which is to duplicate input layers to a number of output layers (1:n) mapping. The feature is enabled by prepending a "+" to the mapping statement. The following statement will first select layer 5/0 and additionally copy it to layer 1000/0:

```
5/0
+5/0: 1000/0
```

Unmapping removes the mapping for a specific layer or range. It is specified by prepending "-" to the mapping expression. The following statement will map all datatypes of layer 5 to 0 except for datatype 10 which is not considered.

```
5/*: 5/0
-5/10
```

Unmapping cancels the mappings specified previously, so the order of statements becomes important when using unmapping and multi-mapping.

Brackets

Square brackets can be used to imply mapping to the original layer. When putting square brackets around a mapping expression, the default target is "*/*", which means expansion to the original layer. Hence the following statements are identical:

```
[1-10/*]
1-10/* : */*
```

When combining this with "+" for multi-mapping, put "+" in front of the bracket.

You can put round brackets around mapping expressions for visual clarity, specifically when combining them with "-" (unmapping) or "+" (multi-mapping):

```
-(1-10/*)
+(17/0 : 1017/0)
```

2.2. About Layer Specifications

Layer specifications are used in various places, for example in layer mapping files (Layer Mapping Tables). Layer specifications are used inside the database to give a layer a name or a number/datatype pair or both. Layer specifications are the text representation of LayerInfo objects.

Blanks within layer specifications are ignored and can be put between the different components of the specification.

A simple number for the specification will indicate a layer with this layer number and a datatype of zero:

```
17
```

will give layer 17, datatype 0.

A number followed by a slash and another number will indicate a layer number and datatype:

```
17/5
```

will give layer 17, datatype 5.

Layers can be named. Named layers are present in DXF, CIF or other formats which don't use the GDS layer/datatype number scheme. Just giving a name will indicate such a layer:

```
METAL1
```

will give a named layer called "METAL1".

If you want to use a name that is a number, use quotes:

```
"17"
```

will give a named layer called "17".

If you want to use a name that includes blanks, put it into quotes as well:

```
"METAL 1"
```

will give a named layer called "METAL 1" (however, such layer names are usually illegal).

Finally, a layer can have both a name and layer/datatype numbers. In this case, add the layer/datatype number to the name in round brackets:

```
METAL1 (17)
```

will give a layer named "METAL1" with layer 17 and datatype 0 and

```
METAL1 (17/5)
```

will give a layer named "METAL1" with layer 17 and datatype 5.

Layer specifications as targets

When used in a target context (e.g. for layer mapping), a layer specification can use wildcards and relative layer/datatype specifications. Using "*" instead of a layer or datatype number means to reuse the source layer or datatype number. Using "+x" or "-x" for layer or datatype number means to add or subtract "x" from the source layer or datatype number.

2.3. Transformations in KLayout

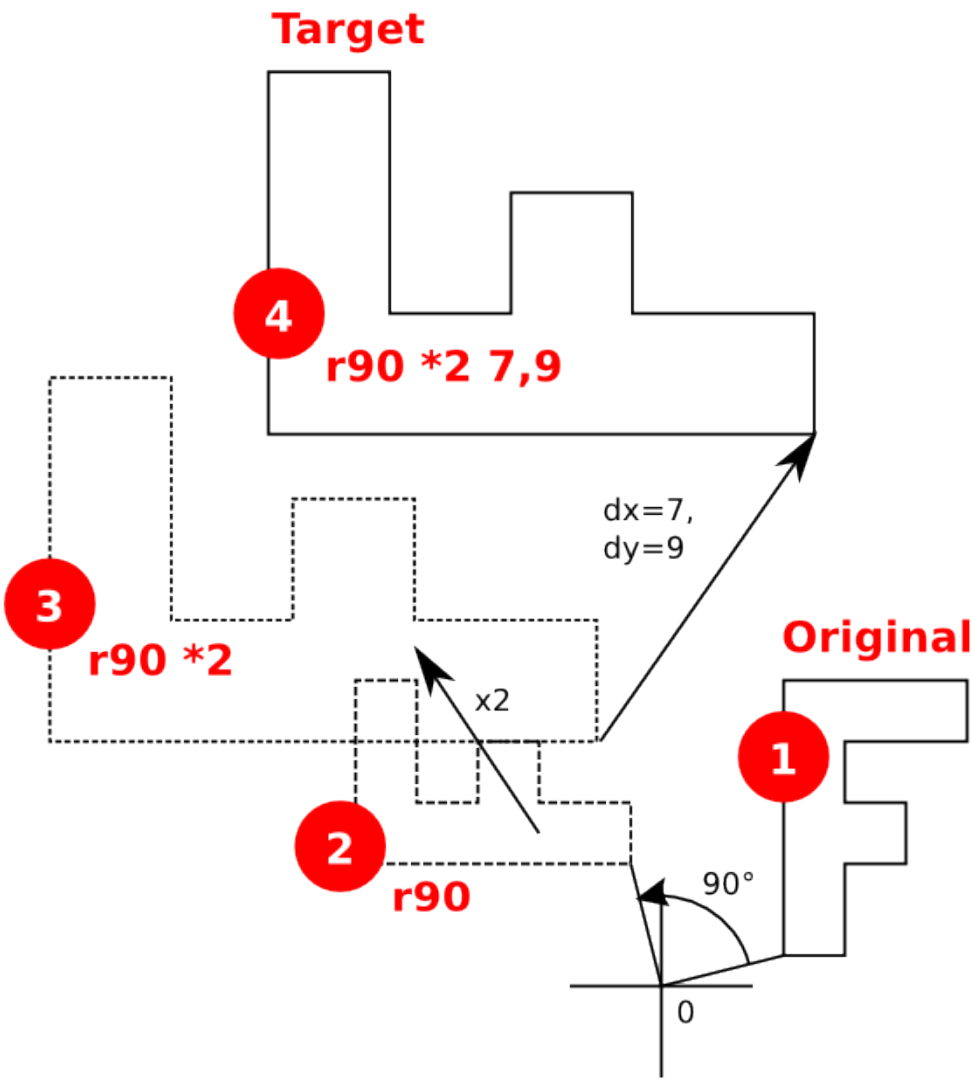
KLayout supports a subset of affine transformations with the following contributions:

- **Rotation and/or mirroring:** rotation by a given angle or mirroring at a given axis.
- **Scaling:** magnification by the given factor.
- **Translation:** a displacement by the given vector.

The execution order is "displacement after rotation, mirroring and scaling". Transformations are used for example to describe the instantiation of a cell. The content of a cell appears in the parent cell after the given transformation has been applied to the content of the cell.

The transformations supported by KLayout cover the transformations employed within GDS2, OASIS and other layout formats. KLayout does not support shearing currently.

The following figure illustrates the effect of the transformation "r90 *2 7,9". This notation specifies a transformation composed of a rotation by 90 degree, a scaling with factor 2 and a displacement by 7 units in x- and 9 units in y-direction. In that example, the "F" shape is first rotated by 90 degree around the origin. Because the "F" is already displaced from the origin, this will also move the "F" shape. The shape then is scaled. Again it will move because every point of the polygon moves away from the origin. Finally it is displaced by the given displacement vector.



The notation shown here is used in many places within KLayout. It is basically composed of the following parts which are combined putting one or more blanks in between. The order the parts are specified is arbitrary: the displacement is always applied after the rotation.

- <x>**,**<y>: A displacement (applied after rotation and scaling) in micron units. If no displacement is specified, "0,0" is assumed.
- **r**<a> or **m**<a>: A rotation by angle "a" (in degrees) or mirroring at the "a" axis (the x axis rotated by "a" degree). If no rotation or mirroring is specified, no rotation is assumed.
- ***<s>: A scaling by the factor "s". If no scaling is specified, no scaling is assumed.

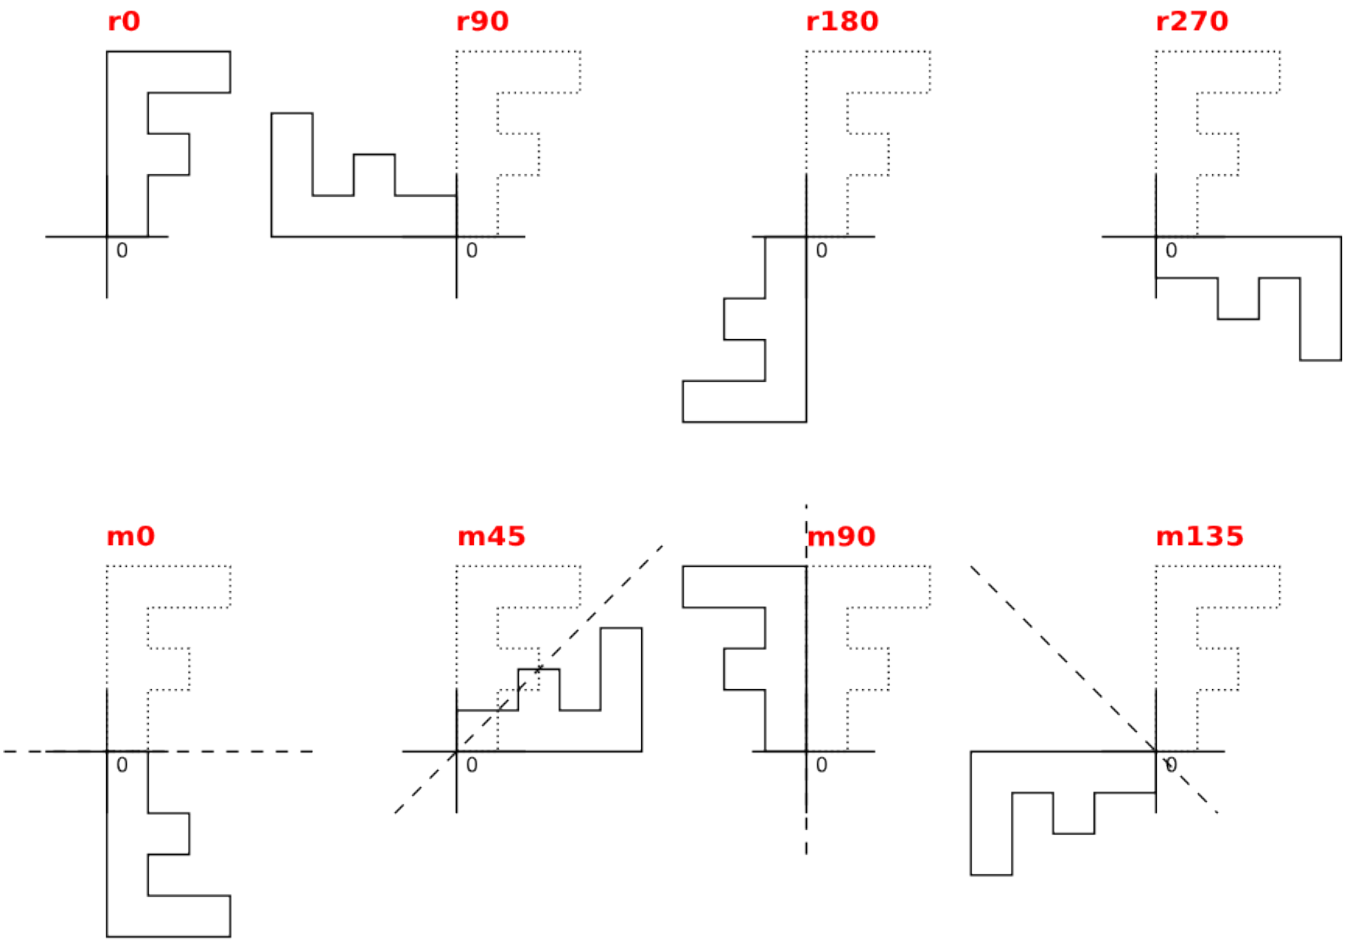
Here are some examples:

- **0,100**: shift 100 units up.
- **r90**: rotation by 90 degree counterclockwise (positive in the mathematical sense).

- **m0**: mirroring at the x-axis.
- **m45 100,-200**: swap x and y (mirror at 45 degree axis), shift 100 units to the right and 200 units down.
- **r22.5 *1.25**: rotate by 22.5 degree and scale by factor 1.25.

The distance units are usually micron. In some cases (i.e. transformations inside a database), the unit is database units and dx and dy are integer values.

Mirroring and rotation are exclusive and mirroring includes a rotation. In fact, a mirror operation at a certain axis is identical to a mirror operation at the x-axis, followed by a rotation by twice the angle "a". The following figure illustrates rotation and mirroring with the eight basic transformations involving rotations by multiples of 90 degree:



KLayout is not restricted to these basic operations. Arbitrary angles are supported (i.e. "r45" or "m22.5"). Usually however, this implies grid snapping and other issues. This also is true for arbitrary scaling values. KLayout is also more effective when using simple transformations involving only rotations by multiples of 90 degree and do not use scaling.

Coding transformations

Note that mirroring at an axis with a given angle "a" is equivalent to mirroring at the x axis followed by a rotation by twice the angle "a". For example:

```
m45 == m0 followed by r90
```

When coding transformations, two parameters are used to represent the rotation/mirror part: a rotation angle and a flag indicating mirroring at the x axis. The mirroring is applied before the rotation. In terms of these parameters, the basic transformations are:

Rotation angle (degree)	Mirror flag = False	Mirror flag = True
0	r0	m0
90	r90	m45
180	r180	m90
270	r270	m135

Transformation objects

Transformation objects are convenient objects to operate with. They represent a transformation (technically a matrix) consisting of an angle/mirror and a displacement part. They support some basic operations:

- Concatenation: `T = T1 * T2`
  `T` is transformation `T2` applied, then `T1` (note this order)
- Inversion: `TI = T.inverted()`
  `TI` is the inverse of `T`, i.e. `TI * T = T * TI = 1` where `1` is the neutral transformation which does not modify coordinates
- Application to geometrical objects: `q = T * p`
  where `p` is a box, polygon, path, text, point, vector etc. and `q` is the transformed object

Vectors and Points

In KLayout there are two two-dimensional coordinate objects: the vector and the point. Basically, the vector is the difference between two points:

```
v = p2 - p1
```

Here `v` is a vector object while `p1` and `p2` are points.

Regarding transformations, vectors and points behave differently. While for a point, the displacement is applied, it is not for vectors. So

```
p' = T * p = M * p + d
v' = T * v = M * v
```

Here `M` is the 2x2 rotation/mirror matrix part of the transformation and `d` is the displacement vector

The reason why the displacement is not applied to a vector is seen here:

```
v' = T * v
   = T * (p2 - p1)
   = T * p2 - T * p1
   = (M * p2 + d) - (M * p1 + d)
   = M * p2 + d - M * p1 - d
   = M * p2 - M * p1
   = M * (p2 - p1)
```

where the latter simply is:

```
v' = M * v
```

Simple transformations

Simple transformations are represented by DTrans or Trans objects. The first operates with floating-point displacements in units of micrometers while the second one with integer displacements in database units. "DTrans" objects act on "D" type floating-point coordinate shapes (e.g. DBox) while "Trans" objects act on the integer coordinate shapes (e.g. Box).

The basic construction parameters of "DTrans" and "Trans" are:

```
Trans(angle, mirror, displacement)
DTrans(angle, mirror, displacement)
```

"displacement" is a DVector (for DTrans) or a Vector (for Trans).

"angle" is the rotation angle in units of 90 degree and "mirror" is the mirror flag:

angle	mirror = False	mirror = True
0	r0	m0
1	r90	m45
2	r180	m90
3	r270	m135

Complex transformations

Complex transformations in addition to the simple transformations feature scaling (magnification) and arbitrary rotation angles. Other than simple transformations they do not necessarily preserve a grid and rounding is implied. Furthermore they imply a shift is physical scale which renders them difficult to use in physical frameworks (e.g. DRC). Hence their use is discouraged for certain applications.

The basic classes are DCplxTrans for the micrometer-unit (floating-point) version and ICplxTrans for the database-unit (integer) version. The construction parameters are:

```
ICplxTrans(angle, mirror, magnification, displacement)
DCplxTrans(angle, mirror, magnification, displacement)
```

Here, "angle" is the rotation angle in degree (note the difference to "Trans" and "DTrans" where the rotation angle is in units for 90 degree. "magnification" is a factor (1.0 for "no change in scale").

There are two other variants useful for transforming coordinate systems: CplxTrans takes integer-unit objects and converts them to floating-point unit objects. It can be used to convert from database units to micrometer units when configured with a magnification equal to the database unit value:

```
T = CplxTrans(magnification: dbu)
q = T * p
```

The other variant is VCplxTrans which converts floating-point unit objects to integer-unit ones. These objects are generated when inverting "CplxTrans" objects.

2.4. About Expressions

Beside a ruby and Python programming API, KLayout provides support for simple expressions in some places. In particular this feature is employed to generate dynamic strings, for example when deriving the label text for a ruler.

String interpolation

The feature of inserting dynamic content into a string is called interpolation. The Syntax KLayout uses for string interpolation is a dollar character followed by the expression which is evaluated. Simple expressions can be put directly after the dollar character. Others must be put into brackets.

Every dollar expression is evaluated and the expression is substituted by the result string. For example:

String	Evaluates to
`An irrational number: $sqrt(2).`	`An irrational number: 1.4142136`
`1+2 is $(1+2).`	`1+2 is 3.`

String interpolation plays a role where expressions are used to generate dynamic strings. When expressions are used as standalone features (i.e. as parts of a custom layout query - see About Custom Layout Queries), string interpolation is not supported inside string constants, but strings can be built dynamically using the "+" operator.

Basic data types

Expressions use different data types to represent strings or numeric values. The following data types are supported currently:

Type	Examples
Numeric	`1.2` `-0.5e-6`
String	`"abc"` `'x'`
Boolean	`true` `false`
Array	`[1,5,4]`
Undefined (no value)	`nil`

Apart from that, all RBA objects are supported with their methods (see Class Index). For example, that is a valid expression which gives a value of 100:

```
Box.new(-10, 0, 90, 60).width
```

In a boolean context (i.e. the conditional evaluation "condition ? expr1 : expr2"), "nil" and the boolean "false" will render false, while all other values render true. This follows the Ruby convention and in effect, unlike some other languages, a numeric value if 0 is not treated as "false" but as "true"!

Constants

The following constants are defined currently:

Constant	Description
`M_PI`	The mathematical constant 'pi'
`M_E`	The mathematical constant 'e'
`false`	'false' boolean value
`true`	'true' boolean value
`nil`	The 'undefined' value

Operators and precedence

KLayout's expressions support the following operators with the given precedence:

Prec.	Operator	Data types	Result type	Description
1	(...)	Any		Grouping of sub-expressions
2	[...,...]	Any	Array	Array formation
3	!...	Boolean	Boolean	Logical 'not'
3	~...	Numeric	Numeric	Bitwise 'not' (evaluated as 32 bit integers)
3	-...	Numeric	Numeric	Negation
4	...^...	Numeric	Numeric	Bitwise 'xor' (evaluated as 32 bit integers)
4	...&...	Numeric	Numeric	Bitwise 'and' (evaluated as 32 bit integers)
4	...|...	Numeric	Numeric	Bitwise 'or' (evaluated as 32 bit integers)
5	...%...	Numeric	Numeric	Modulo
5	.../...	Numeric	Numeric	Division
5	...*...	Numeric	Numeric	Product
		Numeric*String	String	String multiplication (n times the same string)
6	...-...	Numeric	Numeric	Subtraction
6	...+...	Numeric	Numeric	Addition
		String	string	Concatenation
7	...<<...	Numeric	Numeric	Bit shift to left
7	...>>...	Numeric	Numeric	Bit shift to right
8	...==...	Any	Boolean	Equality
8	...!=...	Any	Boolean	Inequality
8	...<=...	Any	Boolean	Less or equal
8	...<...	Any	Boolean	Less
8	...>=...	Any	Boolean	Greater or equal
8	...>...	Any	Boolean	Greater
8	...~...	String	Boolean	Match with a glob expression
8	...!~...	String	Boolean	Non-match with a glob expression
9	...&&...	Boolean	Boolean	Logical 'and'
9	...||...	Boolean	Boolean	Logical 'or'
10	...?...:...	Boolean?Any:Any	Any	Conditional evaluation

The match operators work on strings. They use the glob pattern notation (as used in the shell for example) and support substring matching with the usual bracket notation. Substrings can be referred to by "$n" later, where n is the nth bracket. For example:

Expression	Result
`"foo" ~ "f*"`	true
`"foo" ~ "bar"`	false
`"foo" !~ "bar"`	true
`"foo" ~ "f(*)"; $1`	"oo"

Method calls

Expressions support all the objects provided by KLayout for the Ruby API. Objects are values inside expressions like integers or strings are. Sometimes, objects can be manipulated with the operators as well (like "box1 + box2"). The most important way to work with objects however are methods.

The dot calls a method on an object. Before the dot an expression must be given which results in an object, or a class name must be given. In the latter case, static methods will be called. After the dot, a valid method name is expected.

Important note: the method names used inside expressions usually is equivalent to the names mentioned in the class documentation. Setter methods like "box_with=" can be used as targets in assignments, i.e.

```
shape.box_width = 20
```

Boolean predicates (like "is_box?") are used **without** the question mark because that is reserved for the decision operator (".. ? .. : .."):

```
shape.is_box
```

Concatenation of expressions

The semicolon separates two expressions. The value of that compound expression is the value of the last one.

Keyword arguments

Most methods support keyword arguments similar to Python. For example you can write:

```
CplxTrans.new(rot = 45.0)
```

This is more explicit than writing the individual arguments and allows giving one argument without having to insert the default values for the previous ones.

Keyword arguments are not supported for the built-in functions such as "sqrt" and a few built-in methods.

Variables

Depending on the context, some variables may be already defined. For example, when used for generating ruler dimension labels, "D" is a predefined variable that is the length of the ruler. See the specific documentation on these variables.

Inside expressions, variables can be defined to store intermediate results for example. To define a variable use the "var" keyword followed by the variable name and an optional initialisation. Assignment of values can be done with the "=" operator. For example, the following expression gives the result 4:

```
var x = 3; x = x + 1; x
```

Special variables

Special variables start with a dollar character. Currently the only special variables available are "$1..9" which is the 1 to 9nth substring match of the last match expression.

Special constants

In the context of a layout, various additional constant expressions are supported:

Distance and area units

A value with a unit is automatically converted to database units. For example, "`0.15 um`" will give 150 if the database unit of the layout is 1 nm. See below for a list of units available. Supported units are:

Unit	Description
`nm`	Nanometers
`um`, `mic`, `micron`	Micrometers
`mm`	Millimeters
`m`	Meters
`nm2`	Square nanometers
`um2`, `mic2`, `micron2`	Square micrometers
`mm2`	Square millimeters
`m2`	Square meters (for very big chips)

Layer index constants

A layer given in the common notation and enclosed in angle brackets is converted to a layer index. For example: "`<16/0>`" will be converted to the layer index of the layer with layer number 16 and datatype 0.

Cell index constants

A cell name enclosed in double angle brackets will be converted to the index of that cell, for example "`<<TOP>>`".

Functions

KLayout's expressions support the following functions:

Function	Data types	Result type	Description
`absolute_file_path(x)`	String	String	Convert a relative file path to an absolute one
`absolute_path(x)`	String	String	Returns the absolute path component of a file specification
`abs(x)`	Numeric	Numeric	Returns the absolute value of a number
`acos(x)`	Numeric	Numeric	Inverse cosine function
`asin(x)`	Numeric	Numeric	Inverse sine function
`atan2(x,y)`	Numeric	Numeric	Inverse tangent of x/y
`atan(x)`	Numeric	Numeric	Inverse tangent function
`basename(x)`	String	String	Returns the basename component of a file specification
`ceil(x)`	Numeric	Numeric	Round up
`combine(x,y)`	String	String	Combines the path components x and y using the system specific separator
`cosh(x)`	Numeric	Numeric	Hyperbolic cosine function
`cos(x)`	Numeric	Numeric	Cosine function
`env(x)`	String	String	Access an environment variable
`error(x)`	String		Raise an error
`exp(x)`	Numeric	Numeric	Exponential function
`extension(x)`	String	String	Returns the extension component of a file specification
`file_exists(x)`	String	Boolean	Returns true if the given file exists

Function	Data types	Result type	Description
`find(s,t)`	String	Numeric	Finds the first occurrence of a t in s and returns the position (where 0 is the first character)
`floor(x)`	Numeric	Numeric	Round down
`gsub(s,x,y)`	String	String	Substitute all occurrences of a x in s by y
`is_array(x)`	Any	Boolean	True if the argument is an array
`is_dir(x)`	String	Boolean	Returns true if the given path is a directory
`is_nil(x)`	Any	Boolean	True if the argument is undefined
`is_numeric(x)`	Any	Boolean	True if the argument is numeric
`is_string(x)`	Any	Boolean	True if the argument is a string
`item(a,i)`	Array	Any	Access a certain item of an array
`join(a,s)`	Array, String	String	Join all array members in a into a string using the separator s
`len(x)`	String	Numeric	Return the length of a string
`log10(x)`	Numeric	Numeric	Base 10 logarithm function
`log(x)`	Numeric	Numeric	Natural logarithm function
`max(a,b ...)`	Numeric	Numeric	Maximum of the given arguments
`min(a,b ...)`	Numeric	Numeric	Minimum of the given arguments
`path(x)`	String	String	Returns the path component of a file specification
`pow(x,y)`	Numeric	Numeric	Power function (x to the power of y)
`rfind(s,t)`	String	Numeric	Finds the last occurrence of a t in s and returns the position (where 0 is the first character)
`round(x)`	Numeric	Numeric	Round up or down
`sinh(x)`	Numeric	Numeric	Hyperbolic sine function
`sin(x)`	Numeric	Numeric	Sine function
`split(t,s)`	String	Array	Splits t into elements using the separator s
`sprintf(f,a ...)`	String, Any	String	Implement of 'C' sprintf. Provides not all features but the most commonly used ones (precision, field width, alignment, zero padding, 'e', 'g', 'f', 'd', 'x', 'u' and 's' formats)
`sqrt(x)`	Numeric	Numeric	Square root
`substr(t,f[,l])`	String	String	Return a substring of t (starting from position f with length l). 'l' is optional. If omitted, the tail of the string is returned.
`sub(s,x,y)`	String	String	Substitute the first occurrence of a x in s by y
`tanh(x)`	Numeric	Numeric	Hyperbolic tangent function
`tan(x)`	Numeric	Numeric	Tangent function
`to_f(x)`	Any	Numeric	Convert argument to numeric if possible
`to_i(x)`	Any	Numeric (integer)	Convert argument to numeric (32 bit integer)
`to_s(x)`	Any	String	Convert argument to string

2.5. About Variant Notation

KLayout employs a certain notation to enter variant types. Variant types are data items which are either numerical or text information and are used specifically for property names and values. In that case, the type of information is important, and a simple edit box won't be sufficient to enter the information. For example, "1" could either be a text "1" or the number 1. To solve that issue, KLayout uses the following notation:

Notation	Description	Example
#...	An integer value	`#17`
##...	A floating-point value	`##0.5`

'...' or "..."	A text string which can contain any character. You can use the backslash character to escape quotes if you want to use quotes in your text string. To use the backslash character inside the text, use a double backslash (\\).	`'A text'`
		`'A \'quoted text\''`
		`'A single \\ character'`

A word (letters, digits and the underscore)	Taken as a text string	`NAME`

2.6. About LEF/DEF Import

KLayout supports import of LEF and DEF files. Because LEF and DEF import is substantially different from a single-file reader, this functionality is wrapped in an import feature rather than a standard file format reader. For example, reading a DEF file without accessing the library LEF files does not make much sense. Therefore the import feature requires additional information beyond the simple file name, specifically the list of LEF files to load additionally and the order in which to do so.

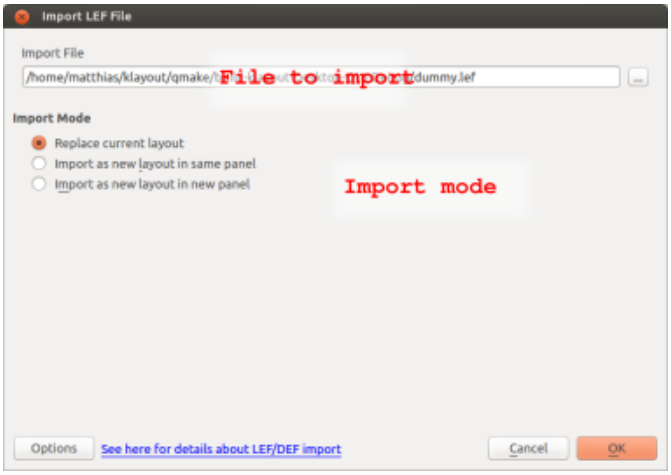
You can find the import feature in the "File/Import" submenu. Choose "LEF" to import a single LEF file (plus potentially more LEF files from the technology specific settings) or "DEF/LEF" to import a DEF file plus additional LEF files.

In the import dialog, the files to import are selected. The top edit box specifies the main file to import (the LEF file in the LEF import case or the DEF file in the DEF import case. Use the "..." button to browse for the file. In the DEF import case, additional LEF file can be specified which are imported before the DEF file is read. You can add LEF files to the list using the "+" button and remove the selected LEF files using the "x" button. The order of LEF files matters - the technology LEF file (if there is one) should be read first. The LEF files are read in the order they appear in the list. You can move entries up using the "up" button and down using the "down" button.

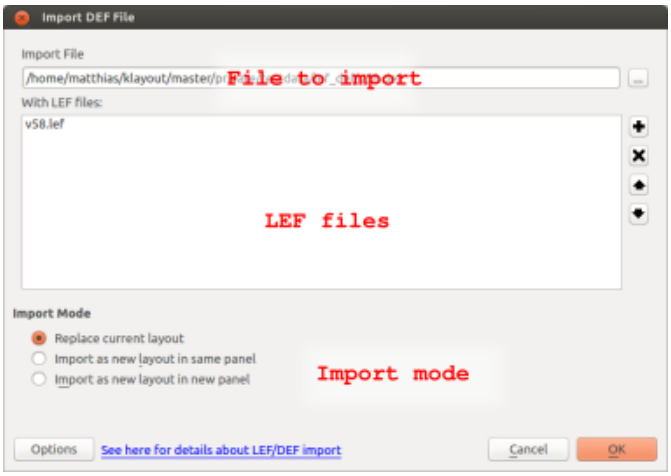
If you browse for a DEF file, KLayout will automatically fill the list of LEF files with the LEF files found at the location of the DEF file. LEF files are searched for relative to the DEF file path. Unless an absolute path is specified for the LEF file, KLayout will look relative to the path of the DEF file.

In both LEF or DEF import case you have the choice to read the layout into the existing view (add to the current layout or overwrite the current one) or open a new view using the "Import Mode" options.

The following image shows the LEF import dialog:

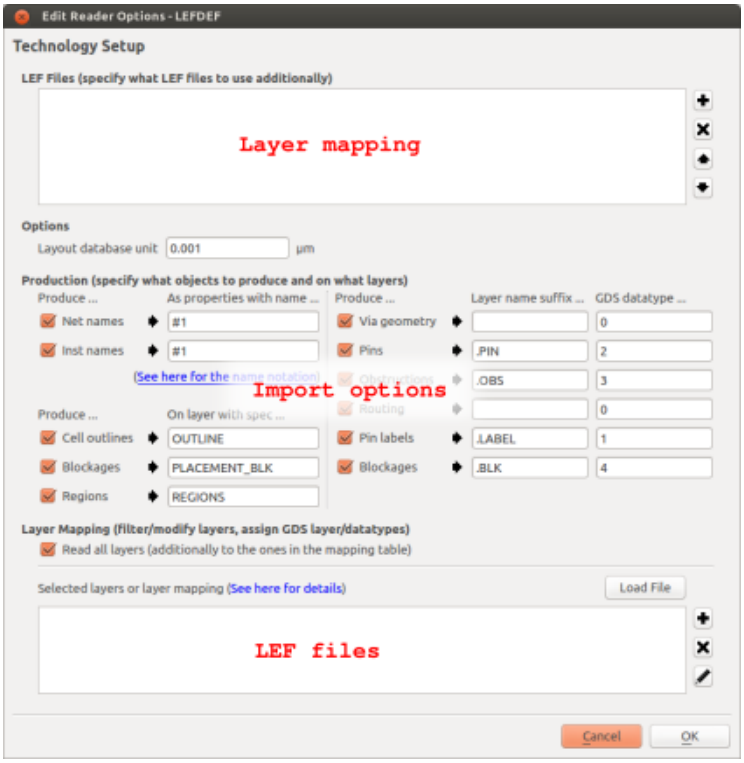


And this one is the DEF import dialog:



LEF and DEF import can be configured in many ways. The configuration of the LEF/DEF import feature is attached to a technology, so there can be individual configurations per technology. For a description of the technology feature, see About Technology Management. The import feature uses the current technology. The current technology can be selected from the main toolbar's technology selector if specific technology settings exist. Otherwise, the default technology will be used.

You can edit the import settings using the "Options" button from the import dialogs. This will open a dialog for editing the settings attached to the selected technology. The settings basically consist of three parts: the layer mapping, the LEF files which are always read before the LEF files specified per DEF file and various import settings. The following image shows the LEF/DEF import options dialog:



Layer Mapping

By default, no layer mapping is specified. Layer mapping can be employed to confine input to certain layers or layer/purpose pairs and to specify mapping of LEF layers/purposes to GDS layer/datatypes.

In the Options part you will learn how the DEF/LEF importer generates layers. Basically, layers are generated from the LEF/DEF layer name plus some suffix describing the purpose. For example, pin geometry will be put to "Metal1.PIN" for "Metal1" geometry if the suffix for the "pin" purpose is set to ".PIN". In addition, the LEF/DEF reader will already assign some GDS layer/datatype, the layer is either the position of the layer in the layer list if there is a technology LEF file or a consecutive number based on the alphabetic order of the layer names. The datatype can be specified for each purpose.

However, that may not be sufficient to convert a DEF file to a certain GDS representation. Usually there is a layer mapping table, for example "Metal1.PIN" should be put to GDS layer 17, datatype 6. In order to facilitate such a use case, KLayout allows specification of a layer mapping table. The basis for the table is the layer name plus the suffix defined for the particular purpose. In the previous example, the mapping would be:

```
Metal1.OBS : 100/22
```

You can disable all other layer/purpose pairs by unchecking the "Read all layers" option at the top of the layer mapping table. If this option is enabled, KLayout will generate the GDS layers using the scheme described above for all layers it does not find in the mapping table.

LEF Files

You can specify a list of LEF files to load before any other LEF files. This feature is intended to allow specification of a technology LEF file containing the layer definitions or any standard library which should be present for every macro built on that technology. You can add and delete LEF files using the "+" and "x" button respectively. You can move files up and down using the "up" and "down" arrow buttons. The LEF files are read in the given order, so the technology LEF file must be the first in the list.

Options

On the left side of the option panel, two basic options are provided:

- **Produce net names:** Check this option to assign user properties with the net name to the net shapes in DEF files. The user property name used for that purpose can be specified in the edit box below the check box. Use KLayout's variant notation (see About Variant Notation) to specify value and type of the property name.
- **Produce inst names:** Check this option to assign user properties with the instance name to the component instances created by DEF import. The user property name used for the instance name can be specified in the edit box below the check box. Use KLayout's variant notation (see About Variant Notation) to specify value and type of the property name.
- **Produce cell outlines:** If this option is checked, outline shapes are produced for the macros and the design (for DEF import). The layer to be used can be specified in the edit box below. You can use KLayout's usual layer specification notation, i.e. "OUTLINE" for a named layer without GDS layer/datatype value, "10/0" for GDS layer 10, datatype 0 without a name or "OUTLINE (10/0)" for a combination of both. The outline layer is subject to layer mapping as well, so the layer map can be used alternatively to assign GDS layer/datatype numbers.
- **Produce blockages:** If this option is checked, placement blockages are produced as polygons on the layer given right of the check box. Use KLayout's layer notation to specify the layer (see "Produce cell outlines").
- **Produce regions:** If this option is checked, regions are produced as polygons on the layer given right of the check box. Use KLayout's layer notation to specify the layer (see "Produce cell outlines").

On the right side, the default layer generation for various purposes can be configured. In all cases, a layer suffix can be set which is just added to the layer name and a default GDS datatype can be set. Please note, that the GDS datatype may be overruled by a layer map if one is set. All contributions can be disabled individually.

The purposes available are:

- **Via geometry:** generated for shapes making up a via.
- **Pins:** generated for shapes making up a pin.
- **Obstructions:** generated for obstruction area markers.

- **Routing:** generated for routing geometry.
- **Pin labels:** generated for pin labels.
- **Blockages:** generated for (component) blockages.

Note: if the suffix of two purposes is identical, the default GDS datatype should be identical as well. Otherwise it is not defined which layer will be generated. Vice versa, the GDS datatypes should be different for different layer suffixes.

2.7. Connectivity

Use the connectivity page to specify the conductor layers and their connections. On a conductor layer, all touching or overlapping shapes are connected. A connection is made between conductor layer when the shapes of the two conductor layers overlap. Optionally a via layer can be specified which must be present to make a connection between the two conductor layer.

To specify a conductor layer

- Use "layer/datatype" notation to specify explicit GDS layers and datatypes.
- Enter the layer name to specify either a named layer or a symbolic layer. Symbolic layers must be defined in the symbol table (see Symbolic Connectivity Layers) and can be computed from boolean expressions.
- Instead of using a symbolic layer, enter a expression directly without defining a symbol (see Symbolic Connectivity Layers). Inside the expressions
    - Use "layer/datatype" notation to specify an original layer with explicit GDS layers and datatypes.
    - Use the name to specify a named original layer or to refer to a different symbolic layer defined in a symbol entry.
    - Use the operators '+', '*', '-' and '^' to specify logical OR, AND, NOT and XOR respectively. The precedence of evaluation is '^' and '*' before '+' and '-'.
    - Use round brackets to group expressions.

By creating conductor layers with boolean expressions, it is possible for example to separate an active area layer of a CMOS transistor into source and drain regions by subtracting the gate poly. Symbolic layers are useful to use "speaking" names for layers instead of the numeric layer/datatype specification. Please note, that the net tracer is considerably slower when using boolean expressions.

2.8. The 2.5d View

The "2.5d view" offers a semi-3d view of the layout. It's not a full 3d view as the layers are only extruded vertically into layers with a certain thickness. The view cannot model process topology, but it can visualize wiring congestions in a three-dimensional space or the vertical relative dimensions of features of the process stack.

Currently, the performance is limited, a rough number for a practical limit is around 100k polygons. The 2.5d view is only available, if KLayout was compiled with OpenGL support.

In order to use the tool, you will need a script generating the material stack. Such a script is a variant of a DRC script (see Design Rule Check (DRC)). The DRC language is used to import or generate polygon layers which are then extruded and placed on a certain z level.

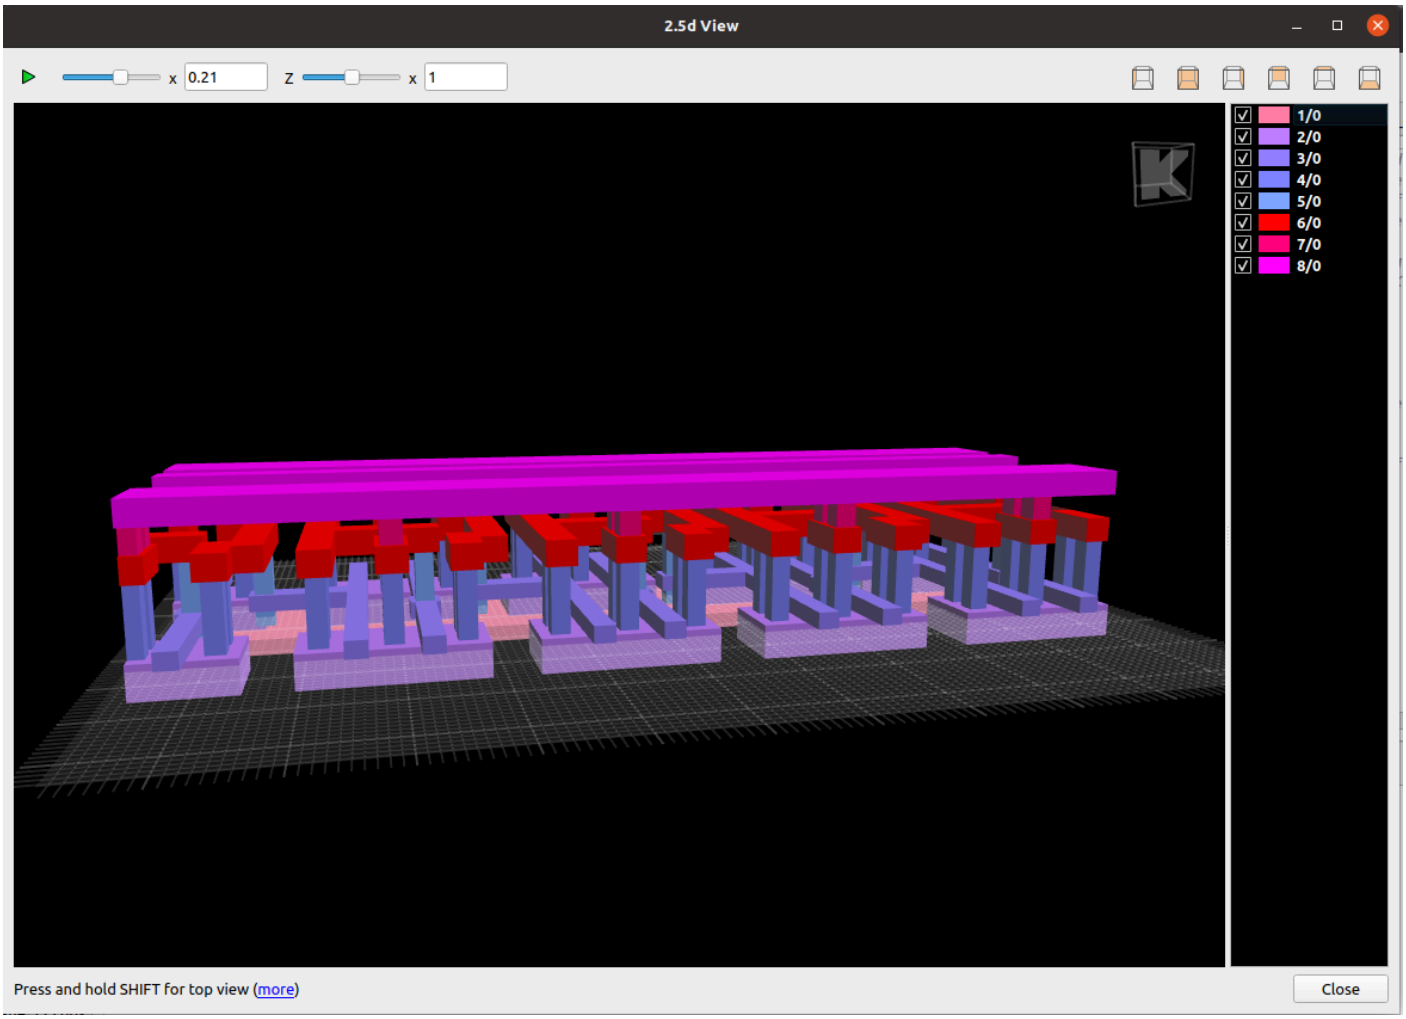
To create a new script, use "Tools/2.5d View/New 2.5d Script". This will create a new script in the macro editor.

A simple script is this one. It takes two layers - 1/0 and 2/0 - and extrudes then in a stacked fashion, the first with 200nm thickness and the second one with 300nm:

```
z(input(1, 0), zstart: 0.1.um, height: 200.nm)  # extrudes layer 1/0 to a height of 200nm starting at z=100nm
z(input(2, 0), height: 300.nm)                  # adds layer 2/0 for the next 300nm
```

To run the script, use the "Run" button from the macro IDE or pick the script from the script list in the "Tools/2.5d View" menu. If your script is not shown in that menu, check if it is configured to be bound to a menu item.

After the script was executed, the 2.5d window is displayed. If you closed that window, you can re-open it with "Tools/2.5d View/Open Window". The window will show the layout section visible in the layout view. To refresh the scene - also after changing the script - either run the script again from the macro IDE or use the green "re-run" button in the upper left corner of the 2.5d view window.



2.5d Script Anatomy

As mentioned, a 2.5d script is a variant of a DRC script. You can basically use all features of DRC, specifically boolean operations. Some practical restrictions exist:

- You should not use external sources ("source" statement) as the 2.5d view is related to the loaded layout
- Report generation or "output" statements are permitted, but do not make much sense in the context of 2.5d view scripts.

2.5d scripts utilizes the DRC language with these two additional functions:

- z(layer [, options])

  Extrudes the given layer. "layer" is a DRC layer (polygon, edge or even edge pair). "options" declare the z extrusion and display parameters.

- zz([options]) { block }

  Declares a material group which combines multiple "z" statements under a single display group. This allows generating 3d material geometries which are more than a single extruded plane. The display parameters then are specified within "zz" for all "z" calls inside the block.

"z" Function (plane extrusion)

The layer argument of the function is a DRC layer which is rendered as an extruded sheet. Further arguments control the height, z location and colors. When used inside the "zz" block, the color options of the "z" calls are ignored and taken from "zz" instead.

Options for this function are:

- **zstart**: specifies the bottom coordinate of the extruded sheet. If this option is not given, the top coordinate of the previous "z" statement is used.
- **zstop**: specifies the top coordinate of the extruded sheet. Alternatively you can use "height".
- **height**: specifies the extrusion height. Alternatively you can use "zstop".
- **color**: specifies the color to use as a 24 bit hex RGB triplet (use "0xrrggbb" to specify the color similar to the HTML notation "#rrggbb"). A color specification gives a single color with not differentiation of frame and wall colors.
- **frame**: specifies the frame color to use as a 24 bit hex RGB triplet. If only a frame color is specified, the geometry will be rendered as wire frame only.
- **fill**: specifies the fill (wall) color to use as a 24 bit hex RGB triplet. This allows specifying a different color for wall and frame when used with "frame".
- **like**: specifies to use the same colors than used for some layer in the layout view. If the layer is an original layer (i.e. taken from "input"), "like" defaults to the original layer's source. If given, "like" needs to be a string representation of the layer source (e.g. "7/0" for layer 7, datatype 0).
- **name**: gives the material a name for displaying in the material list.

Examples for the extrusion options:

```
z(layer, 0.1 .. 0.2)               extrude layer to z = 0.1 to 0.2 um
z(layer, zstart: 0.1, zstop: 0.2)  same as above
z(layer, zstart: 0.1, height: 0.1) same as above, but with height instead of zstop
z(layer, height: 200.nm)           extrude layer from last z position with a height of 200nm
```

Examples for display options:

```
z(..., color: 0xff0000)            use bright red for the material color (RGB)
z(..., frame: 0xff0000)            use bright red for the frame color (combine with "fill" for the fill
 color)
z(..., fill: 0x00ff00)             use bright green for the fill color along (combine with "frame" for the
 frame color)
z(..., like: "7/0")                borrow style from layout view's style for layer "7/0"
z(..., name: "M1")                 assigns a name to show for the material
```

"zz" Function (material groups)

The "zz" function forms a display group which clusters multiple "z" calls. The basic usage is with a block containing the "z" calls. As DRC scripts are Ruby, the notation for the block is either "do .. end" or curly brackets immediately after the "zz" call:

```
zz( display options ... ) do
  z(layer1, extrusion options ... )
  z(layer2, extrusion options ... )
  ...
end
```

The "z" calls do not need to have colors or other display options as they are taken from "zz".

Material groups allow forming more complex, stacked geometries. Here is an example forming a simple FinFET geometry using boolean and a sizing operation:

```
gate = input(1, 0)
active = input(2, 0)

z(active, zstart: 0, height: 20.nm, name: "ACTIVE")

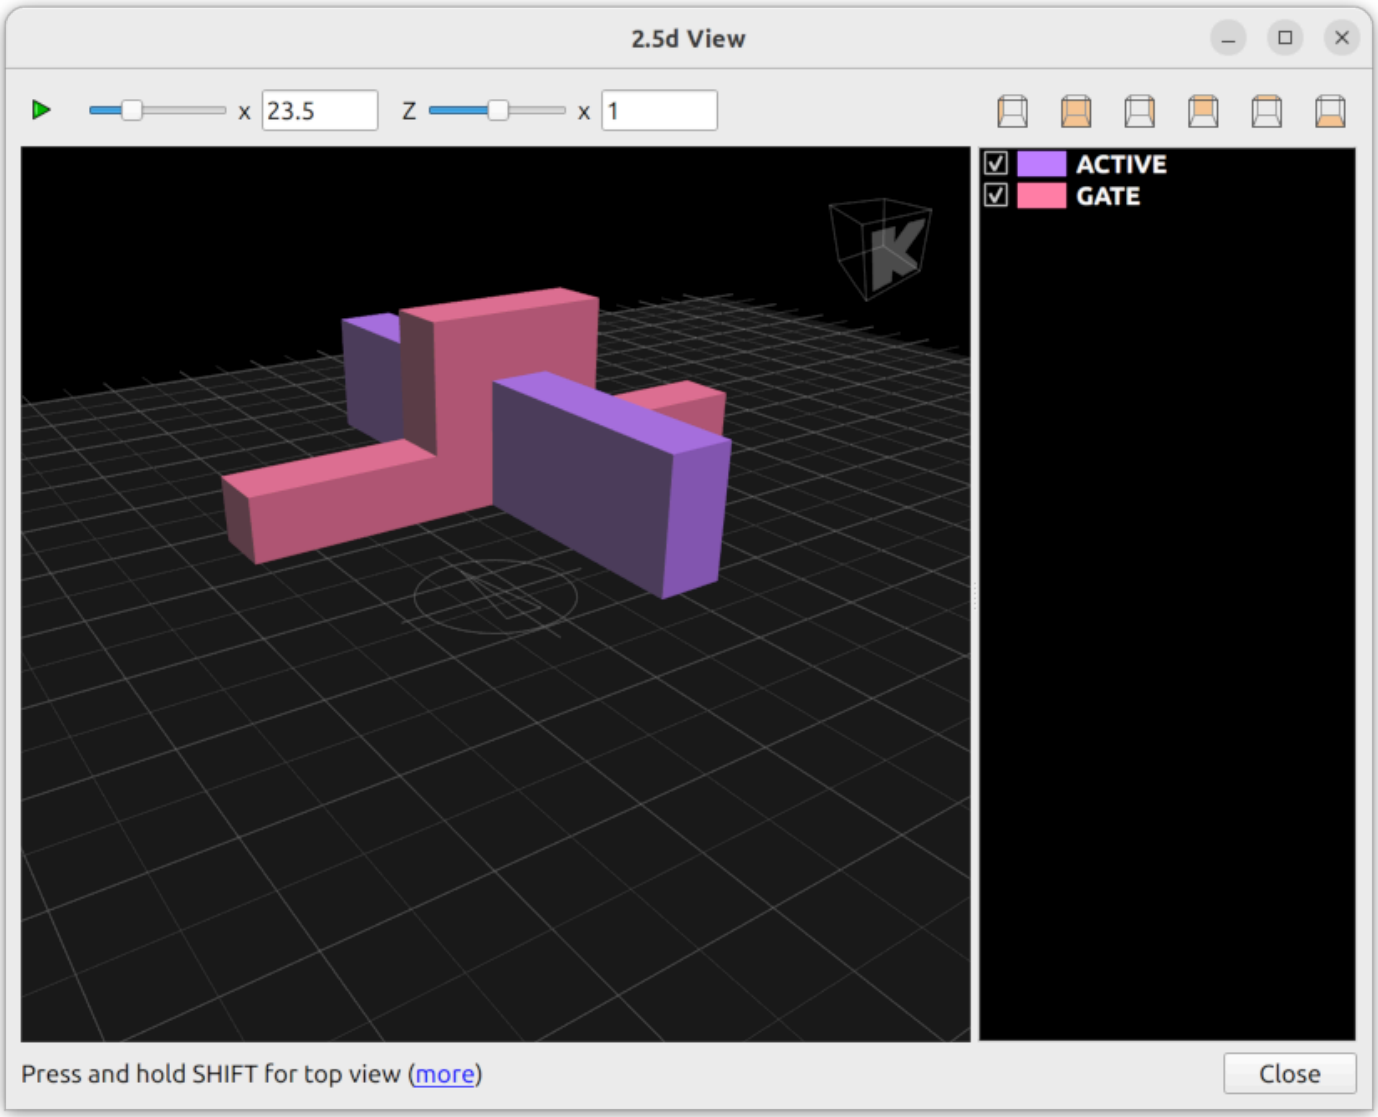
zz(name: "GATE", like: "1/0") do

  active_sized = active.sized(10.nm)
  gate_over_active_sized = active_sized & gate

  z(gate - active, zstart: 0, height: 10.nm)
  z(gate_over_active_sized - active, height: 10.nm)
  z(gate_over_active_sized, height: 10.nm)

end
```

Which renders this result:



Navigating the 2.5d View

The navigation is based on the movement of the camera while the scene is formed by the extruded layout. The scene can be scaled to provide zoom features. Scaling and rotation is relative to the pivot point which is indicated by the compass icon on the ground plane.

This is a short list of the navigation controls which act on the camera:

- Dragging with the right mouse button down: change azimuth and elevation angle
- Dragging with the middle mouse button down: move the pivot up and down or left and right
- Mouse wheel: moves the pivot forward and backward
- Control key + mouse wheel: magnify or shrink the layout
- Press and hold shift key: switch to top level view (see below)
- Up/down keys: move the pivot forward or backward

- Left/right keys: move the pivot to the left or the right
- Control + up/down keys: change the elevation angle
- Control + left/right keys: change the azimuth angle

In top level view, the navigation is slightly different:

- Dragging with the right mouse button down: change azimuth angle
- mouse wheel: magnify or shrink the layout
- Up/down/left/right keys: move the pivot on the horizontal plane

Note: if the Shift key does not switch to top level view, click into the scene view once.

Colors in the 2.5d View

While the 2.5d view window is open, the layout view is still active. Layer colors are applied also to the 2.5d view. Changing the fill color will change the 2.5d view's face color. The frame color will be applied to the wire frame. If a hollow stipple is selected, only the wire frame is shown. If a layer is made invisible in the layout view, the corresponding blocks will also be made invisible in the 2.5d view.

Other Controls

The left zoom slider changes the overall scale factor. The right slider only changes the z (height) axis zoom factor. This is useful as in many cases, the real height profile will result in a rather flat arrangement. Increasing the z zoom factor will exaggerate the vertical axis hence making height variations more pronounced.

The edit boxes next to the scale sliders allow entering the scale factors manually.

The button bar at the top right side holds the view presets. Use them to reset the window to front view, top view etc.

Material Visibility

Using the check boxes from the material view right of the scene view you can disable materials, so they are no longer rendered. From the material list's context menu, you can hide or show all materials or just the selected ones.

2.9. Symbolic Connectivity Layers

Use the symbol table to specify derived layers and to assign names to layer/datatype combinations. A symbolic layer must have a name which can be used in the connectivity table instead of the original layers. In addition, an expression must be specified that defines the contents of the layer.

Inside the expressions

- Use "layer/datatype" notation to specify an original layer with explicit GDS layers and datatypes.
- Use the name to specify a named original layer or to refer to a symbolic layer defined in another entry.
- Use the operators '+', '*', '-' and '^' to specify logical OR, AND, NOT and XOR respectively. The precedence of evaluation is '^' and '*' before '+' and '-'.
- Use round brackets to group expressions.

Examples:

17	Abbreviation for GDS layer 17, datatype 0
2/0*17/0	Logical AND between layer 2 and 17, both datatype 0
2*(5+7)	Logical AND between layer 2 and the logical OR combination of 5 and 7
ACTIVE-POLY	Logical NOT between the symbolic layer ACTIVE (defined in another entry) and POLY (also defined in another entry).

2.10. About Layer Sources

KLayout implements a concept of "layer views". The layer list is made up of such layer views. A "view" is basically a specification of what is shown how. The "how" part is given by the colors, stipples, styles etc. The "what" part is given by the source specification.

The most important part of the source specification is the layer number or name. But the source specification is much more powerful. Basically the source specification offers the following capabilities:

- Specify the layer where the shapes are taken from, either by layer and datatype or name
- Transform the layout before it is drawn
- Property filter: draw only shapes whose user properties match a given expression
- Override the hierarchy levels on which the shapes are drawn

Specifying the source layer

The source layer specifies from which actual data layer to take the drawn shapes from. The most simple form of a source specification is "layer/datatype" (i.e. "5/0") or the layer name, if an OASIS layer name (or a named layer in general) is present. This specification can be enhanced by a layout index. The first layout loaded in the panel is referred to which "@1" or by omitting this specification. The source specification "10/5@2" therefore refers to layer 10, datatype 5 of the second layout loaded in the panel.

Source specifications can be wildcarded. That means, either layer, datatype or layout index can be specified by "*". In this case, such a layer view must be contained in a group and the group parent must provide the missing specifications. For example, if a layer is specified "10/*" and the parent is specified "*/5", the effective layer looked for will be "10/5". Unlike the behaviour for the display styles, the children override (or specialize) the parent's definition in the case of the source specification.

For more information refer to Removing And Adding Layers To The Layer Set.

Transforming the layout

A geometrical transformation is specified by appending a transformation in round brackets to the layer/datatype source specification.

For example, "(r90)" specifies a rotation by 90 degree counter-clockwise. "(0,100.0 m45 *0.5)" will shrink the layout to half the size, flip at the 45 degree-axis (swap x and y axes) and finally shift the layout by 100 micron upwards.

Transformations accumulate over the layer hierarchy. This means, that if a layer is transformed and the layer is inside a group whose representative specifies a transformation as well, the resulting transformation is the combination of the layer's transformation (first applied) and the group representative's transformation.

Multiple transformations can be present. In this case, the layout is shown in multiple instances.

For more information refer to Transforming Views And Property Selectors.

Property filters

It is possible to specify a property filter. A property filter specifies an expression and only shapes for which that expression applies are shown. The expression operates on user properties and the syntax allows comparison of properties with a given key against a given value. Boolean operators are available. That way, complex expressions can be created.

The property filter is specified in square brackets. For example:

```
10/5 [#43==X]
```

With this source specification, the layer will show all shapes from layer 10, datatype 5 which have a user property with number 43 and value string "X".

For more information refer to Transforming Views And Property Selectors.

Overriding the hierarchy levels

By default, only the hierarchy levels that are selected in the hierarchy level selection boxes are shown, i.e. if levels 0 to 1 are selected, just the top level shapes and instances are shown. This selection can be modified for certain layers or layer groups. To specify a different hierarchy selection for a certain layer, use an optional source specification element, the hierarchy level selector.

For example:

`#*`	Display all hierarchy levels
`#0..1`	Display top level only
`#..5`	Override upper level with 5
`#2..`	Override lower level with 2
`#..*`	Override upper level setting by "all levels"

For more information refer to Specifying Explicit Hierarchy Levels For One Layer Or A Layer Group.

2.11. About Macro Development

Basics

KLayout supports macro programming with the Ruby or Python language. Macros are basically Ruby or Python scripts that are executed by the integrated interpreter. In order to enable macro programming, the program has to be built with support by either one of those languages.

As a special kind of macros, DRC and LVS scripts are available for editing and debugging too. These scripts are basically Ruby scripts but run in a customized environment so that specific functions are provided. For more details on these kind of scripts see Design Rule Check (DRC) and Layout vs. Schematic (LVS).

In a simple scenario, scripts can be stored in simple text files and loaded by KLayout using the "-rm" or "-r" command-line option. "-rm" will run a script and then execute the normal application. "-r" will run a script and then exit the application.

In addition, KLayout supports special macro files with the suffix ".lym". Those files are XML files that store the macro code along with additional information, for example the description text, the interpreter language and certain flags. These flags tell KLayout to run the macro automatically when starting up for example. In addition, KLayout can present such macros in the "Macros" menu without having to register a specific menu extension.

Macros can be technology specific. This means, they are packaged with a technology and are associated with the technology in the user interface: if they provide a menu item, this item will only become visible when the respective technology is active.

KLayout also offers an integrated development environment (IDE) that allows editing and debugging of Ruby and Python scripts. It offers a simple debugger with the ability to set breakpoints and to interact with the current context while in a breakpoint. An interactive "console" allows entering and evaluating of expressions. This feature is available also when execution has stopped in a breakpoint, so the console can be used to evaluate or modify variables in the current context. Watch expressions are supported as well: a series of expressions can be configured which is evaluated and displayed in a breakpoint. With Python scripts, the local context can be inspected in the "Inspector" window: the variables available in the local context are listed with their values.

While the debugger is open, execution will slow down somewhat and undesired interactions may happen - specifically when developing UI components. To mitigate this problem, debugging can be disabled in the macro IDE.

KLayout defines certain folders which it scans for macro files. Each directory is scanned recursively. It can contain subdirectories with more macros and can also contain support files such as images or additional Ruby or Python modules. That allows organizing macros in modules where each module contains the root module files and supporting files.

KLayout looks for macros in the following places:

- The "macros" or "pymacros" folders in the installation path. The installation path is where the KLayout binary resides. KLayout cannot modify macros that are stored in that path. This is the "global" repository. Usually that repository is shared between all users. An administrator can use this location to install macros globally.
- The "macros" or "pymacros" folders in KLayout's user specific application folder. On Unix that is "~/.klayout/macros". This is the "local" repository. Any user can store his or her own macros here.
- Plain Ruby or Python files can be kept inside "ruby" and "python" directories next to "macros" and "pymacros". In contrast to "macros" and "pymacros", the locations of "ruby" and "python" paths are added to the Ruby or Python search paths. This makes those folders useful for keeping plain Ruby or Python libraries. Generic ".lym" files cannot reside there and those locations are not scanned for autorun macros.
- DRC and LVS scripts are kept inside "drc" and "lvs" folders respectively.
- In addition, further repositories can be given on the command line with the "-j" option. This allows adding development repositories which are under configuration management and contain the latest code for the macros. Those repositories are called "project" repositories.
- Technology folders: each technology folder can carry a "macros" or "pymacros" subfolder where technology-specific macros are kept. See About Technology Management for details about technologies.
- Macros can be kept in packages and installed from a remote repository. See About Packages for details about packages.

The macro IDE will store Python and Ruby macros separately in "macros" and "pymacros" for easier management, but technically these folders are equivalent. KLayout will automatically derive the interpreter from the context stored in ".lym" files or the file extension (".rb" or ".py").

You can also add custom places using the "Add Location" entry from the repository browser's context menu (right mouse click). These locations will be added to the tree. That setting is stored in the setup, so it will be available when KLayout is started again. You can remove places again by using "Remove Location" from the macro tree's context menu.

KLayout will scan these places for files and present them in the macro development IDE's repository browser. You can edit the files and their properties and run the macros from the IDE. KLayout's IDE supports these file types:

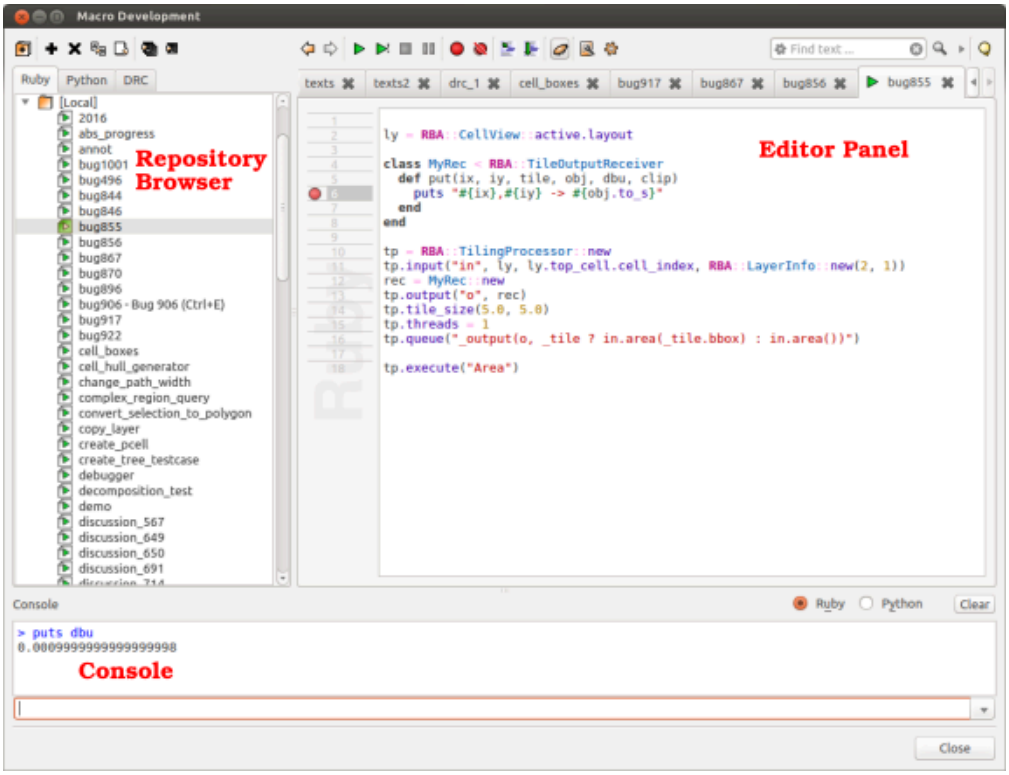
- ".lym": generic KLayout macros.
- ".rb": plain Ruby files. Such files can be imported into KLayout macros by Ruby's "require" or "load" method.
- ".py": plain Python files. Such files can be imported into KLayout macros by Pythons's "import" method.
- ".txt": text files for documentation for example.

Other files can be stored inside the folders (for example Qt ".ui" files), but they won't be shown in the IDE.

The macro development IDE

The macro development IDE consists of three parts: the repository browser, the editor panel and the console. The repository browser allows browsing of the macro repositories and to add new files, to move files, to delete files, to import plain ruby files as KLayout macros and to rename files. In the editor panel, the macro or other files can be edited, breakpoints can be set and the macro can be run. In the console, Ruby expressions can be entered and evaluated. This also works while KLayout is in a breakpoint. That feature evaluating of expressions in the current context and to modify variables. The console also shows the output of the Ruby scripts when they are run in the context of the IDE.

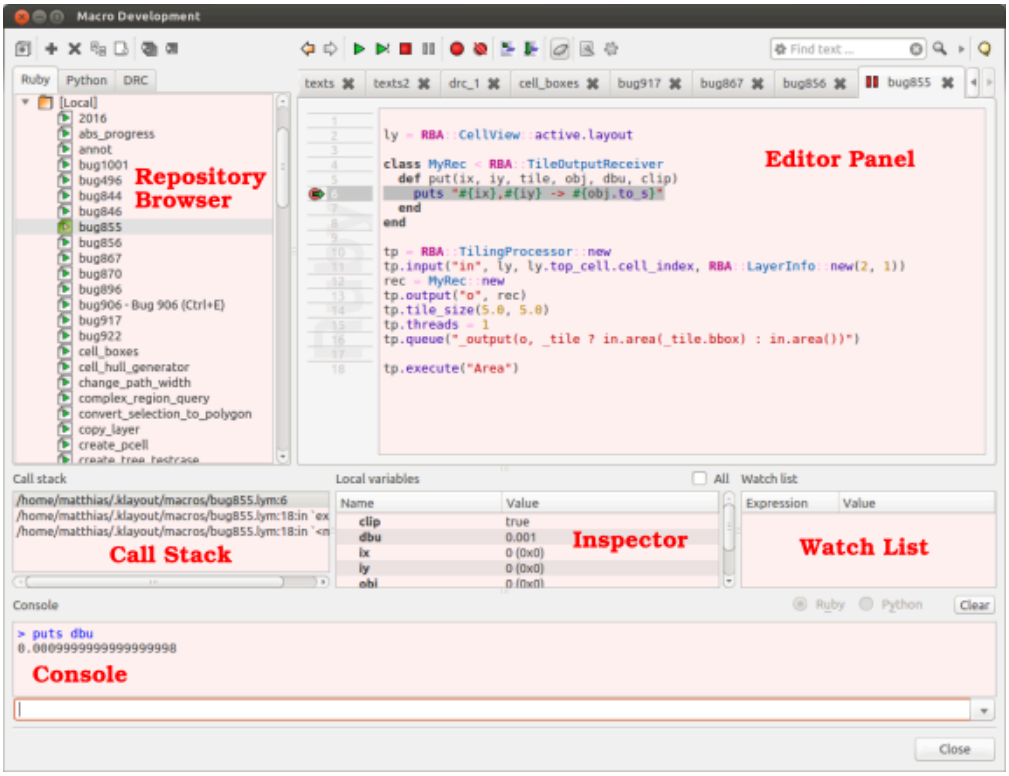
The following image shows the IDE with the three main parts:



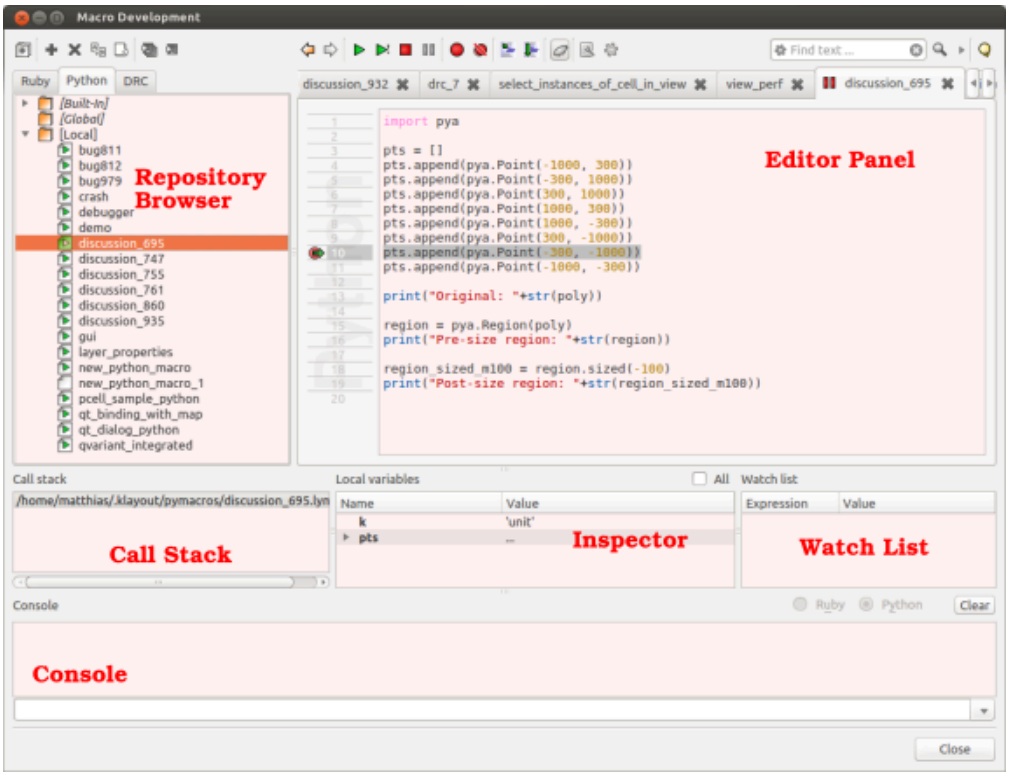
When the debugger enters a breakpoint, the IDE also shows the call stack. By clicking on an entry in the call stack panel, the editor will open the respective file and position the cursor at that line. A watch window shows the watch expressions with their evaluated values.

Watch expressions are evaluated every time a breakpoint it hit. They can be managed using the "Add", "Edit", "Delete" and "Clear" functions from the context menu (right click on the watch list). For Python scripts, the local variables of the currently selected stack context can be browsed in the "Inspector" window in the middle. Currently this feature is not available for Ruby scripts.

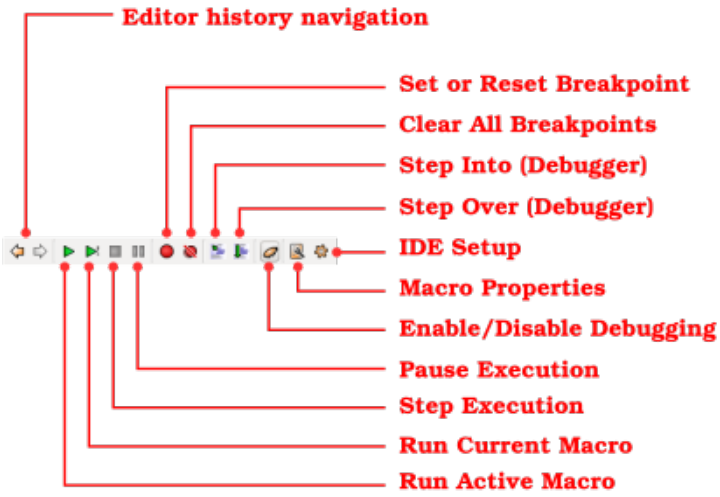
The following image shows the IDE in breakpoint mode for Ruby scripts:



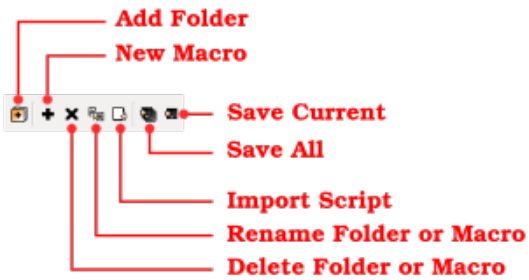
The following image shows the IDE in breakpoint mode for Python scripts:



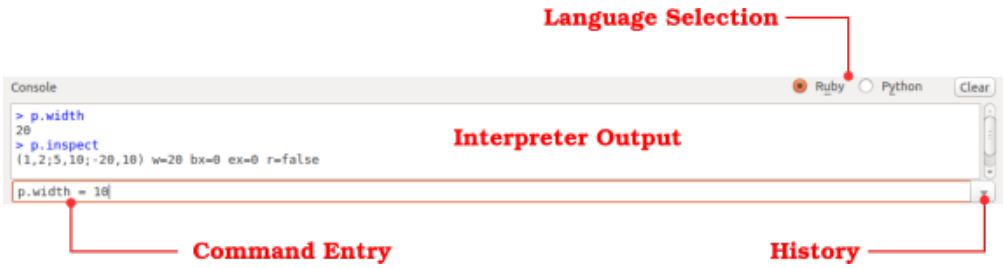
The editor panel features a toolbar with several tool buttons. The following image shows the toolbar and the buttons with their function:



Also the repository browser features a toolbar with more tool buttons. The following image shows that toolbar and the buttons with their function:



Finally the console panel allows interactive executing of Ruby or Python expressions. The following image shows the console elements and their function:



Basic tasks

Creating a new macro

To create a new macro, first open the tab to select a language you want to use. Choose the branch in the repository browser where you want to create the macro. Press the "+" button above the repository browser. A dialog will come up in which you can select a template. A template is basically the initial content of the macro plus some default settings. After the macro is created, the new entry is highlighted and the name can be changed to the desired new name.

Editing the macro

After the macro has been created, it is shown in the editor window. Other macros or files can be opened in the editor by double-clicking at their name. Depending on the type of file, the editor provides some basic syntax highlighting. Each file is opened in a separate tab. The tabs can be closed by clicking at the "x" button in the tab.

To save the current edits to the files, press the "Save all files" or the "Save current file" button in the repository browser.

Search and search & replace is available in the editor panel in the search box. The search a text, enter the text in the search box and hit Return. Use the "Find next" button to find the next occurrence of the text. Click on the "RE" button to enable regular expressions in the search function. To enable "Replace" mode, open the replace text edit box by clicking on the little arrow right to the search tools. Enter the text to replace the search text into the edit box and use "Replace all" to replace all occurrences or use "Replace and search" to replace the current occurrence and highlight the next one.

Running the macro

To run the macro, press the "Run current script" or the "Run script from the current tab" button in the editor panel. "Run current" will run the script that was run the last time, irregardless if the script is the one currently shown in the editor panel. That way, it is possible to run the same script while editing support files for example. "Run script from the current tab" will always run the script from the current tab.

When the macro runs, output will be sent to the console below the editor panel. Breakpoints can be set or reset with the "Set breakpoint" button or the F9 key in the editor panel. Go to the line where you want to change the breakpoint and use "Set breakpoint" to set or reset the breakpoint on the current line. All breakpoints can be cleared with the "Clear all breakpoints" button.

While the macro is running or in a breakpoint, the execution can be aborted with the "Stop script" button. Execution can be interrupted with the "Pause script" button. In that case, KLayout will interrupt the script execution at the current position.

When in a breakpoint, single-line step-by-step is supported with the "Step into" button or the F11 key. Stepping over a block or procedure call is supported with the "Step over" button or the F10 key. Please note that "Step over" will also step over blocks.

While KLayout has stopped the execution of the script, the console can be used to examine variables in the current context or to modify their values. Ruby expressions entered into the console are simply executed in the current context.

When the macro editor window is open, macros will be run under debugger control. This will considerably slow down macro execution and create issues when you develop macros that integrate deeply into the system (for example macros filtering Qt events from the application). To avoid issues, debugging can be disabled by selecting or unselecting the "Enable debugging" button in the editor's toolbar. If the button is checked (shown pressed), debuggin is enabled and breakpoints can be used. If debugging is disabled, breakpoints will be ignored.

Working with the repository browser

The repository browser provides a tab for each category of macros. "DRC" is a special category which provides macros that perform a DRC. Such macros are basically Ruby scripts that are executed in the context of a DRC engine and hence supply different functionality. Still, they execute in the usual context and breakpoints, watch expressions and similar can be used. The other categories are macros executing either in a Ruby or in a Python interpreter.

Within the repository browser, you can add new folders using the "New folder" button. Before you do so, select the branch of the repository where you want to create the new folder. The new folder will be highlighted and the name can be edited.

To delete files and folders, select the file or folder in the browser and click the "Delete" button (the "x"). Caution: deleting a file or folder cannot be undone currently.

To rename a file or folder, select the entry in the browser and click on the "Rename" button and enter the new name. To move files or folder, simply drag and drop them to the desired target location.

Pain ruby scripts can be imported into the repository as KLayout macro files. Select the branch where you want to import the files in the repository browser, click on the "Import" button and select the file to import. ".rbm" files will automatically be set to "auto-run".

Configuring macros

A macro can be configured in several ways:

- Description: a macro can be given a description text. This text is shown in the repository browser and in the menu if a macro a configured to be shown in the menu.
- Version: the version will be used in a later stage to check dependencies between packages. Currently the version is not used. When used, enter a string of the form "v0.v1.v2" where v0 is the major version, v1 the minor version and v2 the patch. For example: "1.7.1".
- Prolog and Epilog: these are statements which are executed before the script is started and after the script has been run respectively.
- Run on start-up: if this flag is set, the macro is automatically run when KLayout starts. This feature is required for macros defining libraries for example. "Run early on startup" is a special option which makes sure the macro is run at the very beginning of the process. Such macros can be use to supply classes and features for other macros that use the normal "run on start-up" mode.
- Show in menu: with this flag, KLayout will show the macro in the "Macros" menu. That is a simple way to run macros outside the IDE.
- Bind to a key: with key binding, a macro can be run when a certain key combination is pressed. That is another way to run a macro outside the IDE.

The macro properties can be edited using the "Edit properties" button in the editor panel.

Migrating code

Before version 0.22, KLayout did not have a concept of macro IDE, macro folders, interpreters and generic macros. Ruby code written for the pre-0.22 system can be imported into the macro management system of KLayout using the "Import" function from the repository browser toolbar. ".rbm" files are marked as "autorun" in order to emulate the behavior of KLayout 0.21 and previous versions. ".rb" files are converted into KLayout macros without any further assumption. ".rb" files can also simply be copied into the macro directories. However, such files are regarded as secondary sources in KLayout. Typically those are files that are loaded by other macros. Importing a file makes code a generic source (".lym" file) with enhanced capabilities.

After importing the code the macro can be attached to a menu entry by setting "Show in menu" on the properties page. It is also possible to assign keyboard shortcuts. If either the menu item is selected or the key specified in the shortcut is pressed, the macro is executed.

This feature is more convenient to use than the scheme used previously. Until KLayout 0.22 it was only possible to register a macro with a specific menu entry by performing the registration in the code. The disadvantage of this approach is that when the macro code is re-executed, the menu item is registered again and appears in the menu twice. It is therefore more convenient to remove the menu registration code and let KLayout register the macro in the menu by setting the menu binding properties accordingly.

Hints

The editor and IDE can be configured using the "Setup" button in the editor panel. That dialog allows configuring fonts and colors to be used in the editor and the behavior of the debugger in some respects.

The documentation of the Ruby and Python classes exposed by KLayout is available in KLayout's online help system here.

2.12. Macros in Menus

KLayout allows installing macros as menu entries. Each time that menu entry is selected, the macro will be executed. To configure a macro for installation in the menu, open the macro in the macro development environment and open the macro properties dialog.

The macro is configured to be shown in the menu by checking the "Show in menu" check box. That also enables two other fields: the menu path and the group name.

The menu path specifies the position where the macro shall be put. A macro path is a sequence of symbolic names separated by a dot. For example:

- `edit_menu.end` is the end of the "Edit" menu
- `edit_menu.undo` is the "Undo" entry in the "Edit" menu

To obtain a list of the paths available, have a look at the "Key Bindings" page in the "Application" section of the setup dialog ("File/Setup").

The pseudo element "end" denotes the position after the last entry. The same way "begin" indicates the first entry in the menu. The macro will be inserted before the entry indicated by the path. Hence:

- `edit_menu.end`: the macro will be inserted at the end of the "Edit" menu
- `edit_menu.undo`: the macro will be inserted before the "Undo" entry.

If a plus sign follows the macro path element, the new element is inserted **after** this element. For example:

- `edit_menu.undo+`: the macro will be inserted after the "Undo" menu item.

A special form can be used to generate new groups: if the given element does not exist, the menu generator can be instructed to create it by appending the insert point plus the new text string to the element after a ">" character. For example:

- `edit_menu.my_group>end("My Edit Functions").end`: will look for "my_group" and add the new element at the end of this group. If no such group exists, it will be created at the end of the "Edit" menu with the title "My Edit Functions".

If no macro path is specified, the macro is inserted in the "Macros" menu. The description of the macro is used as the menu title. If a shortcut is specified, that shortcut is used for the macro entry as well.

The group name can be used to group together all menu entries with the same group name. Any text is allowed here. A group is separated from the other entries in the menu by a separator line. It is recommended to use the group feature in conjunction with a "end"-terminated menu path which is identical for all entries of the same group. Other uses cases are possible, but the result is not defined.

2.13. About Libraries

Starting with version 0.22, KLayout offers a library concept. Libraries are a way to import cell layout into a layout from the outside and thus a convenient way to provide standard building blocks for the layout. Using a cell from a library is easy: when asked for a cell, select the library where to take the cell from and choose a cell from that library.

Libraries are basically just foreign layouts that are virtually linked to the current layout. When a cell is imported from a library, it is copied into the current layout, so that the current layout by itself is a valid entity.

When a layout containing library references is saved, KLayout stores some meta information in that file which allows it to restore the library links and related information. For GDS, that meta information is stored in a separate top cell. For OASIS, the meta information is stored in special per-cell properties. For other formats, the meta information is not stored currently.

Libraries can be provided in several ways:

- **As ordinary layout files:** Such libraries are simple layout files (GDS, OASIS or other support format). KLayout looks up those libraries in the "libraries" subfolders of the search path and gathers all layout files it finds there into the library repository.

  The search path usually includes the installation site (where the KLayout executable resides) and the application folder (i.e. "~/.klayout" on Linux). Hence libraries can be installed locally (i.e. in "~/.klayout/libraries") or globally (at the installation site).

  For GDS files, the library name will be the LIBNAME of the GDS file. Otherwise it will be the name of the library file minus the extension.

- **Coded libraries:** Such libraries are provided by code, either through shared objects/DLL's or through Ruby code. Basically such code has to provide a layout object containing the library cells. A coded library can also provide PCells (parametrized cells) as library components. Sell About PCells for details about parametrized cells.

Starting with version 0.25, libraries can be provides through packages. This means, they can be downloaded from some repository and can be managed within the package manager. Library installation is very simple this way. Library deinstallation too. See About Packages for details about packages.

2.14. About PCells

Starting with version 0.22, KLayout offers parametrized cells (PCells). PCells are a feature found in other tools to simplify layout by providing generators for common layout building blocks. Parametrized cells do not contain static layout but are created dynamically by code using a given set of parameters.

For example, a circle PCell requires two parameters: the layer where the circle should be produced and the radius of the circle to produce. The code is responsible for creating the circle from these parameters.

Using a PCell is easy: choose the library and the PCell from that library when asked for the cell in the instance options dialog. For PCells, KLayout offers an additional parameters page where it asks for the parameter required by the PCell. The placement of the PCell is done as for simple instances. PCells offer the same instantiation options that normal cells.

KLayout provides a simple library called "Basic" with some useful basic PCells. See About The Basic Library for more details about that library.

Unlike other tools, KLayout offers the unique feature of "guiding shapes". A guiding shape is some kind of "ghost shape" that is not produced as real layout but is present as a part of the PCell instance. It is drawn in the style of the cell frame but can be edited as a normal shape. In particular, a guiding shape can be manipulated with the properties dialog and the partial edit mode. A special case is a point-like shape which can act as a handle of the PCell. In move mode, these shapes can be moved to change the parameter related to that handle.

Another use case for guiding shapes is the rounded path. This PCell uses a path as the input shape and applies rounding to the path's spine corners to compute a new path which smoothly bends around the corners. The radius of the bends is a numerical PCell parameter while the input shape controlling the geometry and the width of the path is the guiding shape.

A PCell implementation consists of at least three parts: a description text, a parameter declaration and a production callback. In addition, a PCell can provide a method that "fixes" parameters according to the PCells consistency rules (coerce parameters). Technically, a PCell is a class implementing a certain interface with these methods.

PCells are usually packed in libraries. PCell libraries can be provided as shared objects/DLL's (in C++) or as Ruby scripts. Because PCell code is only executed if required, performance usually is not the main objective. A Ruby implementation will therefore be sufficient in most cases and is a much easier to maintain. The Ruby approach also benefits from KLayout's integrated development environment.

For an introduction into PCell programming with Ruby, see Coding PCells In Ruby.

2.15. About The Basic Library

The "Basic" library

The "Basic" Library provides some useful generic PCells. One use model is to draw a shape and convert the shape to one of the provided PCells. This use model is suitable for creating Circles, Ellipses, Donuts, Texts and rounded and stroked polygons or rounded paths.

To use that feature, draw the shape and choose "Convert To PCells" from the "Edit"/"Selection" menu. A dialog will be shown where the target PCell can be selected. Only those PCells supporting that shape type will be shown.

The "Basic" library provides the following PCells:

- **TEXT**: A text generator
- **CIRCLE**: A circle
- **DONUT**: A donut (circle with hole)
- **ELLIPSE**: An ellipse
- **PIE**: A pie (a segment of a circle)
- **ARC**: An arc (a segment of a donut)
- **ROUND_PATH**: A rounded path (a path bending around the corners with a given radius)
- **ROUND_POLYGON**: A rounded polygon (a polygon with rounded corners)
- **STROKED_BOX**: A stroked box (the "rim" of a box, optionally with smooth corners)
- **STROKED_POLYGON**: A stroked polygon (the "rim" of a polygon, optionally with smooth corners)

TEXT

The text generator can produce texts in various forms. The following sample shows inverse text, normal text and text with bias and enlarged character spacing:

It's even possible to install custom fonts. Fonts are basically GDS files with the following features:

- One cell per character. Cells must be either named like the character "A", "B", "0" etc. or like the ASCII code in 3-digit decimal notation (i.e. "036" for the dollar character).
- The characters must be drawn in the character cells on layer 1/0. A box defining the extension of the characters (including spacing) must be drawn on layer 2/0. Optionally a background rectangle for the "inverse font" feature can be drawn on layer 3/0.
- One cell called "COMMENT" with text objects defining the basic text properties through their strings, in particular:
- **design_grid=x**: specifies the basic grid the characters are designed on. "x" is the grid in database units.
- **line_width=x**: specifies the line width in database units.
- A comment string which is displayed in the font selection box on the PCell parameters page.

Custom fonts are installed by copying the font file to a folder named "fonts" in one of the places in KLayout's path. The standard font can be found in "src/db/db/std_font.gds" in the source package.

CIRCLE and ELLIPSE

These PCells define a circle and an ellipse. In both cases, the number of interpolation points (per full circle) can be specified. The default is 64 points. A circle features a handle to define the diameter. An ellipse features two handles defining the diameters in x and y direction.

When a shape is converted to a circle or ellipse PCell, the shape's bounding box will be used to define the enclosing box of the circle or ellipse.

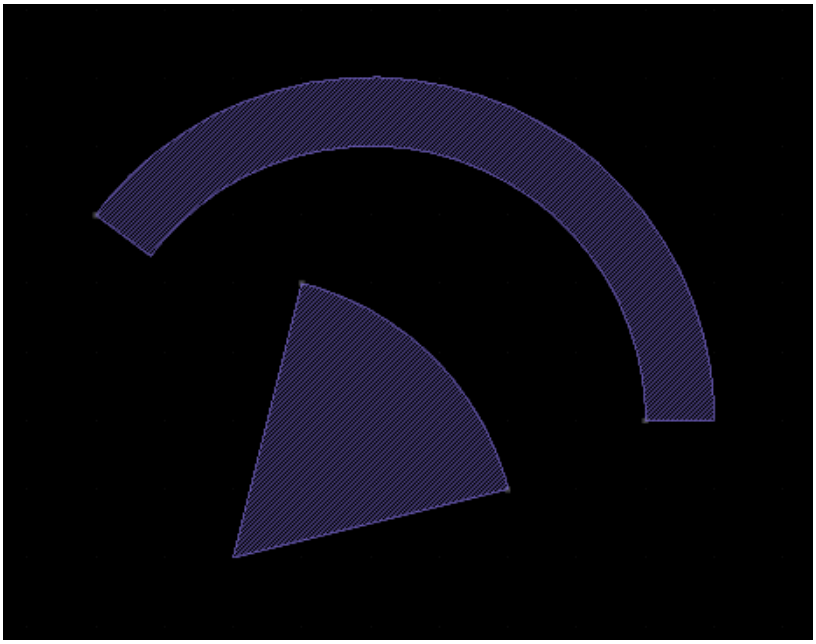
DONUT

The donut PCell creates a circle with a hole. This PCell features the same parameters than the circle but an additional parameter defining the hole radius. For that, it provides two handles - one for the outer and one for the inner radius.

When a shape is converted to a donut, the shape's bounding box will be used to define the enclosing box of the donut and the hole's diameter will be chosen to be half of the outer diameter.

PIE and ARC

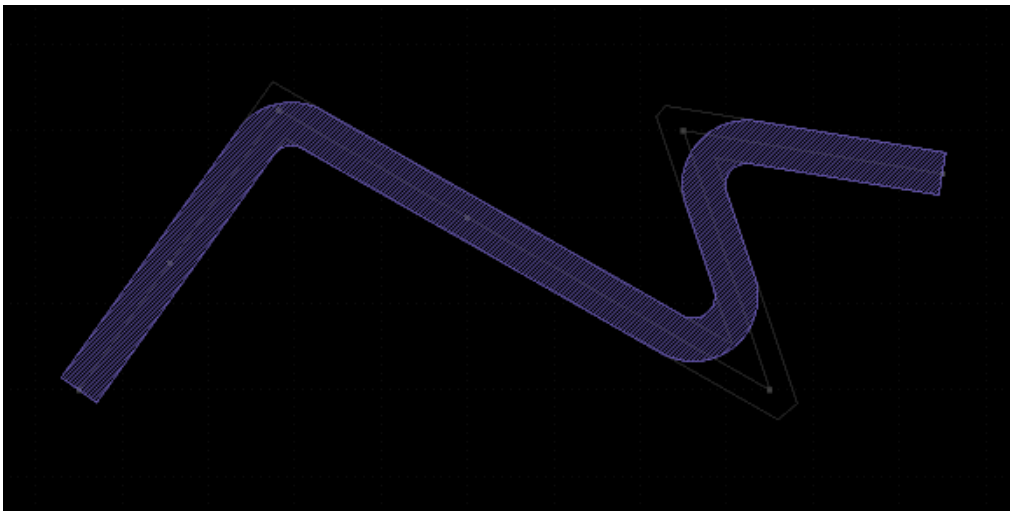
Both of these PCells are segments of circles or donuts. The PIE PCell features two handles to define the radius and start and end angle. The ARC PCell also features two handles to define outer and inner radius as well. The following image shows PIE and ARC in action:



Both PCells do not support conversion of shapes.

ROUND_PATH

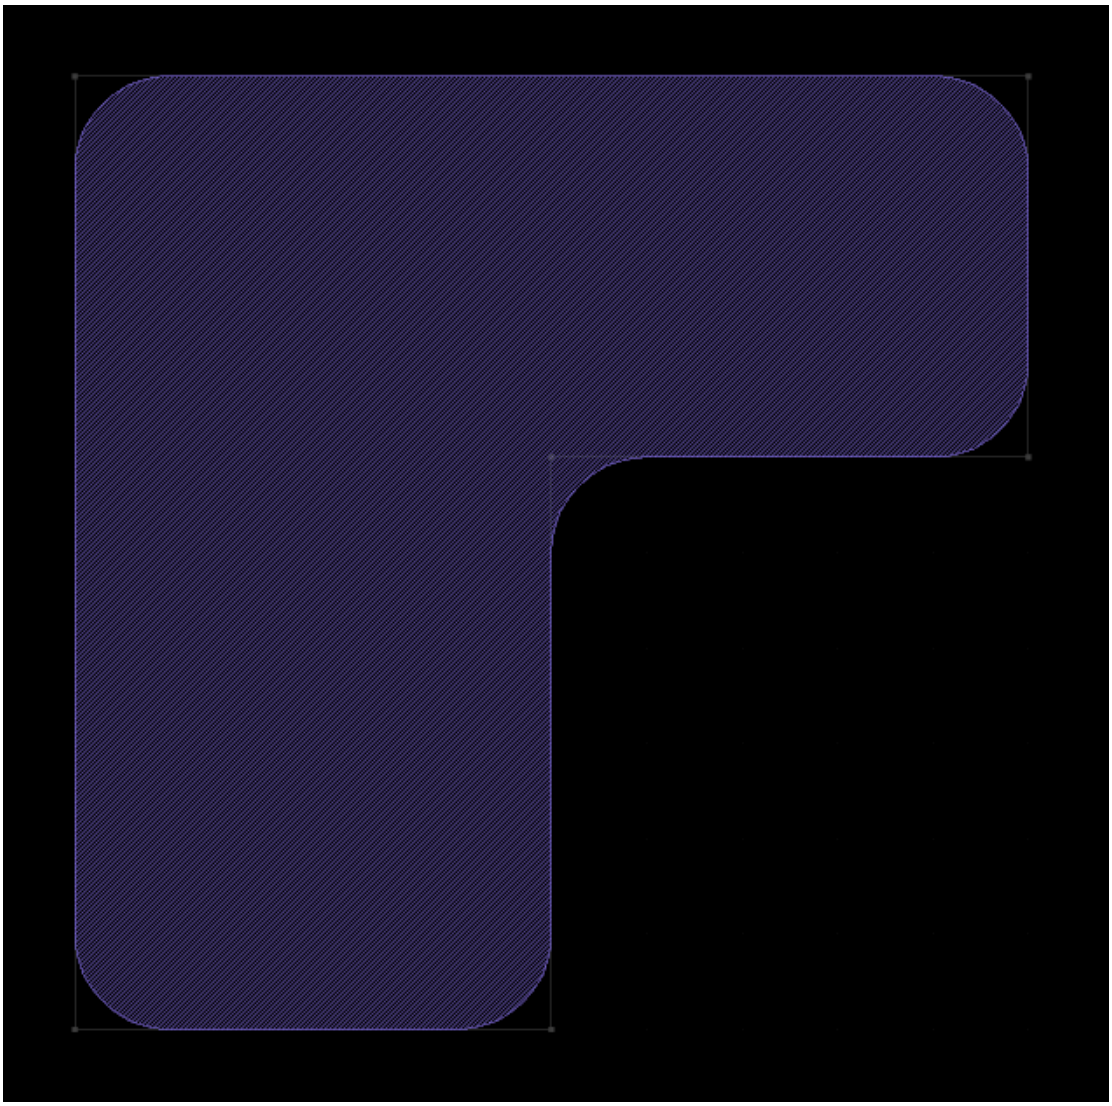
The round path is a PCell that is based on a path object but is capable of smoothing the path's corners by applying a radius. The following image gives an example:



The PCell features a parameter that defines the radius. The path itself can be manipulated as usual, in particular with partial edit mode. Path objects can be converted to ROUND_PATH pcells. In that case, the initial radius will be chosen to be roughly 10 percent of the minimum bounding box dimensions of the original path.

ROUND_POLYGON

The round polygon is a PCell that is based on a polygon object but is capable of smoothing the polygon's corners by applying a radius. The following image gives an example:



The PCell features a parameter that defines the radius. The polygon itself can be manipulated as usual, in particular with partial edit mode. Polygon, box or path objects can be converted to ROUND_POLYGON pcells. In that case, the initial radius will be chosen to be roughly 10 percent of the minimum bounding box dimensions of the original polygon.

STROKED_POLYGON or STROKED_BOX

The stroked polygon or box is a PCell that is based on a polygon object but will produce the "rim" of this polygon. In addition, it can apply corner rounding with a given radius.

The PCell features two parameters that define the radius and width of the "rim" line. The polygon or box itself can be manipulated as usual. Polygon, box or path objects can be converted to STROKED_POLYGON or STROKED_BOX pcells. In that case, the initial radius will be zero. The width of the rim line will be chosen to be roughly 10 percent of the minimum bounding box dimensions of the original polygon. For STROKED_BOX, the bounding box of the original shape will be used as the basic shape.

2.16. About Packages

"Salt" is KLayout's package manager which allows selecting and installing packages from a global repository. Packages make KLayout more tasty. Packages (the "grains") may cover a variety of features:

- Ruby or Python macros
- DRC runsets
- Technologies
- Fonts for the Basic.TEXT PCell
- Static layout libraries
- PCell libraries
- Code libraries for Ruby and Python
- Binary extensions

Packages can depend on other packages - these are installed automatically if a package requires them and they are not installed yet.

Packages are identified by name. A package name needs to be unique in the package universe. You can use a prefixed name like `www.mydomain.org/nameofpackage` to create a non-ambiguous name. Use a slash to separate the prefix from the actual package name. The choice of the prefix is entirely up to you as long as it contains letters, digits, underscores, hypthens or dots. You can use a domain name that is owned by yourself for example. You can use multiple prefixes to further differentiate the packages inside your namespace.

Packages also come with version information, so KLayout can check for updates and install them if required. KLayout will assume strict upward compatibility. This specifically applies to packages that other packages are depending on (such as code libraries). If you need to change them in a non-backward compatible way, you'd need to provide a new package with a different name.

Packages come with some meta data such as authoring information, an optional icon and screen shot image, license information and more. The more information you provide, the more useful a package will become.

The key component for public package deployment is the "Salt.Mine" package repository service. This is a web service that maintains a package index. It does not host the packages, but stores links to the actual hosting site. In order to author a package, you need to upload the package to one of the supported host sites and register your package on the Salt.Mine page. Registration is a simple process and the only information required is the link to your host site and a mail account for confirmation.

Installing Packages

To install external packages, open the package manager with "Tools/Manage Packages". On the "Install New Packages" page, a list of available packages is shown. Select the desired packages and mark them using the check mark button. Marked packages will be downloaded and installed with the "Apply" button.

A filter above the package list allows selecting packages by name. The right panel shows details about the package currently selected.

Updating Packages

To check for updates, use the "Update Packages" tab of the package manager. In the list, those packages for which updates are available are shown. Mark packages for update using the check mark button. Click "Apply" to apply the selected updates.

Uninstalling Packages

To uninstall packages, open the package manager using "Tools/Manage Packages". Go to the "Current Packages" tab. Select a package and use the "Remove Package" button to uninstall the package.

Creating Packages

For package development you can utilize KLayout to initialize and edit the files inside the package folder or populate the folder manually.

KLayout offers initialization of new packages from templates. You can modify that package according to your requirements afterwards. To create a package from a template, open the package manager using "Tools/Manage Packages", go to the "Current Packages" tab and push the "Create (Edit) Package" button. Chose a template from the list that opens and enter a package name (with prefix, if desired). Select "Ok" to let KLayout create a new package based on the template you selected.

The package details can be edited with the "pen" button at the top right of the right details panel. Please specify at least some author information, a license model and a version. If the package needs other packages, the dependencies can be listed in the "Depends on" table. Those packages will be automatically installed together with the new package. The showcase image can be a screen shot that gives some idea what the package will do. The package details are kept in a file called "grain.xml" inside the package folder. You can also edit this file manually. The "grain.xml" is the basic description file for the package.

If the package is a macro or static library package, the macro editor can be used to edit the package files. If the package is a tech package, the technology manager can be used to edit the technology inside the package. To populate the package folder with other files use your favorite editor of KLayout itself for layout files.

Deployment inside your organisation

Once a package is finished, it needs to be deployed to make it available to other users. Deployment basically means to put it on some public place where others can download the package. For local deployment inside an organisation, this can be a web server or a folder on a file server. KLayout talks WebDAV, so the web server needs to offer WebDAV access. A subversion (SVN) server provides WebDAV by default, so this is a good choice. For the packages themselves, Git or WebDAV/Subversion can be used. You need to specify the protocol in the package URL (see below).

After a package has been made available for download, it needs to be entered in the package index. For local deployment, the index can be a file hosted on a web server or on the file system. The package index location needs to be specified by the `KLAYOUT_SALT_MINE` environment variable which contains the download URL of the package index file.

For public deployment, the Salt.Mine service (`http://sami.klayout.org`) is used to register new packages in the package index. By default, KLayout loads the package index from that service, so once your package is registered there, everyone using KLayout will see it.

The Package Index

Public Packages are published on the Salt.Mine server. This is a web service that delivers a packages index with some meta data such as current version, the icon and a brief description. KLayout uses this list to inform users of packages available for installation and available updates. For local deployment, the package index can be served by other ways too. The only requirement is to be accessible by a http, https or file URL.

The basic format of the index is XML with this structure:

```
<salt-mine>
  <salt-grain>
    <name>name</name>
    <version>Version</version>
    <title>Title of the package</title>
    <doc>A brief description</doc>
    <doc-url>Documentation URL</doc-url>
    <url>Download URL</url>
    <license>License model</license>
    <icon>Icon image: base64-encoded, 64x64 max, PNG preferred</icon>
  </salt-grain>
  ...
  <include>URL to include other index files into this one</include>
  ...
</salt-mine>
```

You can include other repositories - specifically the default one - into a custom XML file. This allows extending the public index with local packages.

When the package manager is opened, KLayout will download the index from `http://sami.klayout.org/repository.xml`. You can set the `KLAYOUT_SALT_MINE` environment variable to a different URL which makes KLayout use another dictionary service, i.e. one inside your own organisation. This service can be any HTTP server that delivers a package list in the same format than the Salt.Mine package service. The URL can also be a "file:" scheme URL. In this case, KLayout will download the list from the given file location.

When installing a package, KLayout will simply download the files from the URL given in the package list. KLayout employs the WebDAV protocol to download the files. This protocol is spoken by Subversion and GitHub with the subversion bridge. The latter requires a simple translation of the original Git URL's to obtain the subversion equivalent.

Generic package URLs

Package URLs are the locations from where KLayout will download the package files. The package data is a hierarchy of files. The package description file ("grain.xml") needs to be located at the root of this hierarchy.

A plain package URL will instruct KLayout to download the package file from the given hierarchy using the WebDAV protocol. You can add "svn+" at the front of the URL to make this specification a little more explicit. These are WebDAV/Subversion URLs:

```
https://www.klayout.org/example-package
svn+https://www.klayout.org/example-package
```

Git is another option to host packages. In order to use the Git protocol, add "git+" at the front of the URL:

```
git+https://github.com/klayout/example-package.git
```

This will make KLayout clone the "example-package" repository and use the default branch for checking out the files. It will expect a file named "grain.xml" at the root of the package file hierarchy.

To use a different branch or tag, specify the tag or branch name in square brackes. For example:

```
git+https://github.com/klayout/example-package.git[v1.0]
```

This will use the "v1.0" tag or branch for checking out the files.

It is also possible to have packages in the a subfolder of the repository. To specify the subfolder, separate the subfolder path from the repository URL using "+", like this:

```
git+https://github.com/klayout/repository.git+klayout/package-data[v1.0]
```

This will clone the "repository" project and in this project, KLayout will checkout files from "klayout/package-data" and below. This is also the place, where KLayout expects the "grain.xml" file.

Installation Hooks

Scripts can register an event through Application#on_salt_changed which indicates that packages have been installed or uninstalled.

Packages itself can supply special scripts which are executed after a package was installed or before a package is uninstalled:

- `_install.lym`: if present, this script is executed after the package is installed.
- `_uninstall.lym`: if present, this script is executed before the package is uninstalled.

Both scripts need to be stored in the same location as "grain.xml" and have to use "lym" format. This is the generic XML script format KLayout employs as an interpreter-agnostic script representation.

2.17. About Technology Management

Technology management summarizes features which require a certain interpretation of a layout. In particular, layout layers are assigned a physical meaning, for example via layers or active area layers in CMOS technologies. Since that interpretation often is depending on the technology the product will be fabricated with, the ability to provide multiple setups is summarized as "technology management".

A technology setup implements the following aspects:

- Layer mapping: when the layout reader loads a file that for a certain technology, it can apply a layer mapping, i.e. apply layer names to GDS layers, filter layer etc.
- Layer properties: depending on the technology, the layer display can be configured by providing a technology specific layer properties file.
- Connectivity: the layer stack and the connections made by layers for the net tracer feature.
- Macros: macros associated with the technology. When the corresponding technology is selected (is the one of the current layout), such macros will show up in the menu if they are bound to a menu entry. Otherwise they will be invisible.
- DRC scripts: in the same way, DRC scripts can be associated with a technology.
- Libraries: if a library is associated with a technology, it is shown in the list of available libraries when an instance is created. Library association cannot be edited. Instead, a library installed in the system comes with a technology association itself.
- File format options: technology specific file reader or writer options can be given. When a layout is saved, it will use the writer options from its technology. When loading a layout, the reader options from the active technology will be used.

In the future, more aspects may be added to the technology definition.

There is always one "Default" technology that is used when no technology is specified.

Setting up technologies

Technologies can be set up using the "Technology Manager" in the "Tools" menu. There is always a "Default" technology which provides the settings when no technology is selected. New technologies can be added or technologies can be deleted using the "+" or "x" buttons below the technology tree.

A technology has a name (a short string) and a description. The name is used to identify the technology in various places. The description is the human-readable text that is displayed in the technology selection boxes for example. The short name can be changed by selecting the technology and pressing the "Rename" button or using "Rename" from the technology tree's context menu (right mouse click). The description can be edited on the "General" page.

In the technology manager, below each technology, the components are shown that define the various aspects of a technology. Beside the "General" aspect (names, descriptions) there is a "Layers" component which defines the layer mapping table and layer properties file and the "Connectivity" component which defines the settings for the net tracer.

Using technologies

When more than the default technology is defined, KLayout provides a drop-down menu in the tool bar to select the current technology. The current technology is the technology used when new files are loaded. It is also possible to define the technology to be used on the command line using the "-n" switch (applies to following files and specifies the technology to use by their short name).

The technology of the currently selected layout is shown in the status bar of the main window in the left section. It is possible to switch the technology of a layout already loaded by using the "Layout Properties" dialog from the "File" menu. After switching the technology, the layer properties defined in the technology can be applied and the associated macros or DRC scripts are shown in the menu if they are associated bound to a menu entry or the key binding becomes active if a shortcut is defined for that macro.

Technologies and macros or DRC scripts

Macros or DRC scripts are stored in sub-folders relative to the technology's base path. When no base path is specified or the base path is invalid, macros or DRC scripts cannot be associated. KLayout will look search for macros, if a directory called "macros" is present in the base path. If it finds files with a valid macro suffix there it will associate them with this technology. The same way, KLayout will look for DRC scripts, if a directory called "drc" is present in the base path.

Macros and DRC scripts associated with a technology are shown in the technology manager. To edit or debug scripts of macros, use the macro development environment ("Macros/Macro Development"). If a technology has a macros or DRC scripts folder, the macro or DRC scripts tree in the development environment will show a corresponding top-level branch for that technology.

Multiple technologies can share the same base path - hence it is possible to share macros or DRC scripts between technologies.

Managing technologies

Technologies can be imported and exported to technology files (suffix ".lyt"). This is mainly useful to exchange technology settings between users or technologies.

Except for the default technology, technologies are kept in technology folders in KLayout's application path. They are read from subfolders from the "tech" directories. The technology definition itself is held in a file with extension ".lyt". The technology folder may have subfolders to hold library files, macros, DRC runsets, LEF files and other pieces of the technology package.

Technologies can be managed using packages. Packages are a convenient way to share add-ons between users. Packages can be installed from a common repository and allow easy addition and removal of components. Technologies are one aspect of packages, so it's possible to create packages that contribute one or more technologies. See About Packages for more details.

2.18. About Custom Layout Queries

Layout queries are an advanced feature of KLayout which provides a very generic method to manipulate or search the geometrical or cell information of a layout. The basic concept of custom queries is borrowed from SQL, the language widely used for accessing databases. Instead of working on linear tables with rows and columns, KLayout's queries work on the layout structure which basically a cell tree, a layer set orthogonal to that and per-cell/per-layer geometrical information which itself is divided into shape classes.

Layout queries have a layered structure, like an onion: the core of the query is a cell query which selects one or many cells with or without their children. The cell query can be wrapped by a shape query which addresses the shapes of the selected cells or instances, optionally confined to specific layers. The last layer is formed by the action: this is the activity that KLayout will perform on the selected objects. The default action is simply to report the results. It is also possible to delete the selected objects or to perform a custom operation on them.

On cell and shape level, conditions can be specified which will restrict the operation on a subset of the selected objects. Reports can be sorted by a arbitrary key derived from the current object.

On cell level three different relationship models are supported:

- Individual cells: no hierarchy is involved
- The cell tree: the cell tree is the parent/child relationship without explicit instantiation information
- The cell instance tree: every individual instance of a cell is considered

Expressions play an important part in layout queries, both as actions (assignment type expressions) as well as conditions or for the derivation of sorting keys. See About Expressions for details about expressions. Within expressions, RBA objects are used to represent shapes or instances (see Class Index for a list of classes available). Depending on the context of the query, a variety of functions is available to access the properties of the current item and context.

The key to layout queries is the "Search and Replace" feature: this dialog uses custom queries to emulate simple search and replace functionality on the first three tabs of the dialog ("Delete" is regarded as a special kind of "replacement" here). However, the true power is revealed on the forth page: here you can enter all kind of custom queries. Clicking on "Execute" will run the query and display the results in the right panel.

If a search or replace action is specified on the first three tabs, the corresponding custom layout query will be shown in the entry box of the forth one. That way it is very easy to create a first query using the standard functions, switch to the custom query page and adjust it to fit the specific requirements.

Building queries: cells

The very core of a query is a cell expression. The most simple form of a cell expression is a simple cell name. This expression will select the cell called "RINGO":

```
RINGO
```

Cell expressions can contain wildcard in the "glob" form made popular by the Unix and Windows command line. "*" is for an arbitrary sequence of zero to many characters, "?" for any single character. "{A,B,C}" is for either the character sequence "A", "B" or "C", "[ABC]" is any of the characters "A", "B" or "C" and "[^ABC]" is for any character not "A", "B" or "C". Round brackets can be used to group parts of the string for later reference. If brackets of any kind are used inside a match string, either single or double quotes should be used around match strings in order to avoid ambiguities with other parts of the query syntax.

This expression will select all cells starting with "T":

```
T*
```

Although it is not necessary to do so, it is recommended to mark a cell query explicitly as such using the optional "cells" or "cell" keyword. This query has the same effect than the previous one but is somewhat more robust if used in nested queries we will learn about later:

```
cells T*
```

A cell expression can already be used by its own. The report of such a query will simply contain the cells selected by that expression. If combined with an action, such expressions already provide useful manipulation functionality.

The "delete ..." action will delete the given cells:

```
delete cells T*
```

The "with .. do ..." action can be used to manipulate the cell. This example will rename the cell by replacing the "T" prefix with a "S". The part after "do" is an expression which is evaluated for each hit. Note that "$1" is used to refer to the first matching bracket in the last match. "cell.name" is a method call on the object "cell" which is provided by the query in the context of a cell query. "cell" is a "Cell" object (see Cell) and setting the name will basically rename the cell. The expression used for the assignment will put an "S" in front of the rear part of the name, hence replace "T" by "S":

```
with cells "T(*)" do cell.name = "S"+$1
```

Note the quotes around the "T(*)" match expression. They are necessary to make the brackets part of the match expression rather than the cell query. It is usually a good idea to put the match expression inside quotes to avoid ambiguities.

The last example already demonstrates how a combination of two simple concepts - simple cell queries and expressions - form a new and very generic feature. We will soon learn about the power of that concept.

Building queries: cell trees

Cell queries are the most simple form of core queries. The next level is entered by extending the concept to hierarchies. Cell hierarchies come on two flavors: a parent-to-child relationship tree (the cell tree) and the instantiation tree. In the cell tree, each cell is at most present once in the context of a parent cell, independent of the number of times a cell is used inside a parent cell. The cell tree just describes the fact that a cell is a child cell of another, not how the cell is used. The instance tree adds this detailed information as well: how many times a cell is used and what transformations are applied per such instance.

The cell tree can be accessed within cell queries using the "." operator to separate parent and child cell. The following cell query returns all cells which are children of a cell "A":

```
cells A.*
```

Multiple levels may be nested, for example the following query lists all cells which are second-level children of the "A" cell:

```
cells A.*.*
```

Such expressions form a "path" leading from an initial cell to some cell, which is returned by the query. The "." separates the path elements like the slash or backslash does in a file path.

Top cells can be addressed by a leading "." similar to the leading slash of an absolute file path in Unix. The following query will return all top cells:

```
cells .*
```

Brackets can be used to group parts of the path. That has no immediate effect, but it can be usedful in combination with quantifiers and branches as we will see soon. The following queries are equivalent:

```
cells TOP.*.A
cells TOP(.*.A)
cells TOP(.*)(.A)
```

Please note that brackets can only be put between the dot and the previous element. A query like "cells TOP.(*.A)" is invalid since the opening bracket is after the dot.

Alternative paths can be specified by separating them with a comma. Such alternatives must be put inside brackets. For example, this query selects all cells that are children of "TOP" and start with an "A" or which are second-level children and start with an "E":

```
cells TOP(.A*,.*.E*)
```

Path elements can be made optional with a "?" symbol and expanded an variable number of times using quantifiers like "*" (0 to many) and "+" (one to many) or "{n,m}" (n to m times). Note that you'll have to put the expression subject to the quantifier in brackets in order to avoid ambiguities of the star operator. The following expression will return the A cell in every possible child context of "TOP", i.e. as direct child, second-level child and so on:

```
cells TOP(.*)*.A
```

To understand that query, note that the "*" inside the brackets is forming the match string while the outer star is forming the quantifier. That query reads in expanded form "TOP.A", "TOP.*.A", "TOP.*.*.A" etc.

There is a useful abbreviation for the above case. The following query will also produce "A" in every child context of "TOP":

```
cells TOP..A
```

The double dot operator matches an arbitrary part of the instantiation path before and after a cell even without being anchored at one end. Used before a cell name, it will return all contexts a cell is used in (including top cells and all child contexts). Used after a cell, it will return the cell plus all child cells in each possible context. Used before a cell it will deliver all contexts that cell is used in every top cells. The following query will deliver "TOP" plus all its direct and indirect children:

```
cells TOP..
```

Note that the previous query may deliver the same cell multiple times - once for each context (call path from TOP) it is used in. Hence "TOP.." will basically expand into the cell tree with "TOP" as the root.

In order to get the names of all cells called from a given cell, you can use the "select" action with the cell name and the "sorted by .. unique" output selector to remove duplicates of cell names:

```
select cell_name of cells TOP.. sorted by cell_name unique
```

See below for a description of the "select" action.

Within a path, dynamically computed components can be inserted using the "$(..)" notation which wraps an expression. That expression is evaluated in the context of the previous path component. For example, the following query selects all child cells which are named like their parent with an "A" prefix:

```
cells *.$("A"+cell_name)
```

Building queries: instances

Cell trees can be expanded into instance trees simply by prepending "instances". This will deliver all direct instances of "TOP":

```
instances of TOP.*
```

When asking for instances, more information is available inside the query. For example, the instance's orientation and position is available. With the "instances" specification, array references are expanded into single instances. To keep arrays as such, use "arrays" instead of "instances":

```
arrays of TOP.*
```

Cell or instance queries can be filtered using the "where" clause. After the "where" an expression is expected with a number of predefined variables that reflect the context (see below for the variables available). The following query selects all child cells of "A" where the cell name has a length of 5 characters:

```
cells A.* where len(cell_name)==5
```

Building queries: shapes

So far we have dealt with cells and their instantiations. We enter the next level now by introducing shapes.

Shape queries are built atop of the cell/instance level. A simple example selects all shapes of the cell "TOP":

```
shapes of cell TOP
```

Shape queries can be confined to certain shape types. For example, this confines the query to boxes:

```
boxes from cell TOP
```

Allowed shape type are "boxes", "polygons", "texts" and "paths". In the context of a shape query additional variables are available for expressions. The most important one is "shape" which is a Shape object (see Shape) That objects provides access to the shape addressed in a generic way. Specialization to a specific shape type is possible through the shape specific accessor methods (i.e. "shape.box_width") or the specific objects (i.e. "shape.box").

Multiple shape types can be given with "or" or a comma:

```
boxes or polygons from cell TOP
```

Shape queries can be confined to certain layers. This query will report all shapes from layer 8, datatype 0:

```
shapes on layer 8/0 from cell TOP
```

Intervals can be specified with the hyphen ("-") and multiple layers or intervals can be listed with a comma or semicolon. The following will list the shapes from layer 8, datatype 0 to 10 and layer 9, datatype 0 only (note that "no datatype" is interpreted as datatype 0):

```
shapes on layer 8/0-10, 9 from cell TOP
```

For formats that support named layers only (i.e. DXF), the layer name can be given. The following query lists shapes from layers METAL and POLY (case sensitive!):

```
shapes on layer METAL, POLY from cell TOP
```

Any kind of cell query can be used inside the shape query. If a cell query renders multiple cells, the shape query will be applied to each of the cells returned. If instances are selected by the cell query, the shapes will be reported for each instance. Since the cumulated transformation of a specific instance into the top cell is available through the "path_trans" (database units) or "path_dtrans" (micrometer units) variable, it is possible to transform each shape into the top cell in the instance case. The following expression combines a "with .. do" action with a shape query to flatten all shapes below "TOP":

```
with shapes on layer 6 from instances of TOP.. do
 initial_cell.shapes(<10/0>).insert(shape).transform(path_trans)
```

That expression reads all shapes of cell "TOP" and its children, inserts them into a new layer 10, datatype 0 and transforms the shape after it has been inserted. This expression makes use of the variables "initial_cell" (a Cell object representing the root cell of the cell query), "shape" (a pointer to the currently selected shape and "path_trans" (a Trans object representing the transformation of the current shape into the root cell of the query). It also employs the angle bracket layer constant notation which specifies a layer in the target notation and can be used in place of the layer index value usually used inside the API. Note that the target layer must exist already, i.e. must have been created in "Edit/Layer/New Layer" for example.

Shape queries can be confined with conditions. A condition is entered with a "where" clause plus an expression that selects the shapes. This condition selects shapes with an area of more than 4 square micron (note that the "um2" unit must be given, since it will cause the value to be converted into the database units used internally):

```
shapes from cell TOP where shape.area < 4 um2
```

Shape conditions can be combined with cell conditions. To avoid ambiguities, the cell query must be put into brackets in that case:

```
shapes from (cells * where len(cell_name)==4) where shape.area < 4 um2
```

Actions

Actions specify operations that are to be performed on the results of a query. The default action is to just list the results. In the "Search and replace" dialog, the results will be listed right to the query entry box as a table. Depending on the context of the query, cell names, cell names plus parent cell, cell instances or shapes are listed.

"select" action

The "select" action will compute one or more results from each item returned by the query and present the computed value in a table. The general form is:

`select` expr1, expr2, ... **`from`** query

"expr1", "expr2" ... are expressions. For example this action computes area and perimeter for all shapes of cell "TOP":

```
select shape.area, shape.perimeter from shapes of cell TOP
```

The "select" action offers sorting with optional reduction to unique values:

`select` expr1, expr2, ... **`from`** query **`sorted by`** sort_key

`select` expr1, expr2, ... **`from`** query **`sorted by`** sort_key **`unique`**

Here "sort_key" is an expression which delivers the value by which the output will be sorted. If "unique" is specified, items with identical sort key are reduced to a single output.

"with" action

The "with" action executes an expression on each item returned by the expression. In that sense it is basically equivalent to the "select" action but the results of the operation are discarded and the intention of the expression is to modify the results. The general form of that action is this:

with query **do** expr

For example, this action will move all shapes of cell "TOP" from layer 6 to layer 10, datatype 0:

```
with shapes on layer 6 of cell TOP do shape.layer = <10/0>
```

"delete" action

This action will simply delete the objects selected by the query:

delete query

For example, this query deletes all shapes from layer 6, datatype 0 on cell TOP:

```
delete shapes on layer 6 of cell TOP
```

Variables available per context

Common variables

The following variables are available in all queries:

Name	Value type	Description
layout	Layout	The layout object that this query runs on.

Cell query context

In the plain cell and cell tree context, the following variables are available:

Name	Value type	Description
path	Array	Array with the indexes of the cells in that path. For a plain cell, this array will have length 1 and contain the index of the selected cell only.
path_names	Array	Array with the names of the cells in that path. For a plain cell, this array will have length 1 and contain the name of the selected cell only.
initial_cell	Cell	Object representing the initial cell (first of path)
initial_cell_index	Integer	Index of initial cell (first of path)
initial_cell_name	String	Name of initial cell (first of path)
cell	Cell	Object representing the current cell (last of path)
cell_index	Integer	Index of current cell (last of path)
cell_name	String	Name of current cell (last of path)
hier_levels	Integer	Number of hierarchy levels in path (length of path - 1)
references	Integer	The number of instances of this cell in the parent cell. Array references count as 1. For plain cells, this value is 0.
weight	Integer	The number of instances of this cell in the parent cell. Array references count as multiple instances. For plain cells, this value is 0.
tot_weight	Integer	The number of instances of this cell in the initial cell along the given path. Array references count as multiple instances. for plain cells, this value is 0.

Name	Value type	Description
instances	Integer	Equivalent to "weight", but also available for plain cells. For plain cells, the value represents the number of times, the cell is used in all top cells.
bbox	Box	The cell's bounding box.
dbbox	DBox	The cell's bounding box in micrometer units.
cell_bbox	Box	Same as "bbox" (disambiguator from shape and instance bounding boxes).
cell_dbbox	DBox	Same as "dbbox" (disambiguator from shape and instance bounding boxes).

Instance query context

In an instance query context, the properties of the current instance are available as variables in addition to most of the ones provided by the cell query context. These variables are not available in instance context: "weight", "references" and "tot_weight". Apart from that these additional variable are provided:

Name	Value type	Description
path_trans	ICplxTrans	The transformation of that instance into the top cell. For a plain cell that is a unit transformation.
path_dtrans	DCplxTrans	The transformation of that instance into the top cell in micrometer units. For a plain cell that is a unit transformation.
trans	ICplxTrans	The transformation of that instance (first instance if an array).
dtrans	DCplxTrans	The transformation of that instance (first instance if an array) in micrometer units.
inst_bbox	Box	The instance bounding box in the initial cell.
inst_dbbox	DBox	The instance bounding box in the initial cell in micrometer units.
inst	Instance	The instance object of the current instance.
array_a	Vector	The a vector for an array instance or nil if the instance is not an array.
array_da	DVector	The a vector for an array instance in micrometer units or nil if the instance is not an array.
array_na	Integer	The a axis array dimension or nil if the instance is not an array.
array_b	Vector	The b vector for an array instance or nil if the instance is not an array.
array_db	DVector	The b vector for an array instance in micrometer units or nil if the instance is not an array.
array_nb	Integer	The b axis array dimension or nil if the instance is not an array.
array_ia	Integer	The a index when an array is iterated (0 to array_na). Not available with instance queries with "arrays of ...".
array_ib	Integer	he b index when an array is iterated (0 to array_nb). Not available with instance queries with "arrays of ...".

Shape query context

In the context of the shape query, the following variables are available in addition to the variables made available by the inner cell query. The inner cell query is either a instance query or a cell query:

Name	Value type	Description
bbox	DBox	The shape's bounding box
dbbox	DBox	The shape's bounding box in micrometer units
shape_bbox	Box	Same as "bbox" (disambiguator for cell or instance bounding boxes)
shape_dbbox	DBox	Same as "dbbox" (disambiguator for cell or instance bounding boxes)
shape	Shape	The shape object
layer_info	LayerInfo	The layer description of the current shape's layer

Name	Value type	Description
layer_index	Integer	The layer index of the current shape

2.19. Notation used in Ruby API documentation

Introduction

The documentation of the Ruby API is derived from the C++ declaration of the specific methods. Hence the notation deviates somewhat from the usual documentation of Ruby methods. In particular the following differences are noteworthy:

- **"Static" methods are "class methods":**

  The C++ term "static" refers to methods available within a class without requiring an object. In Ruby, the term "class method" is commonly used to refer to such methods.

- **Different flavors of object arguments:**

  In C++ there are references, pointers and objects passed by value. In Ruby there are only references. RBA maps the C++ concepts to ruby by allowing the "nil" value only for pointer arguments. Pointer arguments are specially marked in the documentation.

- **There is "constness":**

  C++ has the concept of "const" methods and arguments. In C++, an object reference can be "const", which means that the object behind such a reference cannot be modified. A "const" method is a method which can be called on "const" object reference and such a method may not alter the state of the object.

  A method can have "const" reference arguments which means that objects passed through such arguments are not modified by the method. Such arguments are also said to have "in" semantics. Hence, "const" references can be passed to such arguments. In Ruby there is no concept of "constness" or "in" parameters. Every method is allowed to alter the state of the object it is called on and pf the objects it gets as arguments. In that sense, C++ allows specification of a more constraint "contract" between caller and method that is called. RBA emulates constness in Ruby to some extent and it may disallow calling non-const methods on const references or passing const reference to non-const arguments. Return value can also be const pointers which means that the object returned cannot be modified.

- **Strong typing:**

  In C++, arguments and return values are strongly typed. RBA will check the arguments passed to a method and convert them properly. Hence the type of argument is important. "int" type arguments may not be passed strings for example.

  The type system if C++ is also somewhat more restricted: the value range of an integer argument is limited and for example there are unsigned types which cannot be passed negative values. Hence the type of an argument is noted in the documentation. A particular return type is "void" which basically means "no value returned". Strong typing extends to object references and RBA checks if an argument can be converted to the object required.

- **Virtual methods:**

  In C++, a method must be virtual before it can be reimplemented by a derived class. In Ruby all methods are virtual. Since reimplementing a non-virtual method does not have any effect in RBA, virtual methods are marked as such.

General layout of the documentatation

The documentation states the following methods (in that order):

- Public constructors
- Public methods
- Public static methods and constants
- Protected methods (static, non-static and constructors)
- Deprecated methods (protected, public, static, non-static and constructors)

Deprecated methods are listed for reference only. Use of such methods or constants is not recommended because they might be removed in the future.

Examples

Here are some examples for method documentations (signatures):

- ***[virtual]* bool event(QEvent ptr ev)**:

  A virtual method called "event" returning a boolean value (Ruby "true" or "false") and expecting one argument (a pointer to a QEvent object). "ptr" indicates that the argument is a pointer, "arg1" is the argument name.

- **void add_reference(const RdbReference rdb_ref)**:

  A method without return value which expects one parameter. The parameter must be a reference to the RdbReference object. The reference must not be nil since it is not a pointer, but can be a reference to a const object. The name of the argument is "rdb_ref".

- ***[const]* unsigned int num_items**:

  A parameterless const method called "num_items" that delivers the number of items as an unsigned integer value.

- ***[iter]* RdbReference each_reference**:

  An iterator called "each_reference" delivering RdbReference objects.

- ***[signal]* void layoutAboutToBeChanged**:

  A parameterless signal (event) called "layoutAboutToBeChanged" (see Events And Callbacks for details about events or signals).

- ***[signal]* void objectNameChanged(string objectName)**:

  A signal (event) called "objectNameChanged" with one string argument.

2.20. DRC Reference

2.20.1. DRC Reference: DRC expressions

DRC expression objects represent abstract recipes for the Layer#drc universal DRC function. For example, when using a universal DRC expression like this:

```
out = in.drc(width < 2.0)
```

"width < 2.0" forms a DRC expression object. DRC expression objects have methods which manipulate or evaluate the results of this expression. In addition, DRC expressions have a result type, which is either polygon, edge or edge pair. The result type is defined by the expression generating it. In the example above, "width < 2.0" is a DRC width check which renders edge pairs. To obtain polygons from these edge pairs, use the "polygons" method:

```
out = in.drc((width < 2.0).polygons)
```

The following global functions are relevant for the DRC expressions:

- angle
- area
- area_ratio
- bbox_aspect_ratio
- bbox_height
- bbox_max
- bbox_min
- bbox_width
- corners
- covering
- enc
- enclosing
- extent_refs
- extents
- foreign
- holes
- hulls
- if_all
- if_any
- if_none
- inside

- interacting
- iso
- length
- middle
- notch
- outside
- overlap
- overlapping
- perimeter
- primary
- rectangles
- rectilinear
- relative_height
- rounded_corners
- secondary
- separation
- sep
- sized
- smoothed
- space
- squares
- switch
- width
- with_holes

The following documentation will list the methods available for DRC expression objects.

"!" - Logical not

Usage:

- `! expression`

This operator will evaluate the expression after. If this expression renders an empty result, the operator will return the primary shape. Otherwise it will return an empty result.

This operator can be used together with predicates such a "rectangles" to invert their meaning. For example, this code selects all primary shapes which are not rectangles:

```
out = in.drc(! rectangles)
out = in.drc(! primary.rectangles)   # equivalent
```

"&" - Boolean AND between the results of two expressions

Usage:

- `expression & expression`

The & operator will compute the boolean AND between the results of two expressions. The expression types need to be edge or polygon.

The following example computes the partial edges where width is less than 0.3 micrometers and space is less than 0.2 micrometers:

```
out = in.drc((width < 0.3).edges & (space < 0.2).edges)
```

"+" - Boolean OR between the results of two expressions

Usage:

- `expression + expression`

The + operator will join the results of two expressions.

"-" - Boolean NOT between the results of two expressions

Usage:

- `expression - expression`

The - operator will compute the difference between the results of two expressions. The NOT operation is defined for polygons, edges and polygons subtracted from edges (first argument edge, second argument polygon).

CAUTION: be careful not to take secondary input for the first argument. This will not render the desired results. Remember that the "drc" function will walk over all primary shapes and present single primaries to the NOT operation together with the secondaries of that single shape. So when you use secondary shapes as the first argument, they will not see all all the primaries required to compute the correct result. That's also why a XOR operation cannot be provided in the context of a generic DRC function.

The following example will produce edge markers where the width of is less then 0.3 micron but not inside polygons on the "waive" layer:

```
out = in.drc((width < 0.3).edges - secondary(waive))
```

"angle" - Selects edges based on their angle

Usage:

- `expression.angle (in condition)`

This operation selects edges by their angle, measured against the horizontal axis in the mathematical sense.

For this measurement edges are considered without their direction and straight lines. A horizontal edge has an angle of zero degree. A vertical one has an angle of 90 degrees. The angle range is from -90 (exclusive) to 90 degree (inclusive).

If the input shapes are not polygons or edge pairs, they are converted to edges before the angle test is made.

For example, the following code selects all edges from the primary shape which are 45 degree (up) or 135 degree (down). The "+" will join the results:

```
out = in.drc((angle == 45) + (angle == 135))
out = in.drc((primary.angle == 45) + (primary.angle == 135))    # equivalent
```

Note that angle checks usually imply the need to rotation variant formation as cells which are placed non-rotated and rotated by 90 degree cannot be considered identical. This imposes a performance penalty in hierarchical mode. If possible, consider using DRC#rectilinear for example to detect shapes with non-manhattan geometry instead of using angle checks.

The "angle" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.angle".

"area" - Selects the primary shape if the area is meeting the condition

Usage:

- `expression.area (in condition)`

This operation is used in conditions to select shapes based on their area. It is applicable on polygon expressions. The result will be the input polygons if the area condition is met.

See Layer#drc for more details about comparison specs.

The following example will select all polygons with an area less than 2.0 square micrometers:

```
out = in.drc(area < 2.0)
out = in.drc(primary.area < 2.0)   # equivalent
```

The area method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.area".

"area_ratio" - Selects the input polygon according to its area ratio (bounding box area by polygon area)

Usage:

- `expression.area_ratio (in condition)`

This operation is used in conditions to select shapes based on their area ratio. The area ratio is the ratio of bounding box vs. polygon area. It's a measure how "sparse" the polygons are and how good an approximation the bounding box is. The value is always larger or equal than 1. Boxes have a value of 1.

This filter is applicable on polygon expressions. The result will be the input polygon if the condition is met.

See Layer#drc for more details about comparison specs.

The following example will select all polygons whose area ratio is larger than 3:

```
out = in.drc(area_ratio > 3)
out = in.drc(primary.area_ratio > 3)   # equivalent
```

The "area_ratio" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.area_ratio".

"area_sum" - Selects the input polygons if the sum of all areas meets the condition

Usage:

- `expression.area_sum (in condition)`

Returns the input polygons if the sum of their areas meets the specified condition. This condition is evaluated on the total of all shapes generated in one step of the "drc" loop. As there is a single primary in each loop iteration, "primary.area_sum" is equivalent to "primary.area".

See Layer#drc for more details about comparison specs.

"bbox_aspect_ratio" - Selects the input polygon according to the aspect ratio of the bounding box

Usage:

- `expression.bbox_aspect_ratio (in condition)`

This operation is used in conditions to select shapes based on aspect ratios of their bounding boxes. The aspect ratio is computed by dividing the larger of width and height by the smaller of both. The aspect ratio is always larger or equal to 1. Square or square-boxed shapes have a bounding box aspect ratio of 1.

This filter is applicable on polygon expressions. The result will be the input polygon if the bounding box condition is met.

See Layer#drc for more details about comparison specs.

The following example will select all polygons whose bounding box aspect ratio is larger than 3:

```
out = in.drc(bbox_aspect_ratio > 3)
out = in.drc(primary.bbox_aspect_ratio > 3)   # equivalent
```

The "bbox_aspect_ratio" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.bbox_aspect_ratio".

"bbox_height" - Selects the input polygon if its bounding box height is meeting the condition

Usage:

- `expression.bbox_height (in condition)`

This operation acts similar to DRC#bbox_min, but takes the height of the shape's bounding box. In general, it's more advisable to use DRC#bbox_min or DRC#bbox_max because bbox_height implies a certain orientation. This can imply variant formation in hierarchical contexts: cells rotated by 90 degree have to be treated differently from ones not rotated. This usually results in a larger computation effort and larger result files.

The "bbox_height" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.bbox_height".

"bbox_max" - Selects the input polygon if its bounding box larger dimension is meeting the condition

Usage:

- `expression.bbox_max (in condition)`

This operation acts similar to DRC#bbox_min, but takes the larger dimension of the shape's bounding box.

The "bbox_max" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.bbox_max".

"bbox_min" - Selects the input polygon if its bounding box smaller dimension is meeting the condition

Usage:

- `expression.bbox_min (in condition)`

This operation is used in conditions to select shapes based on smaller dimension of their bounding boxes. It is applicable on polygon expressions. The result will be the input polygons if the bounding box condition is met.

See Layer#drc for more details about comparison specs.

The following example will select all polygons whose bounding box smaller dimension is larger than 200 nm:

```
out = in.drc(bbox_min > 200.nm)
out = in.drc(primary.bbox_min > 200.nm)   # equivalent
```

The "bbox_min" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.bbox_min".

"bbox_width" - Selects the input polygon if its bounding box width is meeting the condition

Usage:

- `expression.bbox_width (in condition)`

This operation acts similar to DRC#bbox_min, but takes the width of the shape's bounding box. In general, it's more advisable to use DRC#bbox_min or DRC#bbox_max because bbox_width implies a certain orientation. This can imply variant formation in hierarchical contexts: cells rotated by 90 degree have to be treated differently from ones not rotated. This usually results in a larger computation effort and larger result files.

The "bbox_width" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.bbox_width".

"centers" - Returns the part at the center of each edge of the input

Usage:

- `expression.centers(length)`
- `expression.end_segments(length, fraction)`

This method acts on edge expressions and delivers a specific part of each edge. See layer#centers for details about this functionality.

"corners" - Selects corners of polygons

Usage:

- `expression.corners`
- `expression.corners(as_dots)`
- `expression.corners(as_boxes)`

This operation acts on polygons and selects the corners of the polygons. It can be put into a condition to select corners by their angles. The angle of a corner is positive for a turn to the left if walking a polygon clockwise and negative for the turn to the right. Hence positive angles indicate concave (inner) corners, negative ones indicate convex (outer) corners. Angles take values between -180 and 180 degree.

When using "as_dots" for the argument, the operation will return single-point edges at the selected corners. With "as_boxes" (the default), small (2x2 DBU) rectangles will be produced at each selected corner.

The following example selects all corners:

```
out = in.drc(corners)
out = in.drc(primary.corners)    # equivalent
```

The following example selects all inner corners:

```
out = in.drc(corners > 0)
out = in.drc(primary.corners > 0)    # equivalent
```

The "corners" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.corners".

"count" - Selects a expression result based on the number of (local) shapes

Usage:

- `expression.count (in condition)`

This operation is used in conditions to select expression results based on their count. "count" is used as a method on a expression. It will evaluate the expression locally and return the original result if the shape count in the result is matching the condition.

See Layer#drc for more details about comparison specs.

Note that the expression is evaluated locally: for each primary shape, the expression is evaluated and the count of the resulting edge, edge pair or polygon set is taken. As the primary input will always have a single item (the local shape), using "count" on primary does not really make sense. It can be used on derived expressions however.

The following example selects triangles:

```
out = in.drc(if_any(corners.count == 3))
```

Note "if_any" which selects the primary shape if the argument evaluates to a non-empty result. Without "if_any" three corners are returned for each triangle.

"covering" - Selects shapes entirely covering other shapes

Usage:

- `expression.covering(other) (optionally in conditions)`
- `covering(other) (optionally in conditions)`

This method represents the selector of primary shapes which entirely cover shapes from the other layer. This version can be put into a condition indicating how many shapes of the other layer need to be covered. Use this variant within DRC expressions (also see Layer#drc).

For example, the following statement selects all input shapes which entirely cover shapes from the "other" layer:

```
out = in.drc(covering(other))
```

This example selects all input shapes which entire cover shapes from the other layer and there are more than two shapes from "other" inside primary shapes:

```
out = in.drc(covering(other) > 2)
```

"edges" - Converts the input shapes into edges

Usage:

- `expression.edges`

- `expression.edges(mode)`

Polygons will be separated into edges forming their contours. Edge pairs will be decomposed into individual edges.

Contrary most other operations, "edges" does not have a plain function equivalent as this is reserved for the function generating an edges layer. To generate the edges of the primary shapes, use "primary" explicit as the source for the edges:

```
out = in.drc(primary.edges)
```

The "mode" argument allows selecting specific edges from polygons. Allowed values are: "convex", "concave", "step", "step_in" and "step_out". "step" generates edges only if they provide a step between two other edges. "step_in" creates edges that make a step towards the inside of the polygon and "step_out" creates edges that make a step towards the outside:

```
out = in.drc(primary.edges(convex))
```

In addition, "not_.." variants are available which selects edges not qualifying for the specific mode:

```
out = in.drc(primary.edges(not_convex))
```

The mode argument is ignored when translating other objects than polygons.

"end_segments" - Returns the part at the end of each edge of the input

Usage:

- `expression.end_segments(length)`
- `expression.end_segments(length, fraction)`

This method acts on edge expressions and delivers a specific part of each edge. See layer#end_segments for details about this functionality.

"extended" - Returns polygons describing an area along the edges of the input

Usage:

- `expression.extended([:begin => b,] [:end => e,] [:out => o,] [:in => i], [:joined => true])`
- `expression.extended(b, e, o, i)`

This method acts on edge expressions. It will create a polygon for each edge tracing the edge with certain offsets to the edge. "o" is the offset applied to the outer side of the edge, "i" is the offset applied to the inner side of the edge. "b" is the offset applied at the beginning and "e" is the offset applied at the end.

"extended_in" - Returns polygons describing an area along the edges of the input

Usage:

- `expression.extended_in(d)`

This method acts on edge expressions. Polygons are generated for each edge describing the edge drawn with a certain width extending into the "inside" (the right side when looking from start to end). This method is basically equivalent to the extended method: "extended(0, 0, 0, dist)". A version extending to the outside is extended_out.

"extended_out" - Returns polygons describing an area along the edges of the input

Usage:

- `expression.extended_out(d)`

This method acts on edge expressions. Polygons are generated for each edge describing the edge drawn with a certain width extending into the "outside" (the left side when looking from start to end). This method is basically equivalent to the extended method: "extended(0, 0, dist, 0)". A version extending to the inside is extended_in.

"extent_refs" - Returns partial references to the bounding boxes of the polygons

Usage:

- `expression.extent_refs([ options ])`

The extent_refs operation acts on polygons and has the same effect than Layer#extent_refs. It takes the same arguments. It is available as a method on DRC expressions or as plain function, in which case it acts on the primary shapes.

"extents" - Returns the bounding box of each input object

Usage:

- `expression.extents([ enlargement ])`

This method provides the same functionality as Layer#extents and takes the same arguments. It returns the bounding boxes of the input objects. It acts on edge edge pair and polygon expressions.

The "extents" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.extents".

"first_edges" - Returns the first edges of edge pairs

Usage:

- `expression.first_edges`

This method acts on edge pair expressions and returns the first edges of the edge pairs delivered by the expression.

Some checks deliver symmetric edge pairs (e.g. space, width, etc.) for which the edges are commutable. "first_edges" will deliver both edges for such edge pairs.

"holes" - Selects all holes from the input polygons

Usage:

- `expression.holes`

This operation can be used as a plain function in which case it acts on primary shapes or can be used as method on another DRC expression. The following example selects all holes with an area larger than 2 square micrometers:

```
out = in.drc(holes.area > 2.um)
out = in.drc(primary.holes.area > 2.um)   # equivalent
```

"hulls" - Selects all hulls from the input polygons

Usage:

- `expression.hulls`

The hulls are the outer contours of the input polygons. By selecting hulls only, all holes will be closed.

This operation can be used as a plain function in which case it acts on primary shapes or can be used as method on another DRC expression. The following example closes all holes:

```
out = in.drc(hulls)
out = in.drc(primary.hulls)   # equivalent
```

"inside" - Selects shapes entirely inside other shapes

Usage:

- `expression.inside(other)`
- `inside(other)`

This method represents the selector of primary shapes which are entirely inside shapes from the other layer. Use this variant within DRC expressions (also see Layer#drc).

"interacting" - Selects shapes interacting with other shapes

Usage:

- `expression.interacting(other) (optionally in conditions)`
- `interacting(other) (optionally in conditions)`

See covering for a description of the use cases for this function. When using "interacting", shapes are selected when the interact (overlap, touch) shapes from the other layer.

When using this method with a count, the operation may not render the correct results if the other input is not merged. By nature of the generic DRC feature, only those shapes that interact with the primary shape will be selected. If the other input is split into multiple polygons, not all components may be captured and the computed interaction count may be incorrect.

"length" - Selects edges based on their length

Usage:

- `expression.length (in condition)`

This operation will select those edges which are meeting the length criterion. Non-edge shapes (polygons, edge pairs) will be converted to edges before.

For example, this code selects all edges from the primary shape which are longer or equal than 1 micrometer:

```
out = in.drc(length >= 1.um)
out = in.drc(primary.length >= 1.um)   # equivalent
```

The "length" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.length".

"length_sum" - Selects the input edges if the sum of their lengths meets the condition

Usage:

- `expression.length_sum (in condition)`

Returns the input edges if the sum of their lengths meets the specified condition. This condition is evaluated on the total of all edges generated in one step of the "drc" loop.

See Layer#drc for more details about comparison specs.

"merged" - Returns the merged input polygons, optionally selecting multi-overlap

Usage:

- `expression.merged`
- `expression.merged(min_count)`

This operation will act on polygons. Without a min_count argument, the merged polygons will be returned.

With a min_count argument, the result will include only those parts where more than the given number of polygons overlap. As the primary input is merged already, it will always contribute as one.

The "merged" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.merged".

"middle" - Returns the centers of polygon bounding boxes

Usage:

- `expression.middle([ options ])`

The middle operation acts on polygons and has the same effect than Layer#middle. It takes the same arguments. It is available as a method on DRC expressions or as plain function, in which case it acts on the primary shapes.

"outside" - Selects shapes entirely outside other shapes

Usage:

- `expression.outside(other)`
- `outside(other)`

This method represents the selector of primary shapes which are entirely outside shapes from the other layer. Use this variant within DRC expressions (also see Layer#drc).

"overlapping" - Selects shapes overlapping with other shapes

Usage:

- `expression.overlapping(other) (optionally in conditions)`
- `overlapping(other) (optionally in conditions)`

See covering for a description of the use cases for this function. When using "overlapping", shapes are selected when the overlap shapes from the other layer.

When using this method with a count, the operation may not render the correct results if the other input is not merged. By nature of the generic DRC feature, only those shapes that interact with the primary shape will be selected. If the other input is split into multiple polygons, not all components may be captured and the computed interaction count may be incorrect.

"perimeter" - Selects the input polygon if the perimeter is meeting the condition

Usage:

- `expression.perimeter (in condition)`

This operation is used in conditions to select shapes based on their perimeter. It is applicable on polygon expressions. The result will be the input polygons if the perimeter condition is met.

See Layer#drc for more details about comparison specs.

The following example will select all polygons with a perimeter less than 10 micrometers:

```
out = in.drc(perimeter < 10.0)
out = in.drc(primary.perimeter < 10.0)   # equivalent
```

The perimeter method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.perimeter".

"perimeter_sum" - Selects the input polygons if the sum of all perimeters meets the condition

Usage:

- `expression.perimeter_sum (in condition)`

Returns the input polygons if the sum of their perimeters meets the specified condition. This condition is evaluated on the total of all shapes generated in one step of the "drc" loop. As there is a single primary in each loop iteration, "primary.perimeter_sum" is equivalent to "primary.perimeter".

See Layer#drc for more details about comparison specs.

"polygons" - Converts the input shapes into polygons

Usage:

- `expression.polygons([ enlargement ])`

Generates polygons from the input shapes. Polygons stay polygons. Edges and edge pairs are converted to polygons. For this, the enlargement parameter will specify the edge thickness or augmentation applied to edge pairs. With the default enlargement of zero edges will not be converted to valid polygons and degenerated edge pairs will not become valid polygons as well.

Contrary most other operations, "polygons" does not have a plain function equivalent as this is reserved for the function generating a polygon layer.

This method is useful for generating polygons from DRC violation markers as shown in the following example:

```
out = in.drc((width < 0.5.um).polygons)
```

"rectangles" - Selects all polygons which are rectangles

Usage:

- `expression.rectangles`

This operation can be used as a plain function in which case it acts on primary shapes or can be used as method on another DRC expression. The following example selects all rectangles:

```
out = in.drc(rectangles)
out = in.drc(primary.rectangles)    # equivalent
```

"rectilinear" - Selects all polygons which are rectilinear

Usage:

- `expression.rectilinear`

Rectilinear polygons only have vertical and horizontal edges. Such polygons are also called manhattan polygons.

This operation can be used as a plain function in which case it acts on primary shapes or can be used as method on another DRC expression. The following example selects all manhattan polygons:

```
out = in.drc(rectilinear)
out = in.drc(primary.rectilinear)    # equivalent
```

"relative_height" - Selects the input polygon according to the height vs. width of the bounding box

Usage:

- `expression.relative_height (in condition)`

This operation is used in conditions to select shapes based on the ratio of bounding box height vs. width. The taller the shape, the larger the value. Wide polygons have a value below 1. A square has a relative height of 1.

This filter is applicable on polygon expressions. The result will be the input polygon if the condition is met.

Don't use this method if you can use bbox_aspect_ratio, because the latter is isotropic and can be used hierarchically without generating rotation variants.

See Layer#drc for more details about comparison specs.

The following example will select all polygons whose relative height is larger than 3:

```
out = in.drc(relative_height > 3)
out = in.drc(primary.relative_height > 3)   # equivalent
```

The "relative_height" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.bbox_aspect_ratio".

"rounded_corners" - Applies corner rounding

Usage:

- `expression.rounded_corners(inner, outer, n)`

This operation acts on polygons and applies corner rounding to the given inner and outer corner radius and the number of points n per full circle. See Layer#rounded_corners for more details.

The "rounded_corners" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.rounded_corners".

"second_edges" - Returns the second edges of edge pairs

Usage:

- `expression.second_edges`

This method acts on edge pair expressions and returns the second edges of the edge pairs delivered by the expression.

Some checks deliver symmetric edge pairs (e.g. space, width, etc.) for which the edges are commutable. "second_edges" will not deliver edges for such edge pairs. Instead, "first_edges" will deliver both.

"sized" - Returns the sized version of the input

Usage:

- `expression.sized(d [, mode])`
- `expression.sized(dx, dy [, mode]))`

This method provides the same functionality as Layer#sized and takes the same arguments. It acts on polygon expressions.

The "sized" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.sized".

"smoothed" - Applies smoothing

Usage:

- `expression.smoothed(d [, keep_hv ])`

This operation acts on polygons and applies polygon smoothing with the tolerance d. 'keep_hv' indicates whether horizontal and vertical edges are maintained. Default is 'no' which means such edges may be distorted. See Layer#smoothed for more details.

The "smoothed" method is available as a plain function or as a method on DRC expressions. The plain function is equivalent to "primary.smoothed".

"squares" - Selects all polygons which are squares

Usage:

- `expression.squares`

This operation can be used as a plain function in which case it acts on primary shapes or can be used as method on another DRC expression. The following example selects all squares:

```
out = in.drc(squares)
out = in.drc(primary.squares)    # equivalent
```

"start_segments" - Returns the part at the beginning of each edge of the input

Usage:

- `expression.start_segments(length)`
- `expression.start_segments(length, fraction)`

This method acts on edge expressions and delivers a specific part of each edge. See layer#start_segments for details about this functionality.

"with_holes" - Selects all input polygons with the specified number of holes

Usage:

- `expression.with_holes (in condition)`

This operation can be used as a plain function in which case it acts on primary shapes or can be used as method on another DRC expression. The following example selects all polygons with more than 2 holes:

```
out = in.drc(with_holes > 2)
out = in.drc(primary.with_holes > 2)   # equivalent
```

"|" - Boolean OR between the results of two expressions

Usage:

- `expression | expression`

The | operator will compute the boolean OR between the results of two expressions. '+' is basically a synonym. Both expressions must render the same type.

2.20.2. DRC Reference: Layer Object

"&" - Boolean AND operation

Usage:

- `self & other`

The method computes a boolean AND between self and other.

This method is available for polygon and edge layers. An alias is "and". See there for a description of the function.

"+" - Join layers

Usage:

- `self + other`

The method includes the edges or polygons from the other layer into this layer. The "+" operator is an alias for the join method.

This method is available for polygon, edge and edge pair layers. An alias is "join". See there for a description of the function.

"-" - Boolean NOT operation

Usage:

- `self - other`

The method computes a boolean NOT between self and other.

This method is available for polygon and edge layers. An alias is "not". See there for a description of the function.

"^" - Boolean XOR operation

Usage:

- `self ^ other`

The method computes a boolean XOR between self and other.

This method is available for polygon and edge layers. An alias is "xor". See there for a description of the function.

"and" - Boolean AND operation

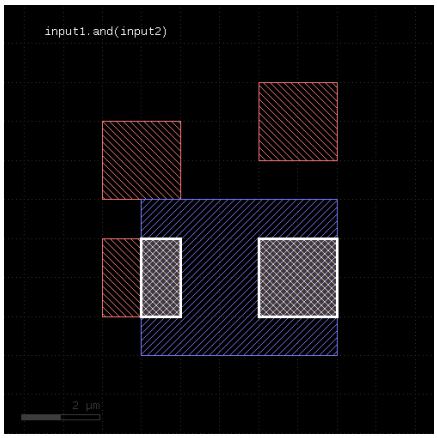
Usage:

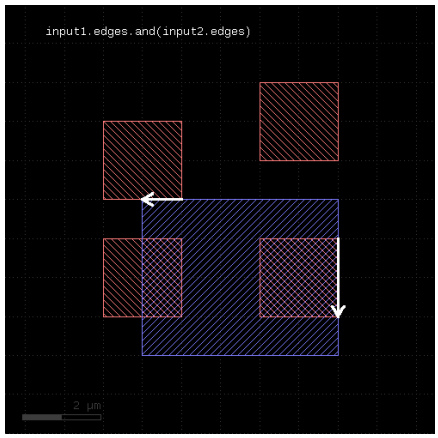
- `layer.and(other [, prop_constraint ])`

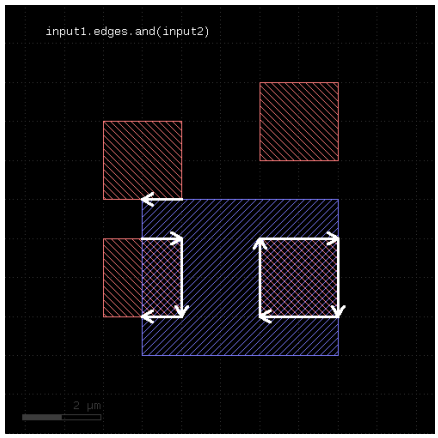
The method computes a boolean AND between self and other. It is an alias for the "&" operator which lacks the ability to specify a properties constraint.

This method is available for polygon and edge layers. If the first operand is an edge layer and the second is a polygon layer, the result will be the edges of the first operand which are inside or on the borders of the polygons of the second operand.

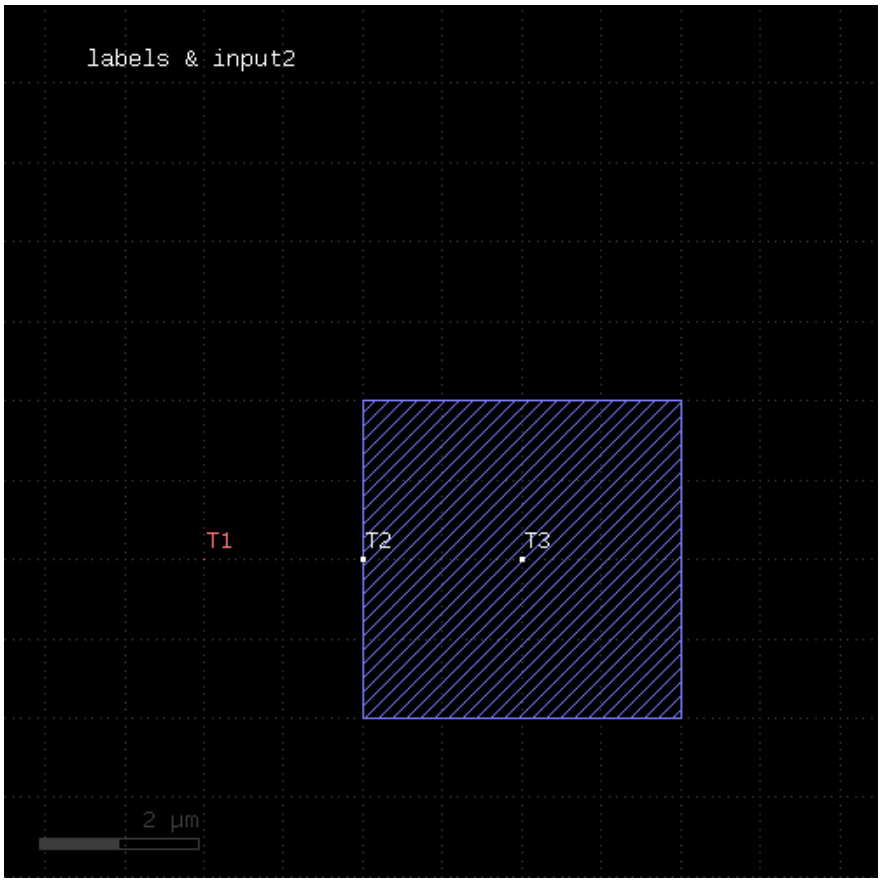
The following images show the effect of the "and" method on polygons and edges (input1: red, input2: blue):







The AND operation can be applied between a text and a polygon layer. In this case, the texts inside or at the border of the polygons will be written to the output (labels: red, input2: blue):



When a properties constraint is given, the operation is performed only between shapes with the given relation. Together with the ability to provide net-annotated shapes through the nets method, this allows constraining the boolean operation to shapes from the same or from different nets.

See prop_eq, prop_ne and prop_copy for details.

"andnot" - Computes Boolean AND and NOT results at the same time

Usage:

- `layer.andnot(other)`

This method returns a two-element array containing one layer for the AND result and one for the NOT result.

This method is available for polygon and edge layers. For polygon layers, the other input must be a polygon layer too. For edge layers, the other input can be polygon or edge.

It can be used to initialize two variables with the AND and NOT results:

```
(and_result, not_result) = l1.andnot(l2)
```

As the AND and NOT results are computed in the same sweep, calling this method is faster than calling AND and NOT separately.

"area" - Returns the total area of the polygons in the region

Usage:

- `layer.area`

This method requires a polygon layer. It returns the total area of all polygons in square micron. Merged semantics applies, i.e. before computing the area, the polygons are merged unless raw mode is chosen (see raw). Hence, in clean mode, overlapping polygons are not counted twice.

The returned value gives the area in square micrometer units.

"bbox" - Returns the overall bounding box of the layer

Usage:

- `layer.bbox`

The return value is a DBox object giving the bounding box in micrometer units.

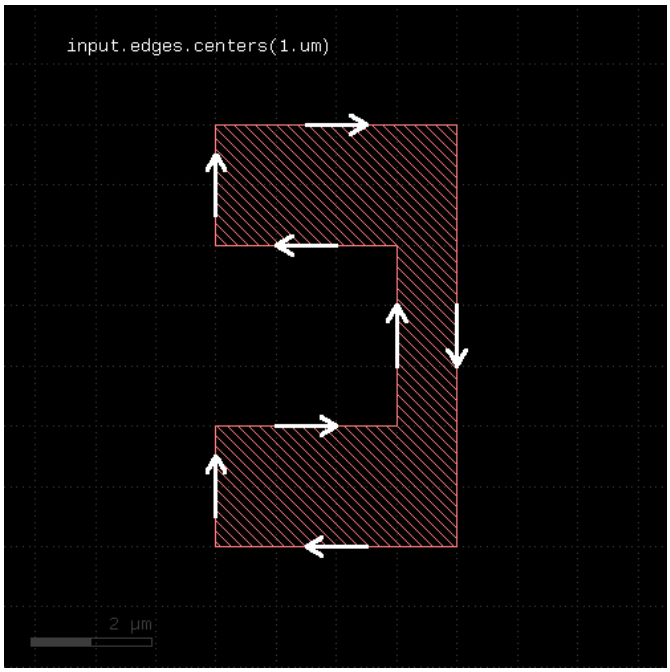
"centers" - Returns the center parts of the edges

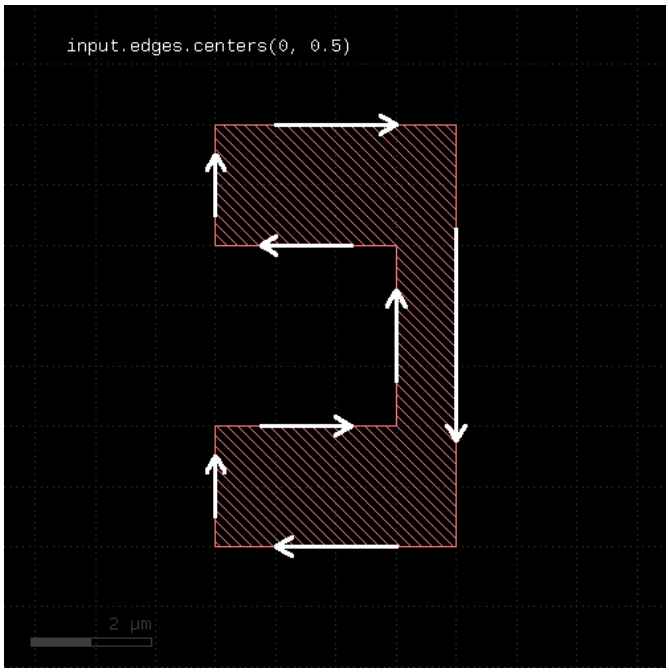
Usage:

- `layer.centers(length)`
- `layer.centers(length, fraction)`

Similar to start_segments and end_segments, this method will return partial edges for each given edge in the input. For the description of the parameters see start_segments or end_segments.

The following images show the effect of the method:





"clean" - Marks a layer as clean

Usage:

- `layer.clean`

A layer marked as clean will provide "merged" semantics, i.e. overlapping or touching polygons are considered as single polygons. Inner edges are removed and collinear edges are connected. Clean state is the default.

See raw for some remarks about how this state is propagated.

"collect" - Transforms a layer

Usage:

- `layer.collect { |object| ... }`

This method evaluates the block for each object in the layer and returns a new layer with the objects returned from the block. It is available for edge, polygon and edge pair layers. The corresponding objects are DPolygon, DEdge or DEdgePair.

If the block evaluates to nil, no object is added to the output layer. If it returns an array, each of the objects in the array is added. The returned layer is of the original type and will only accept objects of the respective type. Hence, for polygon layers, DPolygon objects need to be returned. For edge layers those need to be DEdge and for edge pair layers, they need to be DEdgePair objects. For convenience, Polygon, Edge and EdgePair objects are accepted too and are scaled by the database unit to render micrometer-unit objects. Region, Edges and EdgePair objects are accepted as well and the corresponding content of that collections is inserted into the output layer.

Other versions are available that allow translation of objects into other types (collect_to_region, collect_to_edges and collect_to_edge_pairs).

Because this method executes inside the interpreter, it's inherently slow. Tiling does not apply to this method.

Here is a slow equivalent of the rotated method

```
# Rotates by 45 degree
t = DCplxTrans(1.0, 45.0, false, DVector::new)
```

```
new_layer = layer.collect { |polygon| polygon.transformed(t) }
```

"collect_to_edge_pairs" - Transforms a layer into edge pair objects

Usage:

- `layer.collect_to_edge_pairs { |object| ... }`

This method is similar to collect, but creates an edge pair layer. It expects the block to deliver EdgePair, DEdgePair or EdgePairs objects.

"collect_to_edges" - Transforms a layer into edge objects

Usage:

- `layer.collect_to_edges { |object| ... }`

This method is similar to collect, but creates an edge layer. It expects the block to deliver objects that can be converted into edges. If polygon-like objects are returned, their contours will be turned into edge sequences.

"collect_to_region" - Transforms a layer into polygon objects

Usage:

- `layer.collect_to_region { |object| ... }`

This method is similar to collect, but creates a polygon layer. It expects the block to deliver objects that can be converted into polygons. Such objects are of class DPolygon, DBox, DPath, Polygon, Path, Box and Region.

"corners" - Selects corners of polygons

Usage:

- `layer.corners([ options ])`
- `layer.corners(angle [, options ])`
- `layer.corners(amin .. amax [, options ])`

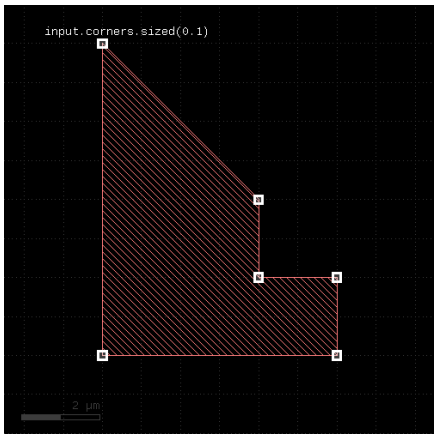
This method produces markers on the corners of the polygons. An angle criterion can be given which selects corners based on the angle of the connecting edges. Positive angles indicate a left turn while negative angles indicate a right turn. Since polygons are oriented clockwise, positive angles indicate concave (inner) corners while negative ones indicate convex (outer) corners

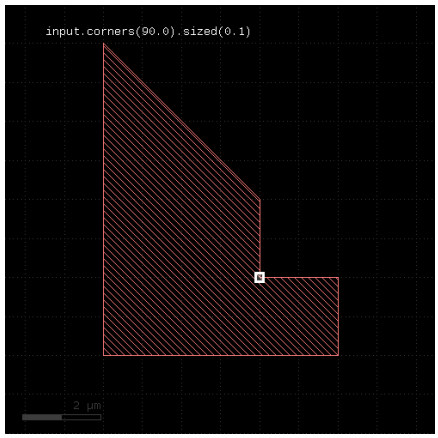
The markers generated can be point-like edges or small 2x2 DBU boxes. The latter is the default.

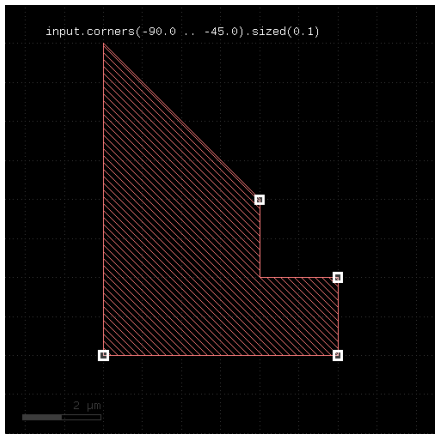
The options available are:

- **as_boxes** : with this option, small boxes will be produced as markers
- **as_dots** : with this option, point-like edges will be produced instead of small boxes
- **as_edge_pairs** : with this option, an edge pair is produced for each corner selected. The first edge is the incoming edge to the corner, the second edge the outgoing edge.

The following images show the effect of this method:







"count" - Returns the number of objects on the layer

Usage:

- `layer.count`

The count is the number of raw objects, not merged regions or edges. This is the flat count - the number of polygons, edges or edge pairs seen from the top cell. "count" can be computationally expensive for original layers with clip regions or cell tree filters.

See hier_count for a hierarchical (each cell counts once) count.

"covering" - Selects shapes or regions of self which completely cover (enclose) one or more shapes from the other region

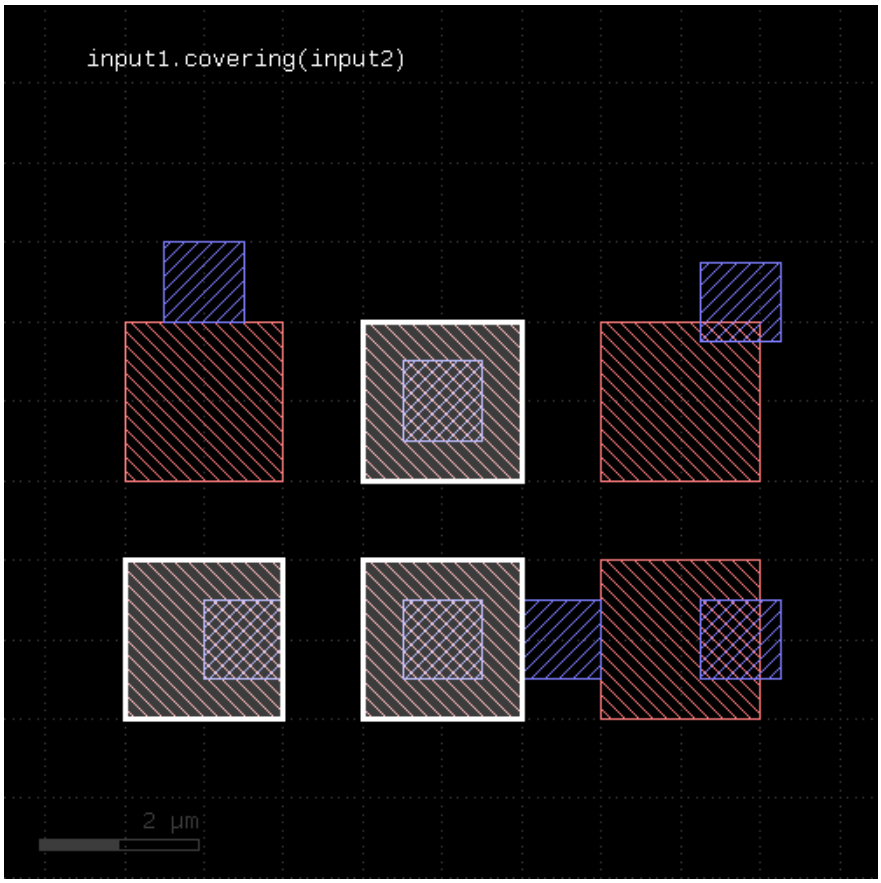
Usage:

- `layer.covering(other)`
- `layer.covering(other, min_count)`
- `layer.covering(other, min_count, max_count)`
- `layer.covering(other, min_count .. max_count)`

This method selects all shapes or regions from self which completly cover shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It returns a new layer containing the selected shapes. A version which modifies self is select_covering.

This method is available for polygons only.

The following image shows the effect of the "covering" method:



A range of counts can be specified. If so, the shape from the primary layer is only selected when covering a given number of shapes from the other layer. For the interpretation of the count see interacting.

The "covering" attribute is sometimes called "enclosing", but this name is used for the respective DRC function (see enclosing).

"data" - Gets the low-level data object

Usage:

- `layer.data`

This method returns a Region, Edges or EdgePairs object representing the underlying RBA object for the data. Access to these objects is provided to support low-level iteration and manipulation of the layer's data.

"drc" - Provides a generic DRC function for use with DRC expressions

Usage:

- `layer.drc(expression [, prop_constraint ])`

This method implements the universal DRC which offers enhanced abilities, improved performance in some applications and better readability.

The key concept for this method are DRC expressions. DRC expressions are formed by using predefined keywords like "width", operators like "&" and methods to build an abstract definition of the operations to perform within the DRC.

When the DRC function is executed, it will basically visit all shapes from the input layer (the layer, the "drc" method is called on)). While it does, it collects the neighbor shapes from all involved other inputs and runs the requested operations on each cluster. Currently, "drc" is only available for polygon layers.

This way, the nature of the "drc" operation is that of the loop over all (merged) input polygons. Within the operation executed on each shape, it's possible to make decisions such as "if the shape has an area larger than something, apply this operation" or similar. This often can be achieved with conventional DRC functions too, but involves potentially complex and heavy operations such as booleans, interact etc. For this reason, the "drc" function may provide a better performance.

In addition, within the loop a single shape from the input layer is presented to the execution engine which runs the operations. This allows using operations such as "size" without having to consider neighbor polygons growing into the area of the initial shape. In this sense, the "drc" function sees the layer as individual polygons rather than a global "sea of polygons". This enables new applications which are otherwise difficult to implement.

Primaries and secondaries

An important concept in "drc" expressions is the "primary". The primary represents a single shape from the input layer. "Secondaries" are shapes from other inputs. Primaries guide the operation - secondaries without primaries are not seen. The "drc" operation will look for secondaries within a certain distance which is determined from the operations from the expression to execute. The secondaries collected in this step will not be merged, so the secondary polygons may be partial. This is important when using measurement operations like "area" on secondary polygons.

Checks

Here is an example for a generic DRC operation which performs a width check for less than 0.5um on the primary shapes. It uses the "width" operator:

```
out = in.drc(width < 0.5.um)
```

Other single or double-bounded conditions are available too, for example:

```
out = in.drc(width <= 0.5.um)
out = in.drc(width > 0.5.um)
out = in.drc(width == 0.5.um)
out = in.drc(width != 0.5.um)
out = in.drc(0.2.um < width < 0.5.um)
```

To specify the second input for a two-layer check, add it to the check function. This example shows how to use a two-layer separation check ("separation"):

```
l1 = input(1, 0)
l2 = input(2, 0)
out = l1.drc(separation(l2) < 0.5.um)
```

The second input of this check function can be a computed expression. In this case the local loop will first evaluate the expression for the second input and then use the result as second input in the check. Note that this computation is performed locally and separately for each primary and its context.

Options for the checks are also specified inside the brackets. For example, to select projection metrics ("projection") for the "width" check use:

```
out = in.drc(width(projection) < 0.5.um)
```

Edges and edge pairs

Although the "drc" function operates on polygon layers, internally it is able to handle edge and edge pair types too. Some operations generate edge pairs, some other generate edges. As results from one operation can be processed further in the DRC expressions, methods are available to filter, process and convert these types.

For example, all checks produce edge pairs which can be converted into polygons using the "polygons" method:

```
out = in.drc((width(projection) < 0.5.um).polygons)
```

Note a subtle detail: when putting the "polygons" method inside the "drc" brackets, it is executed locally on every visited primary polygon. The result in this case is identical to the global conversion:

```
# same, but with "global" conversion:
out = in.drc(width(projection) < 0.5.um).polygons
```

But having the check polygons inside the loop opens new opportunities and is more efficient in general. In the previous example, the local conversion will keep a few edge pairs after having converted them to polygons. In the global case, all edge pairs are collected first and then converted. If there are many edge pairs, this requires more memory and a larger computing overhead for managing the bigger number of shapes.

For the conversion of edges, edge pairs and polygons into other types, these methods are provided:

- "DRC#polygons": converts edge pairs to polygons
- "DRC#extended", "DRC#extended_in", "DRC#extended_out": converts edges to polygons
- "DRC#first_edges", DRC#second_edges": extracts edges from edge pairs
- "DRC#edges": decomposes edge pairs and polygons into edges
- "DRC#corners": can extract corners from polygons

The following example decomposes the primary polygons into edges:

```
out = in.drc(primary.edges)
```

(for backward compatibility you cannot abbreviate "primary.edges" simply as "edges" like other functions).

The previous example isn't quite exciting as it is equivalent to

```
# Same as above
out = in.edges
```

But it gets more interesting, as within the loop, "edges" delivers the edge set for each individual polygon. It's possible to work with this distinct set, so for example this will give you the edges of polygons with more than four corners:

```
out = in.drc(primary.edges.count > 4)
```

Explanation: "count" is a "quantifier" which takes any kind of set (edges, edge pairs, polygons) and returns the set if the number of inhabitants meets the given condition. Otherwise the set is skipped. So it will look at the edges and if there are more than four (per primary shape), it will forward this set.

The same result can be achieved with classic DRC with "interact" and a figure count, but at a much higher computation cost.

Edge and edge/polygon operations

The "drc" framework supports the following edge and edge/polygon operations:

- Edge vs. edge and edge vs. polygon booleans
- Edge vs. polygon interactions ("DRC#interacting", "DRC#overlapping")
- Edge sampling ("DRC#start_segments", "DRC#centers", "DRC#end_segments")

Filters

Filter operators select input polygons or edges based on their properties. These filters are provided:

- "DRC#area": selects polygons based on their area
- "DRC#perimeter": selects polygons based on their perimeter
- "DRC#area_ratio": selects polygons based on their bounding box to polygon area ratio
- "DRC#bbox_aspect_ratio": selects polygons based on their bounding box aspect ratio
- "DRC#relative_height": selects polygons based on their relative height
- "DRC#bbox_min", "DRC#bbox_max", "DRC#bbox_width", "DRC#bbox_height": selects polygons based on their bounding box properties
- "DRC#length": selects edges based on their length
- "DRC#angle": selects edges based on their orientation

For example, to select polygons with an area larger than one square micrometer, use:

```
out = in.drc(area > 1.0)
```

For the condition, use the usual numerical bounds like:

```
out = in.drc(area == 1.0)
out = in.drc(area <= 1.0)
out = in.drc(0.2 < area < 1.0)
```

The result of the area operation is the input polygon if the area condition is met.

In the same fashion, "perimeter" applies to the perimeter of the polygon. "bbox_min" etc. will evaluate a particular dimensions of the polygon's bounding box and use the respective dimension for filtering the polygon.

Note that it's basically possible to use the polygon filters on any input - computed and secondaries. In fact, plain "area" for example is a shortcut for "primary.area" indicating that the area of primary shapes are supposed to be computed. However, any input other than the primary is not necessarily complete or it may consist of multiple polygons. Hence the computed values may be too big or too small. It's recommended therefore to use the measurement functions on primary polygons unless you know what you're doing.

Filter predicates

The "drc" feature also supports some predicates. "predicates" are boolean values indicating a certain condition. A predicate filter works in a way that it only passes the polygons if the condition is met.

The predicates available currently are:

- "DRC#rectangles": Filters rectangles

- "DRC#squares": Filters squares
- "DRC#rectilinear": Filters rectilinear ("Manhattan") polygons

For the same reason as explained above, it's recommended to use these predicates standalone, so they act on primary shapes. It's possible to use the predicates on computed shapes or secondaries, but that may not render the desired results.

Logical NOT operator

The "!" operator will evaluate the expression behind it and return the current primary shape if the input is empty and return an empty polygon set if not. Hence the following filter will deliver all polygons which are not rectangles:

```
out = in.drc(! rectangles)
```

Logical combination operators

The logical "if_any" or "if_all" functions allow connecting multiple conditions and evaluate to "true" (means: a non-empty shape set) if either one input is a non-empty shape set ("if_any") or if all inputs are non-empty ("if_all").

For example, this will select all polygons which are rectangles and whose area is larger than 20 square micrometers:

```
out = in.drc(if_all(rectangles, area > 20.0))
```

"if_all" delivers the primary shape if all of the input expressions render a non-empty result.

In contrast to this, the "if_any" operation will deliver the primary shape if one of the input expressions renders a non-empty result.

The "switch" function allows selecting one input based on the results of an expression. In the two-input form it's equivalent to "if". The first expression is the condition. If it evaluates to a non-empty shape set, the result of the second expression is taken. Otherwise, the result is empty.

Hence the following code delivers all rectangles sized by 100 nm. All other shapes are skipped:

```
out = in.drc(switch(rectangles, primary.sized(100.nm)))
```

A third expression will be considered the "else" branch: the result of this expression will be taken if the first one is not taken. So this example will size all rectangles and leave other shapes untouched:

```
out = in.drc(switch(rectangles, primary.sized(100.nm), primary))
```

If more expressions are given, they are considered as a sequence of condition/result chain (c1, e1, c2, e2, ...) in the sense of "if(c1) return(e1) else if(c2) return(e2) ...". So the e1 is taken if c1 is met, e2 is taken when c1 is not met, but c2 is and so forth. If there is an odd number of expressions, the last one will be the default expression which is taken if none of the conditions is met.

Polygon manipulations

The "drc" operations feature polygon manipulations where the input is either the primary, secondaries or derived shapes. Manipulations include sizing ("sized"), corner rounding ("rounded_corners"), smoothing ("smoothed") and boolean operations.

This example computes a boolean AND between two layers before selecting the result polygons with an area larger than 1 square micrometer. Note that "primary" is a placeholder for the primary shape:

```
l1 = input(1, 0)
l2 = input(2, 0)
```

```
out = l1.drc((primary & l2).area > 1.0)
```

This example demonstrates how the "drc" operation can improve performance: as the boolean operation is computed locally and the result is discarded when no longer required, less shapes need to be stored hence reducing the memory overhead and CPU time required to manage these shapes.

Note that the precise form of the example above is

```
out = l1.drc((primary & secondary(l2)).area > 1.0)
```

The "secondary" operator indicates that "l2" is to be used as secondary input to the "drc" function. Only in this form, the operators of the boolean AND can be reversed:

```
out = l1.drc((secondary(l2) & primary).area > 1.0)
```

Quantifiers

Some filters operate on properties of the full, local, per-primary shape set. While the loop is executed, the DRC expressions will collect shapes, either from the primary, its neighborhood (secondaries) or from deriving shape sets.

Obviously the primary is a simple one: it consists of a single shape, because this is how the loop operates. Derived shape sets however can be more complex. "Quantifiers" allow assessing properties of the complete, per-primary shape set. A simple one is "DRC#count" which checks if the number of shapes within a shape set is within a given range.

Obviously, "primary.count == 1" is always true. So using "count" primaries isn't much fun. So it's better to use it on derived sets. The following condition will select all primary shapes which have more than 13 corners:

```
out = in.drc(if_any(primary.corners.count > 13))
```

Note an important detail here: the "if_any" function will make this statement render primary polygons, if the expression inside gives a non-empty result. Without "if_any", the result would be the output of "count" which is the set of all corners where the corner count is larger than 13.

Expressions as objects

The expression inside the "drc" function is a Ruby object and can be stored in variables. If you need the same expression multiple times, it can be more efficient to use the same Ruby object. In this example, the same expression is used two times. Hence it's computed two times:

```
out = l1.drc(((primary & l2).area == 1.0) + ((primary & l2).area == 2.0))
```

A more efficient version is:

```
overlap_area = (primary & l2).area
out = l1.drc((overlap_area == 1.0) + (overlap_area == 2.0))
```

Note that the first line prepares the operation, but does not execute the area computation or the boolean operation. But when the "drc" function executes the loop over the primaries it will only compute the area once per primary as it is represented by the same Ruby object.

Properties constraints

The method can be given a properties constraint so that it is only performed between shapes with the same or different user properties. Note that properties have to be enabled or generated (e.g. through the DRCLayer#nets method) before they can be used.

Example:

```
connect(metal1, via1)
...

space_not_connected = metal1.nets.drc(space < 0.4.um, props_ne)
```

See props_eq, props_ne and props_copy for details.

Outlook

DRC expressions are quite rich and powerful. They provide a more intuitive way of writing DRC expressions, are more efficient and open new opportunities. DRC development is likely to focus on this scheme in the future.

More formal details about the bits and pieces can be found in the "DRC" class documentation.

"dup" - Duplicates a layer

Usage:

- `layer.dup`

Duplicates the layer. This basically will create a copy and modifications of the original layer will not affect the duplicate. Please note that just assigning the layer to another variable will not create a copy but rather a pointer to the original layer. Hence modifications will then be visible on the original and derived layer. Using the dup method will avoid that.

However, dup will double the memory required to hold the data and performing the deep copy may be expensive in terms of CPU time.

"each" - Iterates over the objects from the layer

Usage:

- `layer.each { |object| ... }`

This method evaluates the block on each object of the layer. Depending on the layer type, these objects are of DPolygon, DEdge or DEdgePair type.

Because this method executes inside the interpreter, it's inherently slow. Tiling does not apply to this method.

"edge_pairs?" - Returns true, if the layer is an edge pair collection

Usage:

- `layer.edge_pairs?`

"edges" - Decomposes the layer into single edges

Usage:

- `layer.edges`
- `layer.edges(mode)`

Edge pair collections are decomposed into the individual edges that make up the edge pairs. Polygon layers are decomposed into the edges making up the polygons. This method returns an edge layer but will not modify the layer it is called on.

Merged semantics applies, i.e. the result reflects merged polygons rather than individual ones unless raw mode is chosen.

The "mode" argument allows selecting specific edges from polygons. Allowed values are: "convex", "concave", "step", "step_in" and "step_out". "step" generates edges only if they provide a step between two other edges. "step_in" creates edges that make a step towards the inside of the polygon and "step_out" creates edges that make a step towards the outside:

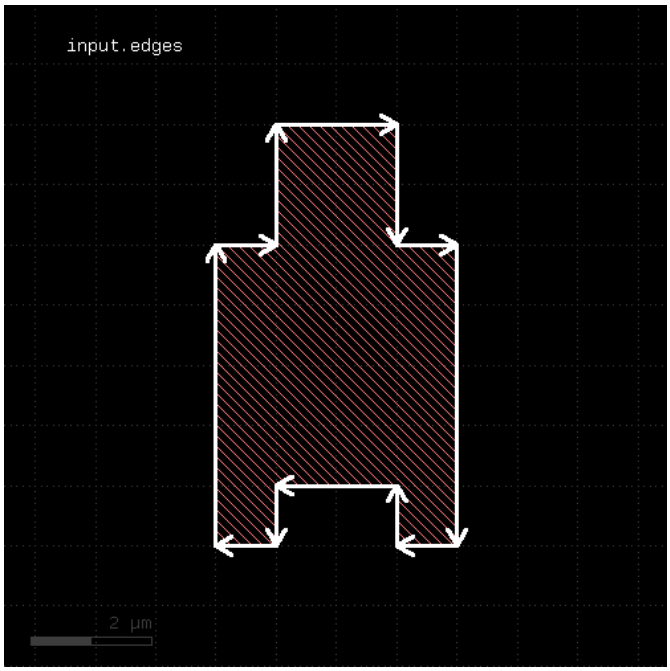
```
out = in.edges(convex)
```

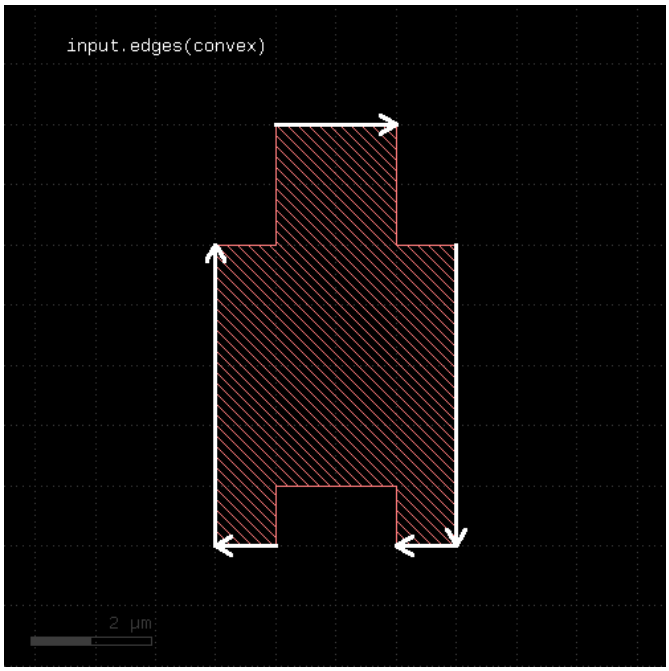
In addition, "not_.." variants are available which selects edges not qualifying for the specific mode:

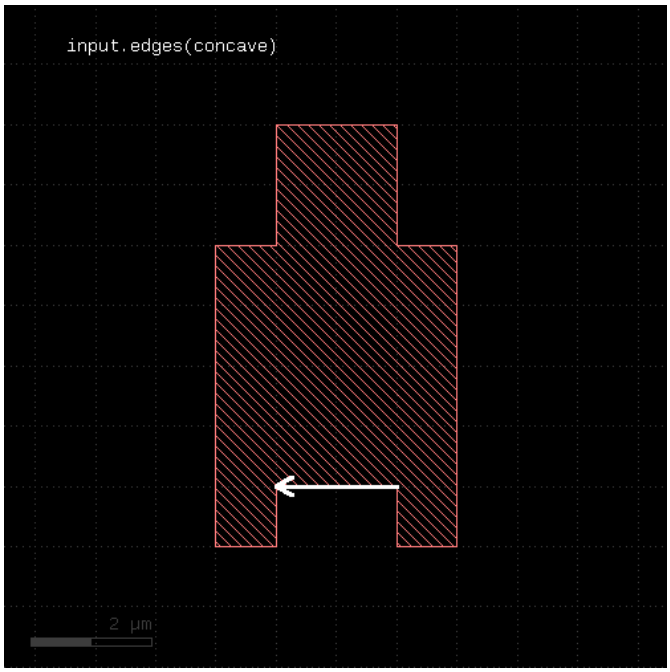
```
out = in.edges(not_convex)
```

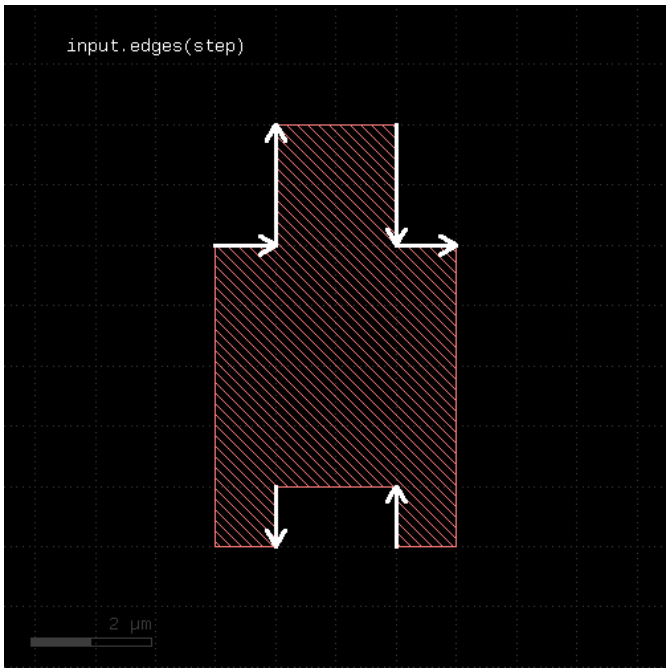
The mode argument is only available for polygon layers.

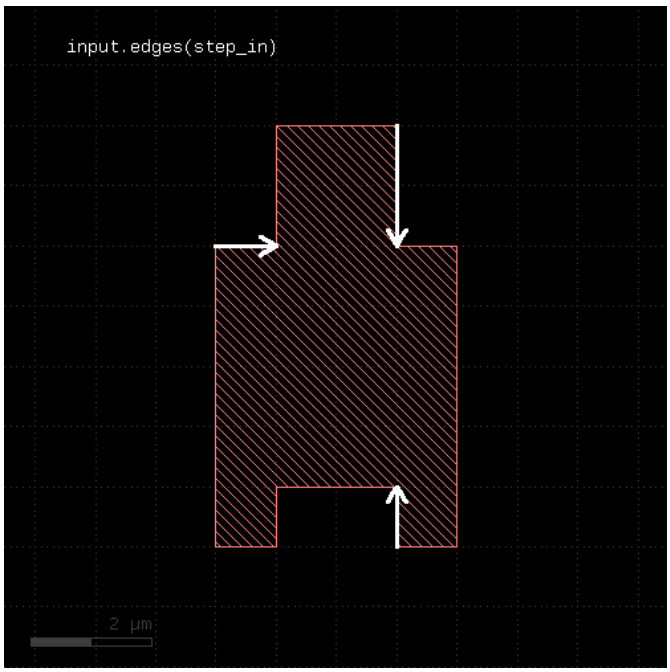
The following images show the effect of the mode argument:

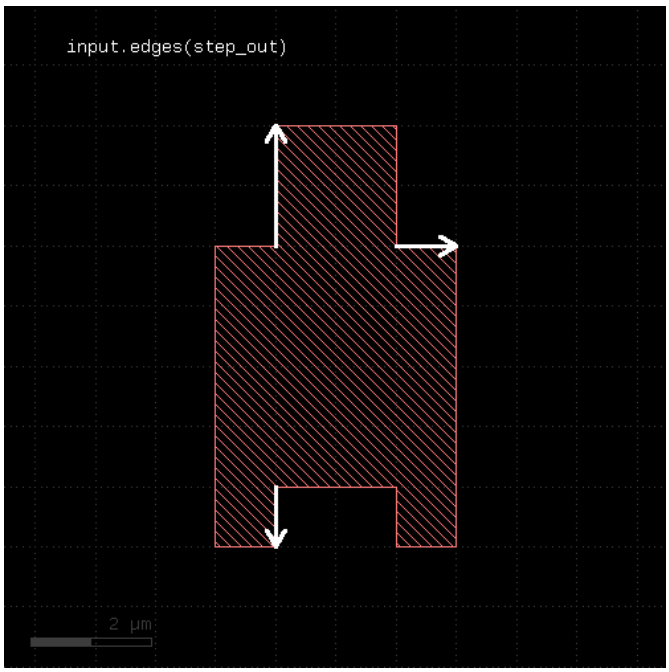












"edges?" - Returns true, if the layer is an edge layer

Usage:

- `layer.edges?`

"enc" - An alias for "enclosing"

Usage:

- `layer.enc(value [, options])`

See enclosing for a description of that method

"enclosed" - An enclosing check (other_layer enclosing layer)

Usage:

- `layer.enclosed(other_layer, value [, options])`

Note: "enclosed" is available as operators for the "universal DRC" function drc within the DRC framework. These variants have more options and are more intuitive to use. See enclosed for more details.

This method checks whether layer is enclosed by (is inside of) other_layer by not less than the given distance value. Locations, where the distance is less will be reported in form of edge pair error markers. Locations, where both edges coincide will be reported as errors as well. Formally such locations form an enclosure with a distance of 0. Locations, where other_layer is inside layer will not be reported as errors. Such regions can be detected by inside or a boolean "not" operation.

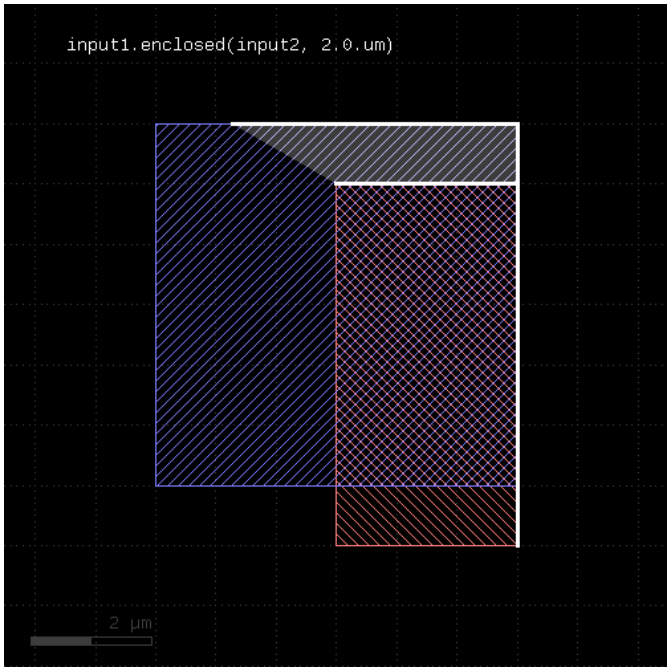
The options are the same as for separation.

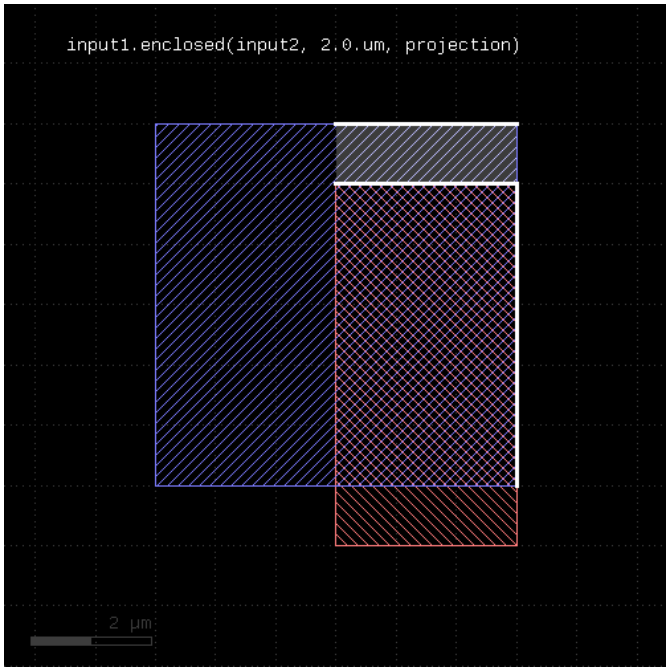
This method is available for edge and polygon layers.

As for the other DRC methods, merged semantics applies.

Distance values can be given as floating-point values (in micron) or integer values (in database units). To explicitly specify the unit, use the unit denominators.

The following images show the effect of two enclosed checks (red: input1, blue: input2):





"enclosing" - An enclosing check (layer enclosing other_layer)

Usage:

- `layer.enclosing(other_layer, value [, options])`
- `layer.enc(other_layer, value [, options])`

Note: "enclosing" and "enc" are available as operators for the "universal DRC" function drc within the DRC framework. These variants have more options and are more intuitive to use. See enclosing for more details.

This method checks whether layer encloses (is bigger than) other_layer by not less than the given distance value. Locations, where the distance is less will be reported in form of edge pair error markers. Locations, where both edges coincide will be reported as errors as well. Formally such locations form an enclosure with a distance of 0. Locations, where other_layer extends outside layer will not be reported as errors. Such regions can be detected by not_inside or a boolean "not" operation.

"enc" is the short form of this method.

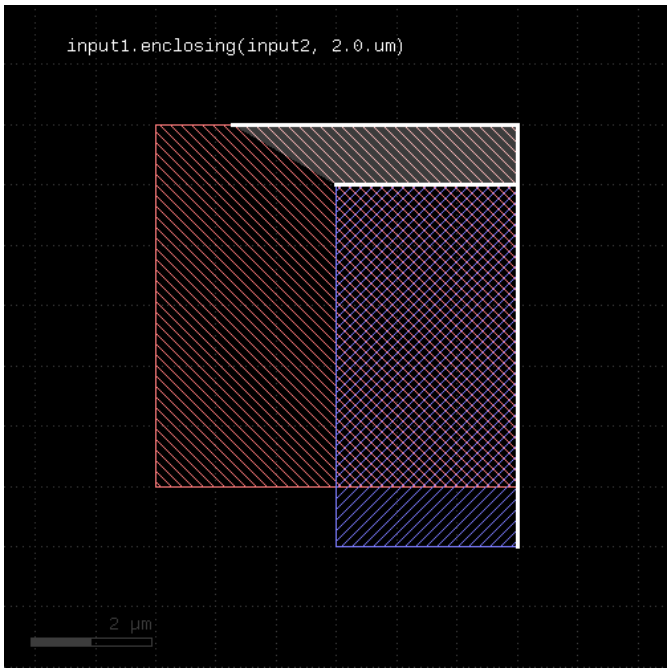
The options are the same as for separation.

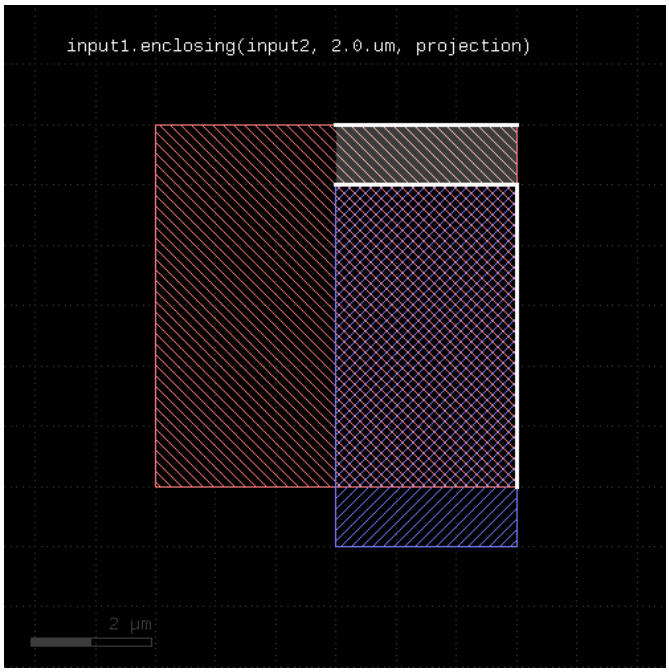
The enclosing method can be applied to both edge or polygon layers. On edge layers the orientation of the edges matters and only edges looking into the same direction are checked.

As for the other DRC methods, merged semantics applies.

Distance values can be given as floating-point values (in micron) or integer values (in database units). To explicitly specify the unit, use the unit denominators.

The following images show the effect of two enclosing checks (red: input1, blue: input2):





"end_segments" - Returns the part at the end of each edge

Usage:

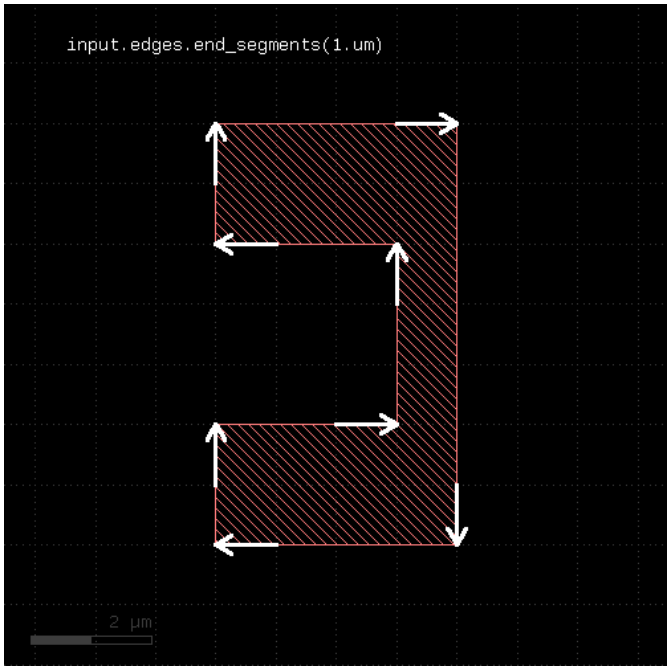
- `layer.end_segments(length)`
- `layer.end_segments(length, fraction)`

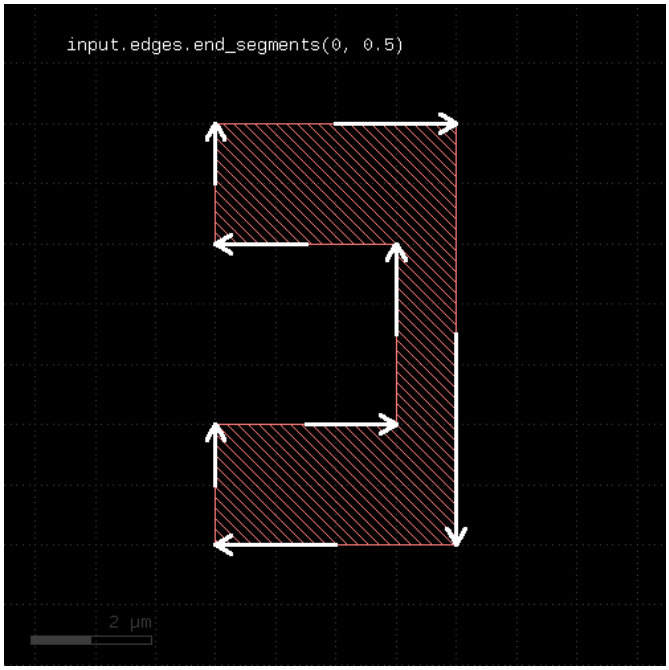
This method will return a partial edge for each edge in the input, located and the end of the original edge. The new edges will share the end point with the original edges, but not necessarily their start point. This method applies to edge layers only. The direction of edges is

defined by the clockwise orientation of a polygon: the end point of the edges will be the terminal point of each edge when walking a polygon in clockwise direction. Or in other words: when looking from start to the end point of an edge, the filled part of the polygon is to the right.

The length of the new edge can be given in two ways: as a fixed length, or a fraction, or both. In the latter case, the length of the resulting edge will be either the fraction or the fixed length, whichever is larger. To specify a length only, omit the fraction argument or leave it at 0. To specify a fraction only, pass 0 to the length argument and specify the fraction in the second parameter. A fraction of 0.5 will result in edges which cover the end half of the edge.

The following images show the effect of the method:





"extended" - Returns polygons describing an area along the edges of the input

Usage:

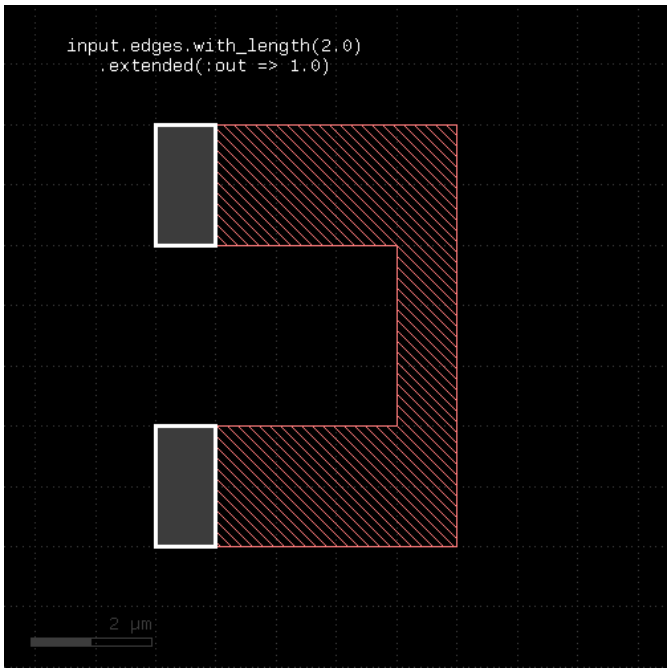
- `layer.extended([:begin => b,] [:end => e,] [:out => o,] [:in => i], [:joined => true])`
- `layer.extended(b, e, o, i)`
- `layer.extended(b, e, o, i, joined)`

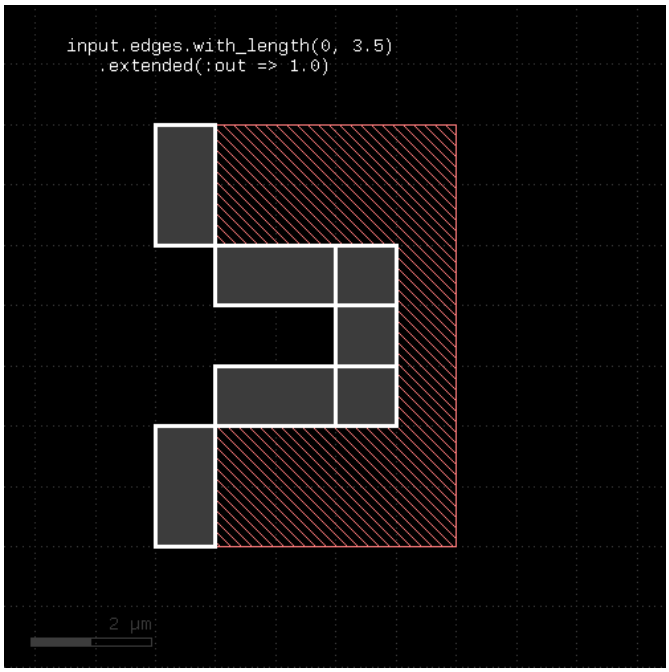
This method is available for edge layers only. It will create a polygon for each edge tracing the edge with certain offsets to the edge. "o" is the offset applied to the outer side of the edge, "i" is the offset applied to the inner side of the edge. "b" is the offset applied at the beginning and "e" is the offset applied at the end.

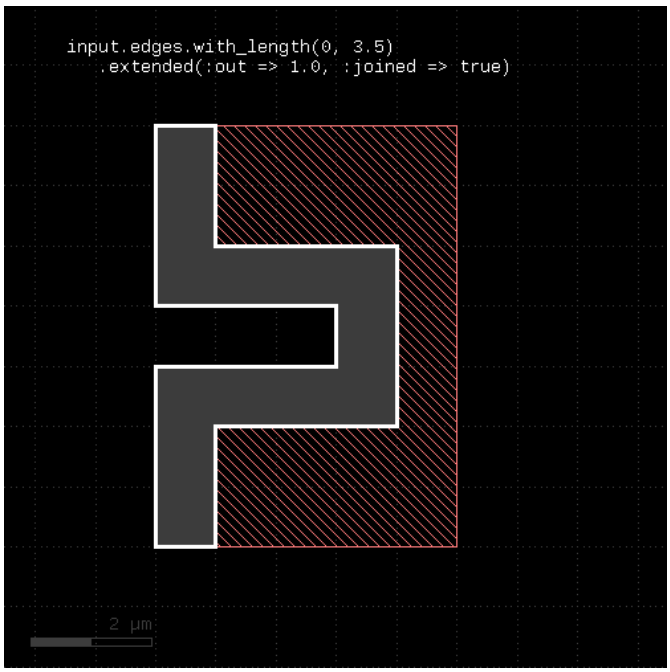
When looking from start to end point, the "inside" side is to the right, while the "outside" side is to the left.

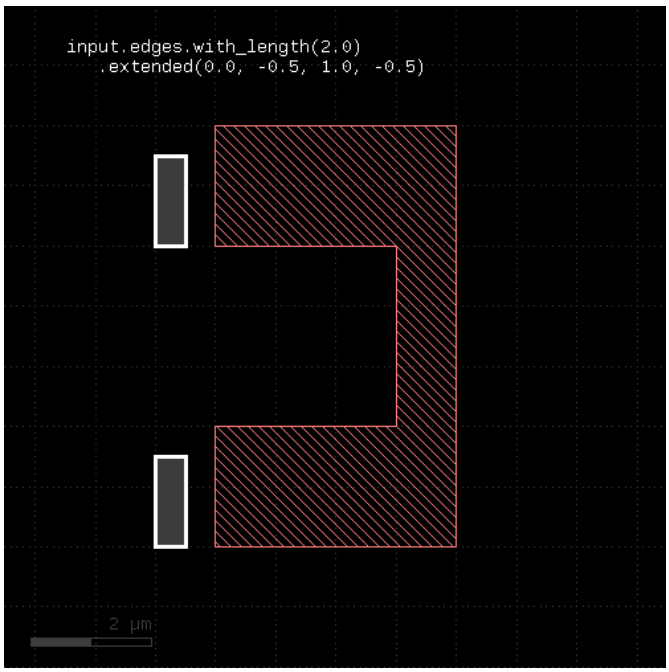
"joined" is a flag, which, if present, will make connected edges behave as a continuous line. Start and end offsets are applied to the first and last unconnected point respectively. Please note that in order to specify joined mode, you'll need to specify "joined" as a keyword in the third form of the method.

The following images show the effects of some parameters:









"extended_in" - Returns polygons describing an area along the edges of the input

Usage:

- `layer.extended_in(d)`

This method applies to edge layers only. Polygons are generated for each edge describing the edge drawn with a certain width extending into the "inside" (the right side when looking from start to end). This method is basically equivalent to the extended method: "extended(0, 0, 0, dist)". A version extending to the outside is extended_out.

"extended_out" - Returns polygons describing an area along the edges of the input

Usage:

- `layer.extended_out(d)`

This method applies to edge layers only. Polygons are generated for each edge describing the edge drawn with a certain width extending into the "outside" (the left side when looking from start to end). This method is basically equivalent to the extended method: "extended(0, 0, dist, 0)". A version extending to the inside is extended_in.

"extent_refs" - Returns partial references to the boundings boxes of the polygons

Usage:

- `layer.extent_refs(fx, fy [, options ])`
- `layer.extent_refs(fx1, fy1, fx2, fx2 [, options ])`
- `layer.extent_refs(ref_spec [, options ])`

This method produces parts of the bounding box of the polygons. It can select either edges, certain points or partial boxes. It can be used the following ways:

- **With a formal specification** : This is an identifier like ":center" or ":left" to indicate which part will be produced.
- **With two floating-point arguments** : These arguments specify a point relative to the bounding box. The first argument is a relative x coordinate where 0.0 means "left side of the bounding box" and 1.0 is the right side. The second argument is a relative y coordinate where 0.0 means "bottom" and 1.0 means "top". The results will be small (2x2 DBU) boxes or point-like edges for edge output
- **With four floating-point arguments** : These arguments specify a box in relative coordinates: a pair of x/y relative coordinate for the first point and another pair for the second point. The results will be boxes or a tilted edge in case of edge output. If the range specifies a finite-area box (height and width are not zero), no adjustment of the boxes will happen for polygon output - i.e. the additional enlargement by 1 DBU which is applied for zero-area boxes does not happen.

The formal specifiers are for points:

- **:center** or **:c** : the center point
- **:bottom_center** or **:bc** : the bottom center point
- **:bottom_left** or **:bl** : the bottom left point
- **:bottom_right** or **:br** : the bottom right point
- **:left** or **:l** : the left point
- **:right** or **:r** : the right point
- **:top_center** or **:tc** : the top center point
- **:top_left** or **:tl** : the top left point
- **:top_right** or **:tr** : the top right point

The formal specifiers for lines are:

- **:bottom** or **:b** : the bottom line

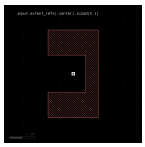
- **:top** or **:t** : the top line
- **:left** or **:l** : the left line
- **:right** or **:r** : the right line

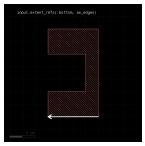
Dots are represented by small (2x2 DBU) boxes or point-like edges with edge output. Lines are represented by narrow or flat (2 DBU) boxes or edges for edge output. Edges will follow the orientation convention for the corresponding edges - i.e. "inside" of the bounding box is on the right side of the edge.

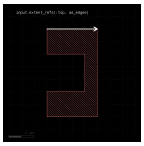
The following additional option controls the output format:

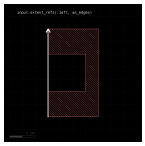
- **as_boxes** : with this option, small boxes will be produced as markers
- **as_dots** or **as_edges** : with this option, point-like edges will be produced for dots and edges will be produced for line-like selections

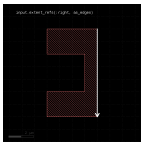
The following table shows a few applications:

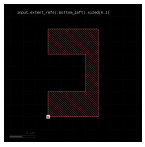


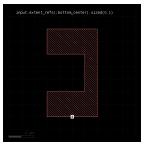


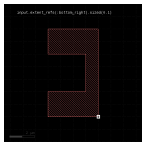


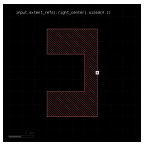


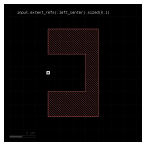


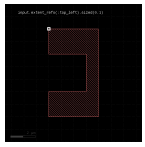


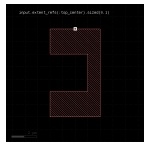


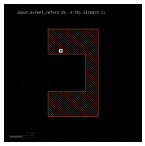


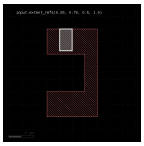












"extents" - Returns the bounding box of each input object

Usage:

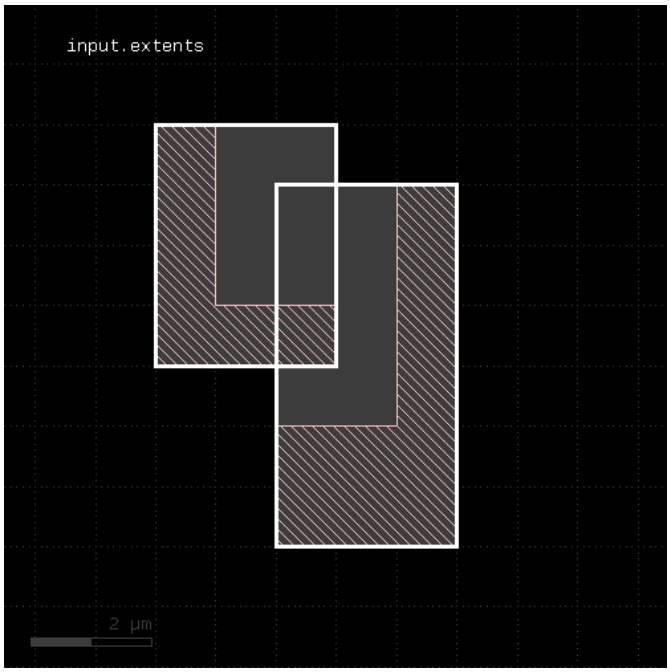
- `layer.extents([ enlargement ])`

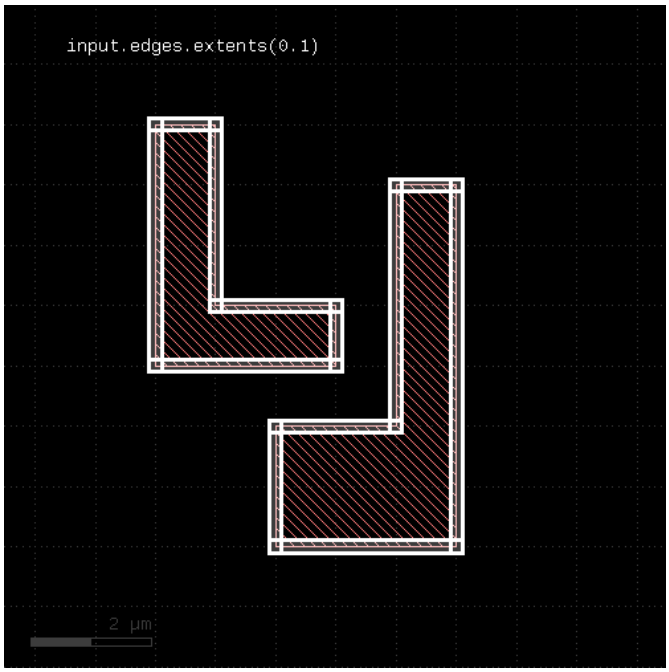
Applies to edge layers, polygon layers on edge pair collections. Returns a polygon layer consisting of boxes for each input object. The boxes enclose the original object.

Merged semantics applies, so the box encloses the merged polygons or edges unless raw mode is chosen (see raw).

The enlargement parameter specifies an optional enlargement which will make zero width/zero height object render valid polygons (i.e. horizontal/vertical edges).

The following images show the effect of the extents method:





"fill" - Fills the region with regular pattern of shapes

Usage:

- `layer.fill([ options ])`

This method will attempt to fill the polygons of the layer with a regular pattern of shapes.

The fill function currently is not available in deep mode.

Options are:

- **hstep(x)** or **hstep(x, y)** : specifies the horizontal step pitch of the pattern. x must be a positive value. A vertical displacement component can be specified too, which results in a skewed pattern.
- **vstep(y)** or **vstep(x, y)** : specifies the vertical step pitch of the pattern. y must be a positive value. A horizontal displacement component can be specified too, which results in a skewed pattern.
- **origin(x, y)** : specifies a fixed point to align the pattern with. This point specifies the location of the reference point for one pattern cell.
- **auto_origin** : lets the algorithm choose the origin. This may result is a slightly better fill coverage as the algorithm is able to determine a pattern origin per island to fill.
- **multi_origin** : lets the algorithm choose the origin and repeats the fill with different origins until no further fill cell can be fitted.
- **fill_pattern(..)** : specifies the fill pattern.

"fill_pattern" generates a fill pattern object. This object is used for configuring the fill pattern content. Fill pattern need to be named. The name will be used for generating the fill cell.

To provide a fill pattern, create a fill pattern object and add shapes to it. The following example creates a fill pattern named "FILL_CELL" and adds a 1x1 micron box on layer 1/0:

```
p = fill_pattern("FILL_CELL")
p.shape(1, 0, box(0.0, 0.0, 1.0, 1.0))
```

See box for details about the box specification. You can also add paths or polygons with path or polygon.

A more compact way of writing this is:

```
p = fill_pattern("FILL_CELL").shape(1, 0, box(0.0, 0.0, 1.0, 1.0))
```

The "shape" method takes several forms:

- `shape(layer, object, object ...)` (1)
- `shape(layer, datatype, object, object ...)` (2)
- `shape(name, object, object ...)` (3)
- `shape(layer_info, object, object ...)` (4)

The first form takes a GDS2 layer number. The datatype is assumed to be 0. The second form takes a GDS layer and datatype number. The third form takes a layer name for layout systems with named layers (like Magic, CIF or DXF). The forth form takes a LayerInfo object to specify the layer. All forms take one to many geometry objects which are written to the respective layer. Geometry objects can either be created using the generator functions (box, polygon, path). The core classes DBox, DPolygon, DPath or DText are also accepted as geometry objects.

The fill pattern can be given a reference point which is used for placing the pattern. The reference point is the one which is aligned with the pattern origin. The following code will assign (-0.5, -0.5) as the reference point for the 1x1 micron rectangle. Hence the reference point is a little below and left of the rectangle which in turn shifts the rectangle fill pattern to the right and up:

```
p = fill_pattern("FILL_CELL")
p.shape(1, 0, box(0.0, 0.0, 1.0, 1.0))
p.origin(-0.5, -0.5)
```

Without a reference point given, the lower left corner of the fill pattern's bounding box will be used as the reference point. The reference point will also defined the footprint of the fill cell - more precisely the lower left corner. When step vectors are given, the fill cell's footprint is taken to be a rectangle having the horizontal and vertical step pitch for width and height respectively. This way the fill cells will be arrange seamlessly. However, the cell's dimensions can be changed, so that the fill cells can overlap or there is a space between the cells. To change the dimensions use the "dim" method.

The following example specifies a fill cell with an active area of -0.5 .. 1.5 in both directions (2 micron width and height). With these dimensions the fill cell's footprint is independent of the step pitch:

```
p = fill_pattern("FILL_CELL")
p.shape(1, 0, box(0.0, 0.0, 1.0, 1.0))
p.origin(-0.5, -0.5)
p.dim(2.0, 2.0)
```

With these ingredients will can use the fill function. The first example fills the polygons of "to_fill" with an orthogonal pattern of 1x1 micron rectangles with a pitch of 2 microns:

```
pattern = fill_pattern("FILL_CELL").shape(1, 0, box(0.0, 0.0, 1.0, 1.0)).origin(-0.5, -0.5)
```

```
to_fill.fill(pattern, hstep(2.0), vstep(2.0))
```

This second example will create a skewed fill pattern in auto-origin mode:

```
pattern = fill_pattern("FILL_CELL").shape(1, 0, box(0.0, 0.0, 1.0, 1.0)).origin(-0.5, -0.5)
to_fill.fill(pattern, hstep(2.0, 1.0), vstep(-1.0, 2.0), auto_origin)
```

The fill function can only work with a target layout for output. It will not work for report output.

The layers generated by the fill cells is only available for input later in the script if the output layout is identical to the input layouts. If you need the area missed by the fill function, try fill_with_left.

"fill_with_left" - Fills the region with regular pattern of shapes

Usage:

- `layer.fill_with_left([ options ])`

This method has the same call syntax and functionality than fill. Other than this method it will return the area not covered by fill cells as a DRC layer.

"first_edges" - Returns the first edges of an edge pair collection

Usage:

- `layer.first_edges`

Applies to edge pair collections only. Returns the first edges of the edge pairs in the collection.

Some checks deliver symmetric edge pairs (e.g. space, width, etc.) for which the edges are commutable. "first_edges" will deliver both edges for such edge pairs.

"flatten" - Flattens the layer

Usage:

- `layer.flatten`

If the layer already is a flat one, this method does nothing. If the layer is a hierarchical layer (an original layer or a derived layer in deep mode), this method will convert it to a flat collection of texts, polygons, edges or edge pairs.

"forget" - Cleans up memory for this layer

Usage:

- `forget`

KLayout's DRC engine is imperative. This means, every command is executed immediately rather than being compiled and executed later. The advantage of this approach is that it allows decisions to be taken depending on the content of a layer and to code functions that operate directly on the layer's content.

However, one drawback is that the engine cannot decide when a layer is no longer required - it may still be used later in the script. So a layer's data is not cleaned up automatically.

In order to save memory for DRC scripts intended for bigger layouts, the DRC script should clean up layers as soon as they are no longer required. The "forget" method will free the memory used for the layer's information.

The recommended approach is:

```
l = ... # compute some layer
...
# once you're done with l:
l.forget
l = nil
```

By setting the layer to nil, it is ensured that it can no longer be accessed.

"hier_count" - Returns the hierarchical number of objects on the layer

Usage:

- `layer.hier_count`

The hier_count is the number of raw objects, not merged regions or edges, with each cell counting once. A high count to hier_count (flat to hierarchical) ratio is an indication of a good hierarchical compression. "hier_count" applies only to original layers without clip regions or cell filters and to layers in deep mode. Otherwise, hier_count gives the same value than count.

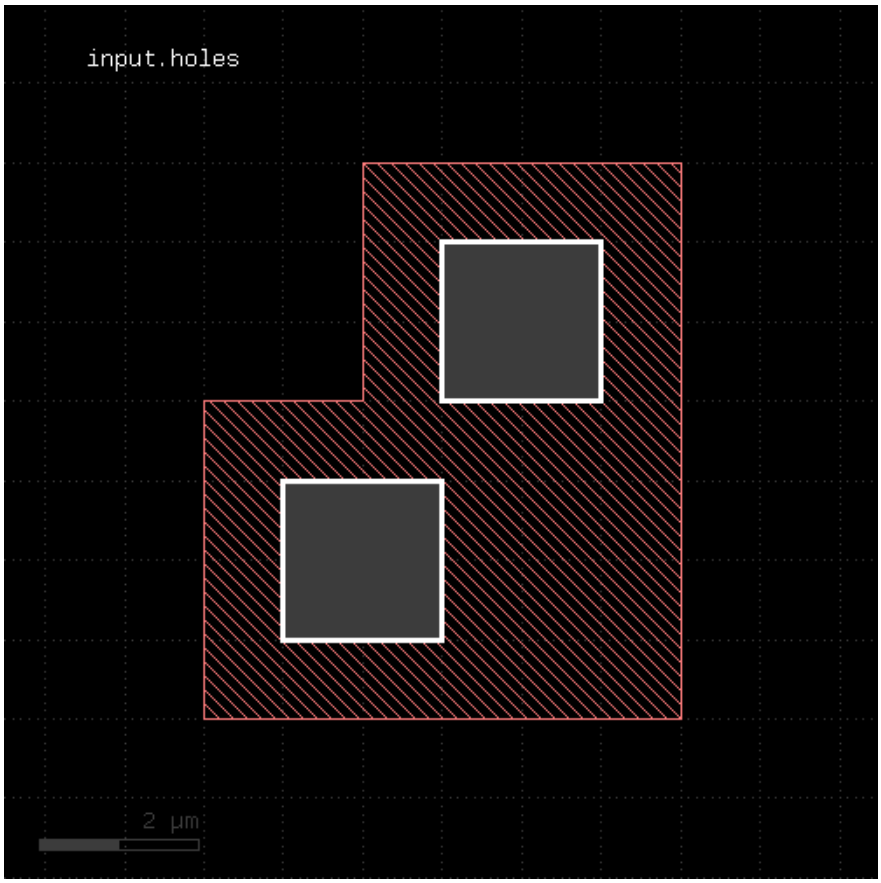
"holes" - Selects all polygon holes from the input

Usage:

- `layer.holes`

This method is available for polygon layers. It will create polygons from all holes inside polygons of the input. Although it is possible, running this method on raw polygon layers will usually not render the expected result, since raw layers do not contain polygons with holes in most cases.

The following image shows the effects of the holes method:



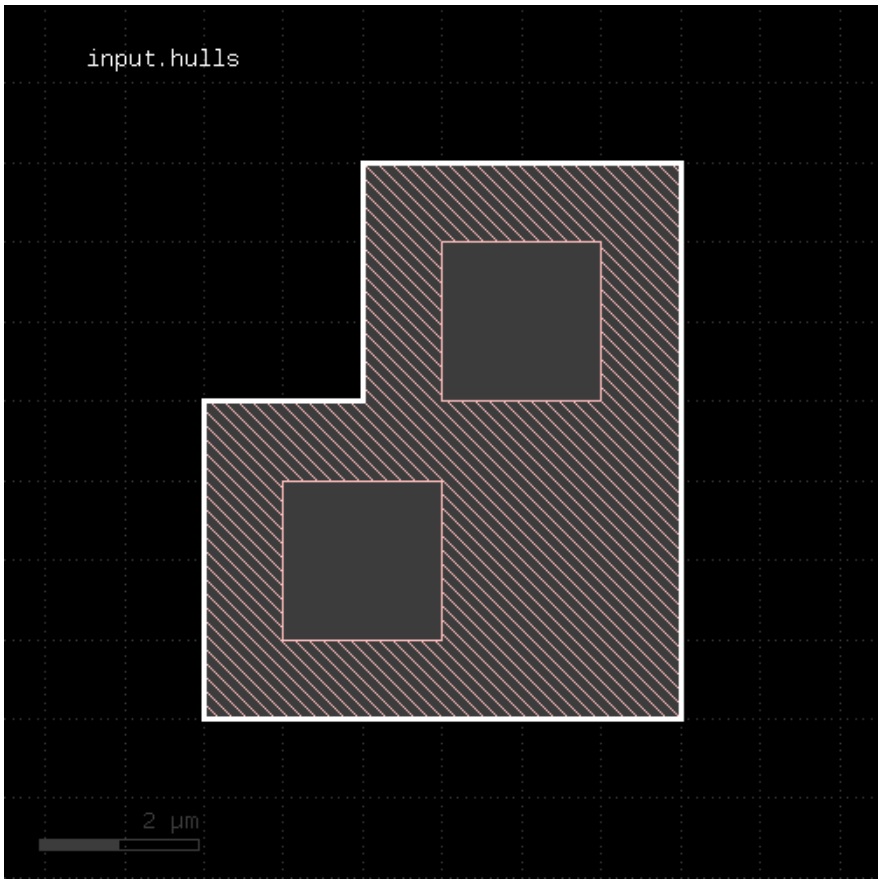
"hulls" - Selects all polygon hulls from the input

Usage:

- `layer.hulls`

This method is available for polygon layers. It will remove all holes from the input and render the hull polygons only. Although it is possible, running this method on raw polygon layers will usually not render the expected result, since raw layers do not contain polygons with holes in most cases.

The following image shows the effects of the hulls method:



"in" - Selects shapes or regions of self which are contained in the other layer

Usage:

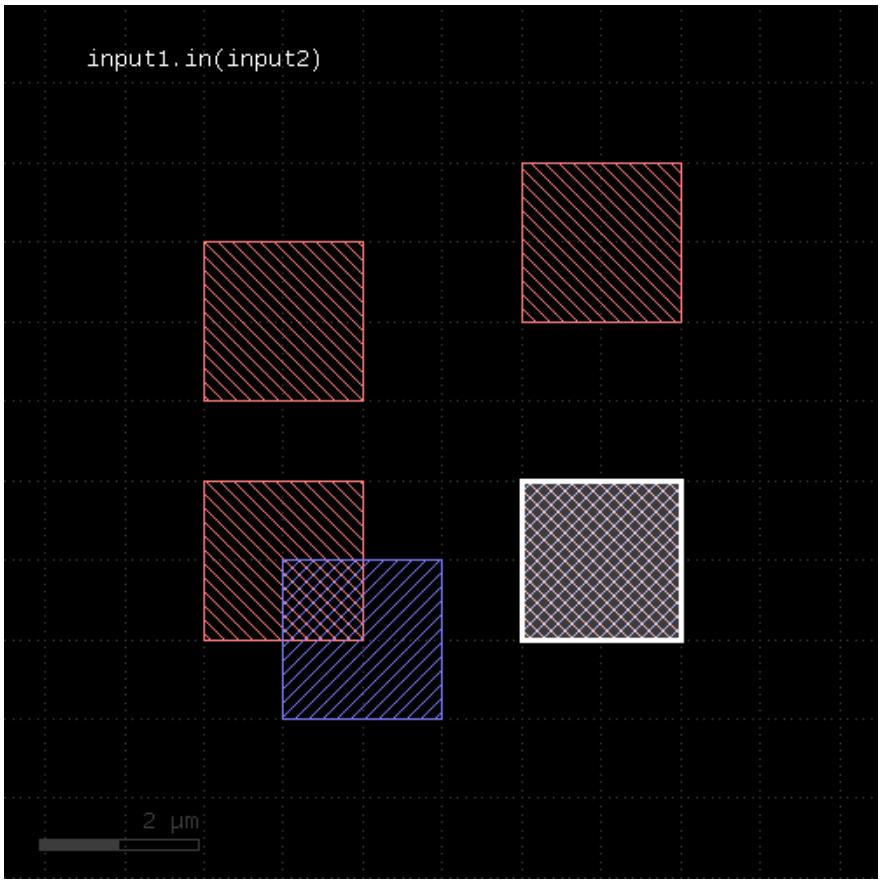
- `layer.in(other)`

This method selects all shapes or regions from self which are contained the other region exactly. It will use individual shapes from self or other if the respective region is in raw mode. If not, it will use coherent regions or combined edges from self or other.

It will return a new layer containing the selected shapes. A method which selects all shapes not contained in the other layer is not_in.

This method is available for polygon and edge layers.

The following image shows the effect of the "in" method (input1: red, input2: blue):



"in_and_out" - Selects shapes or regions of self which are and which are not contained in the other layer

Usage:

- `(in, not_in) = layer.in_and_out(other)`

This method is equivalent to calling in and not_in, but more efficient as it delivers both results in a single call.

"insert" - Inserts one or many objects into the layer

Usage:

- `insert(object, object ...)`

Objects that can be inserted are Edge objects (into edge layers) or DPolygon, DSimplePolygon, Path, DBox (into polygon layers). Convenience methods exist to create such objects (edge, polygon, box and path). However, RBA constructors can used as well.

The insert method is useful in combination with the polygon_layer or edge_layer functions:

```
el = edge_layer
el.insert(edge(0.0, 0.0, 100.0, 0.0)

pl = polygon_layer
pl.insert(box(0.0, 0.0, 100.0, 200.0)
```

"inside" - Selects edges or polygons of self which are inside edges or polygons from the other layer

Usage:

- `layer.inside(other)`

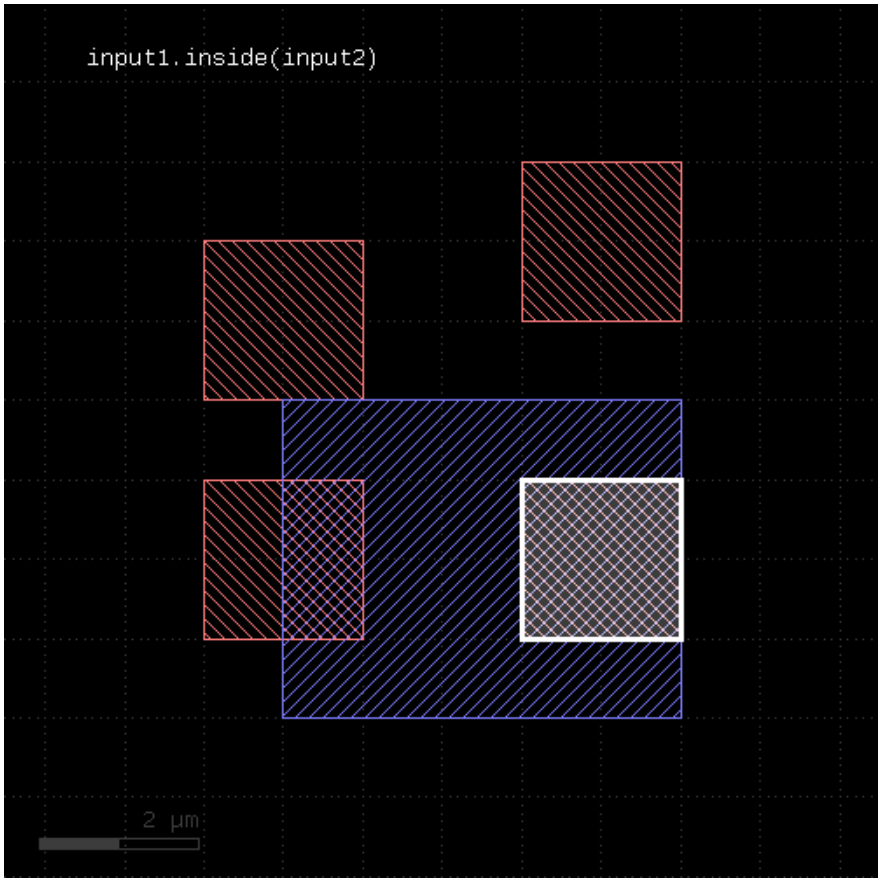
If layer is a polygon layer, the other layer needs to be a polygon layer too. In this case, this method selects all polygons which are completely inside polygons from the other layer.

If layer is an edge layer, the other layer can be polygon or edge layer. In the first case, all edges completely inside the polygons from the other layer are selected. If the other layer is an edge layer, all edges completely contained in edges from the other layer are selected.

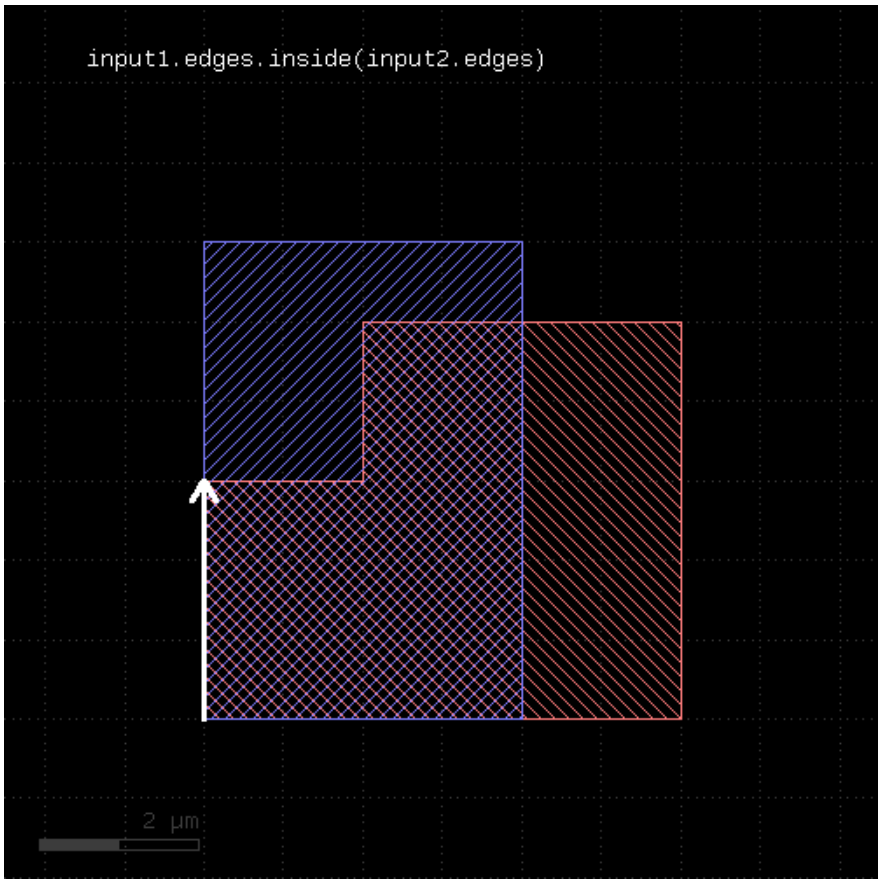
Merged semantics applies - i.e. edges or polygons are joined before the result is computed, unless the layers are in raw mode.

This method returns a new layer containing the selected shapes. A version which modifies self is select_inside. not_inside is a function computing the inverse of inside. split_inside is a function computing both results in a single call. outside is a similar function selecting edges or polygons outside other edges or polygons.

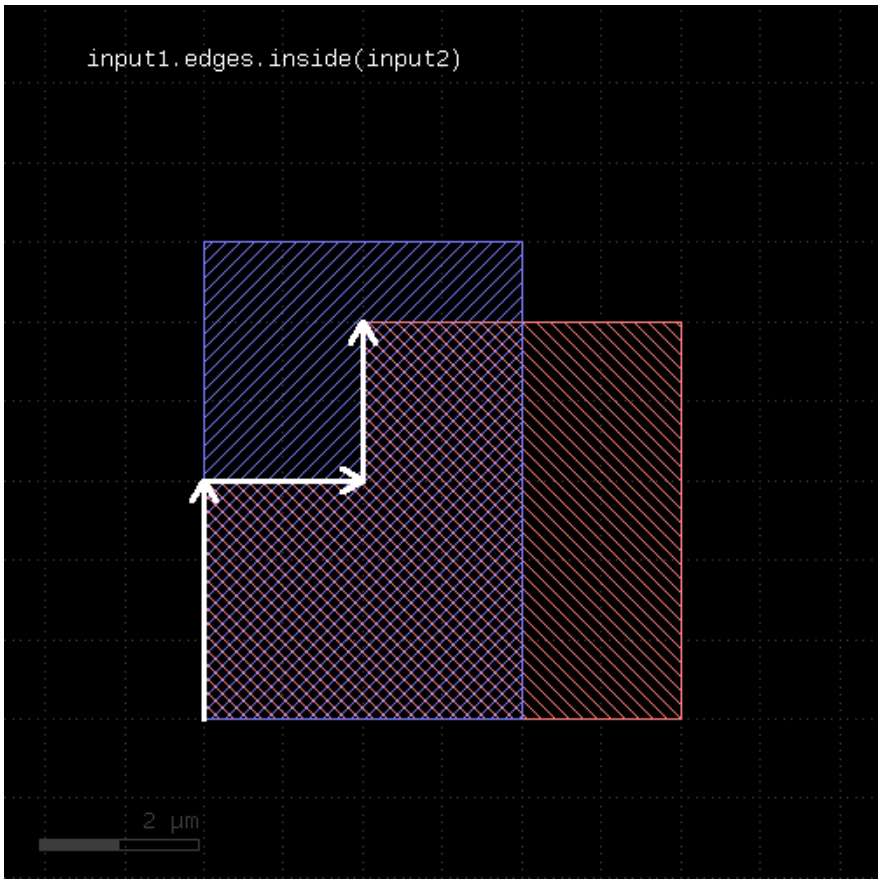
The following image shows the effect of the "inside" method for polygons (input1: red, input2: blue):



The following images show the effect of the "inside" method for edge layers and edge or polygon layers the second input. Note that the edges are computed from the polygons in this example (input1: red, input2: blue):



input1.edges.inside(input2.edges)
2 µm



"inside_outside_part" - Returns the parts of the edges inside and outside the given region

Usage:

- `(inside_part, outside_part) = layer.inside_outside_part(region)`

The method is available for edge layers. The argument must be a polygon layer.

This method returns two layers: the first with the edge parts inside the given region and the second with the parts outside the given region. It is equivalent to calling inside_part and outside_part, but more efficient if both parts need to be computed.

"inside_part" - Returns the parts of the edges inside the given region

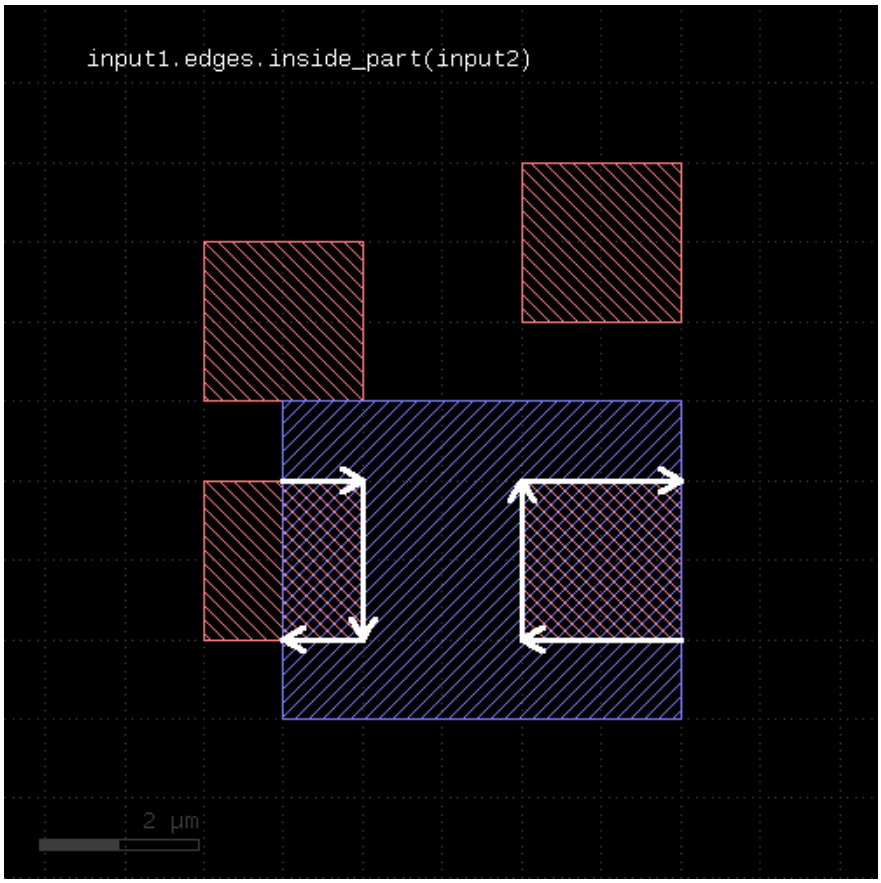
Usage:

- `layer.inside_part(region)`

This method returns the parts of the edges which are inside the given region. This is similar to the "&" operator, but this method does not return edges that are exactly on the boundaries of the polygons of the region.

This method is available for edge layers. The argument must be a polygon layer.

outside_part is a method computing the opposite part. inside_outside_part is a method computing both inside and outside part in a single call.



"interacting" - Selects shapes or regions of self which touch or overlap shapes from the other region

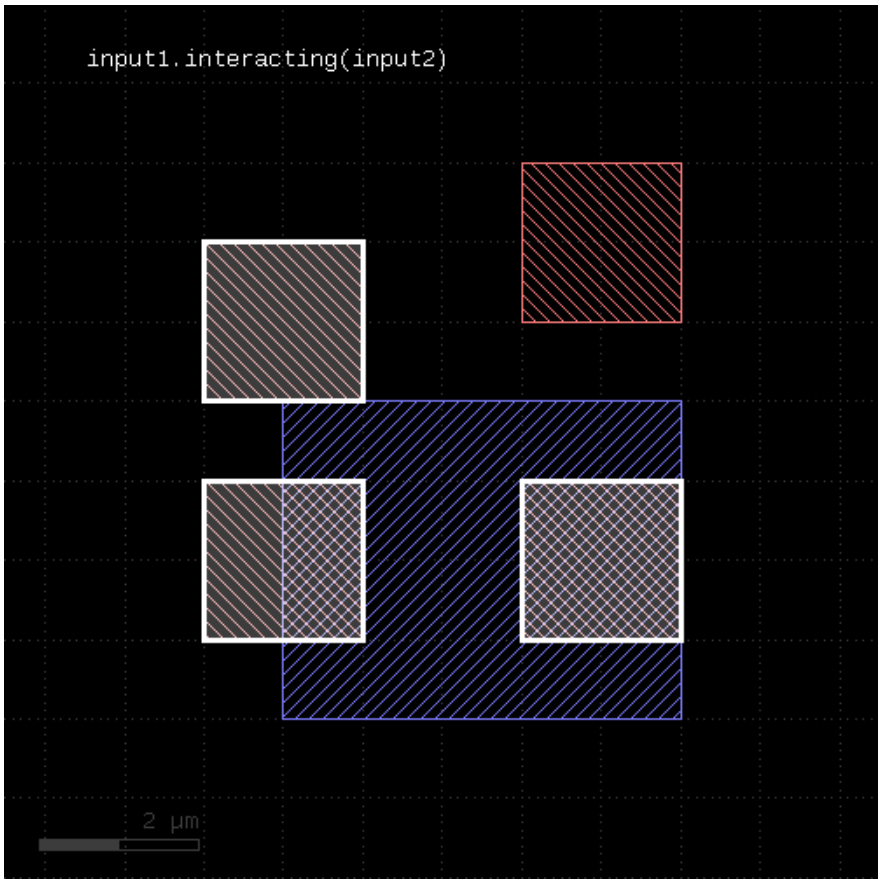
Usage:

- `layer.interacting(other)`
- `layer.interacting(other, min_count)`
- `layer.interacting(other, min_count, max_count)`
- `layer.interacting(other, min_count .. max_count)`

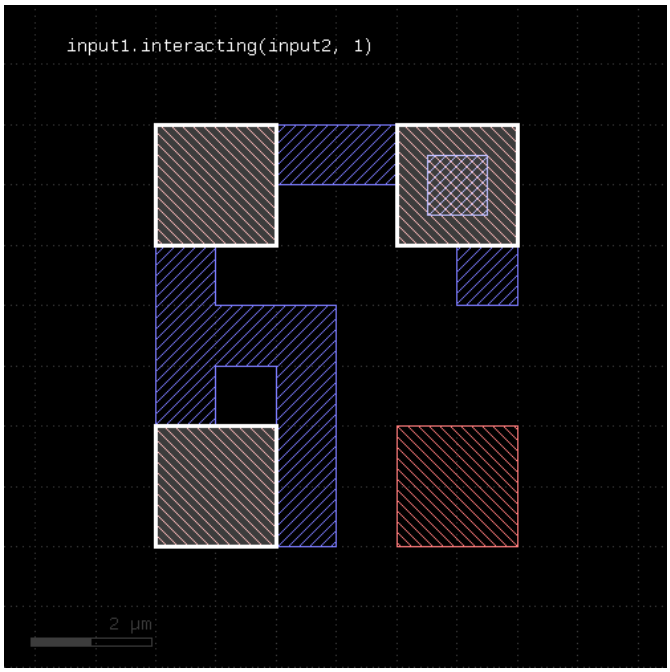
This method selects all shapes or regions from self which touch or overlap shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It returns a new layer containing the selected shapes. A version which modifies self is select_interacting.

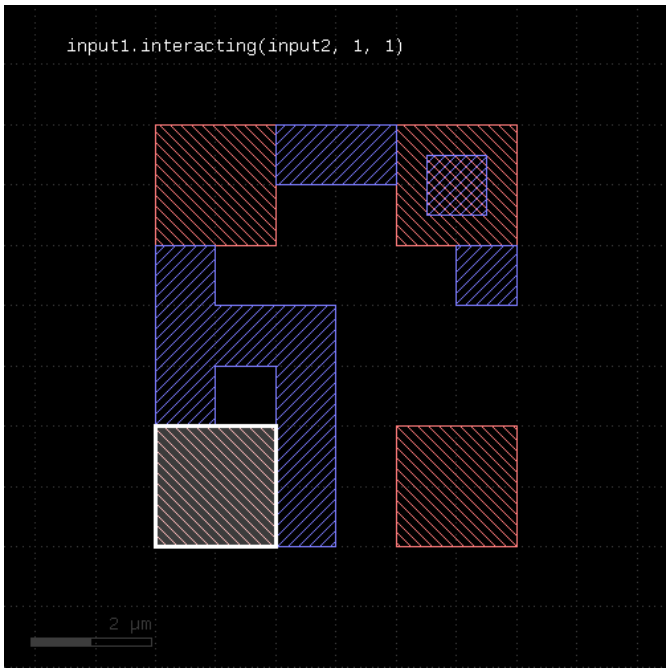
This method is available for polygon, text and edge layers. Edges can be selected with respect to other edges or polygons. Texts can be selected with respect to polygons. Polygons can be selected with respect to edges, texts and other polygons.

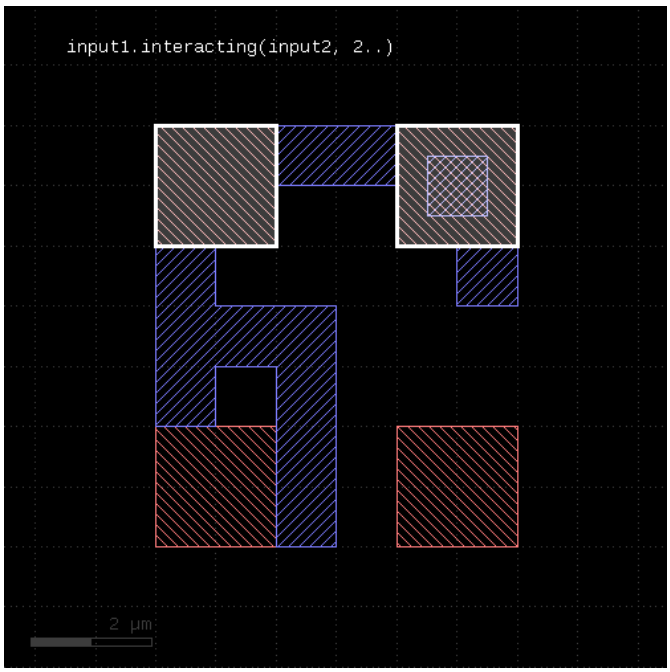
The following image shows the effect of the "interacting" method (input1: red, input2: blue):

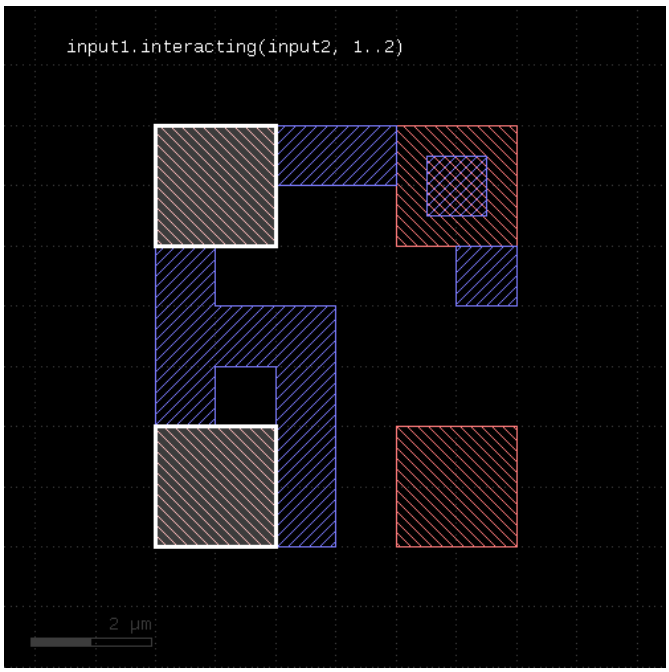


If a single count is given, shapes from self are selected only if they do interact at least with the given number of (different) shapes from the other layer. If a min and max count is given, shapes from self are selected only if they interact with min_count or more, but a maximum of max_count different shapes from the other layer. Two polygons overlapping or touching at two locations are counted as single interactions.









"intersections" - Returns the intersection points of intersecting edge segments for two edge collections

Usage:

- `layer.intersections(edges)`

This operation is similar to the "&" operator, but it does also report intersection points between non-colinear, but intersecting edges. Such points are reported as point-like, degenerated edge objects.

This method is available for edge layers. The argument must be an edge layer.

"is_box?" - Returns true, if the region contains a single box

Usage:

- `layer.is_box?`

The method returns true, if the region consists of a single box only. Merged semantics does not apply - if the region forms a box which is composed of multiple pieces, this method will not return true.

"is_clean?" - Returns true, if the layer is clean state

Usage:

- `layer.is_clean?`

See clean for a discussion of the clean state.

"is_deep?" - Returns true, if the layer is a deep (hierarchical) layer

Usage:

- `layer.is_deep?`

"is_empty?" - Returns true, if the layer is empty

Usage:

- `layer.is_empty?`

"is_merged?" - Returns true, if the polygons of the layer are merged

Usage:

- `layer.is_merged?`

This method will return true, if the polygons of this layer are merged, i.e. they don't overlap and form single continuous polygons. In clean mode, this is ensured implicitly. In raw mode (see raw), merging can be achieved by using the merge method. is_merged? tells, whether calling merge is necessary.

"is_raw?" - Returns true, if the layer is raw state

Usage:

- `layer.is_raw?`

See clean for a discussion of the raw state.

"iso" - An alias for "isolated"

Usage:

- `layer.iso(value [, options])`

See isolated for a description of that method

"isolated" - An inter-polygon isolation check

Usage:

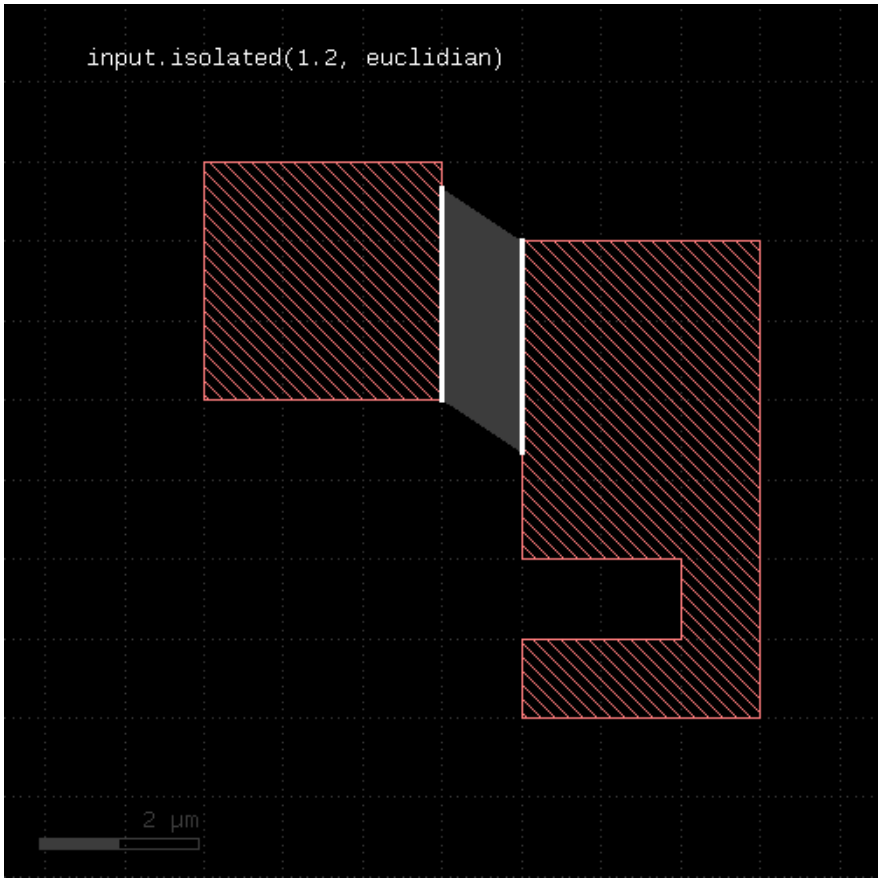
- `layer.isolated(value [, options])`
- `layer.iso(value [, options])`

Note: "isolated" and "iso" are available as operators for the "universal DRC" function Layer#drc within the DRC framework. These variants have more options and are more intuitive to use. See isolated for more details.

See space for a description of this method. "isolated" is the space check variant which checks different polygons only. In contrast to space, the "isolated" method is available for polygon layers only, since only on such layers different polygons can be identified.

"iso" is the short form of this method.

The following image shows the effect of the isolated check:



"join" - Joins the layer with another layer

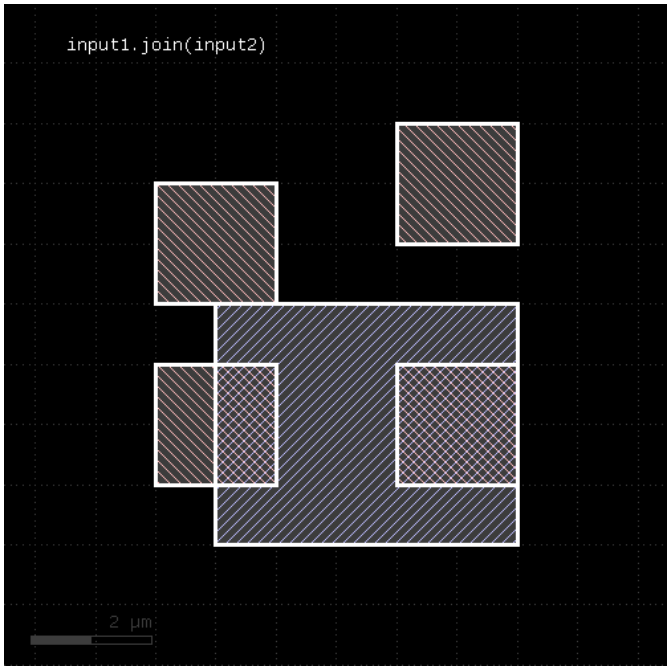
Usage:

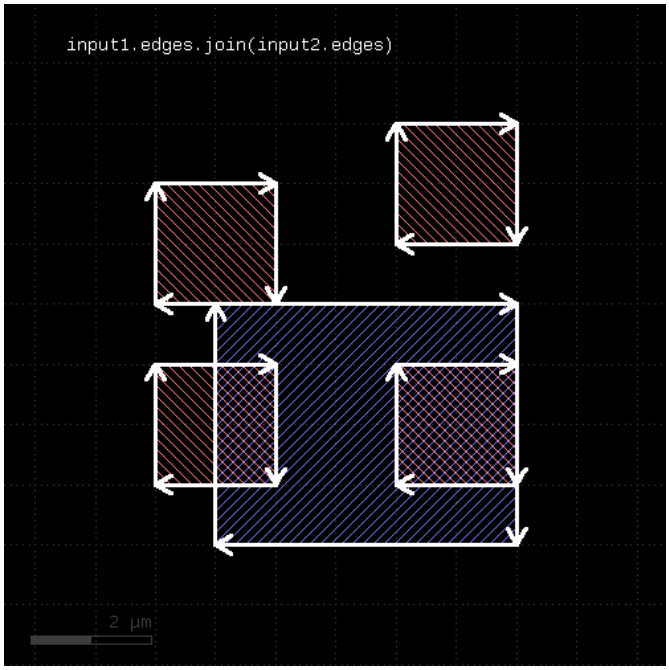
- `layer.join(other)`

The method includes the edges or polygons from the other layer into this layer. It is an alias for the "+" operator.

This method is available for polygon, edge and edge pair layers.

The following images show the effect of the "join" method on polygons and edges (input1: red, input2: blue):





"length" - Returns the total length of the edges in the edge layer

Usage:

- `layer.length`

This method requires an edge layer. It returns the total length of all edges in micron. Merged semantics applies, i.e. before computing the length, the edges are merged unless raw mode is chosen (see raw). Hence in clean mode (see clean), overlapping edges are not counted twice.

"map_props" - Selects properties with certain keys and allows key mapping

Usage:

- `layer.map_props({ key => key_new, .. })`

Similar to select_props, this method will map or filter properties and and take the values from certain keys. In addition, this method allows mapping keys to new keys. Specify a hash argument with old to new keys.

Property values with keys not listed in the hash are removed.

Note that this method returns a new layer with the new properties. The original layer will not be touched.

For example to map key 2 to 1 (integer name keys) and ignore other keys, use:

```
layer1 = input(1, 0, enable_properties)
layer1_mapped = layer1.map_props({ 2 => 1 })
```

See also select_props and remove_props.

"merge" - Merges the layer (modifies the layer)

Usage:

- `layer.merge([overlap_count])`

Like merged, but modifies the input and returns a reference to the new layer.

"merged" - Returns the merged layer

Usage:

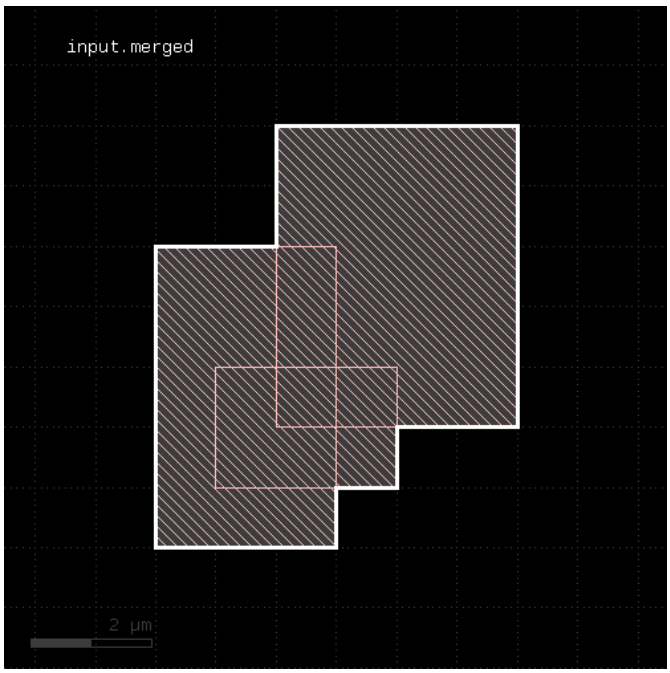
- `layer.merged([overlap_count])`

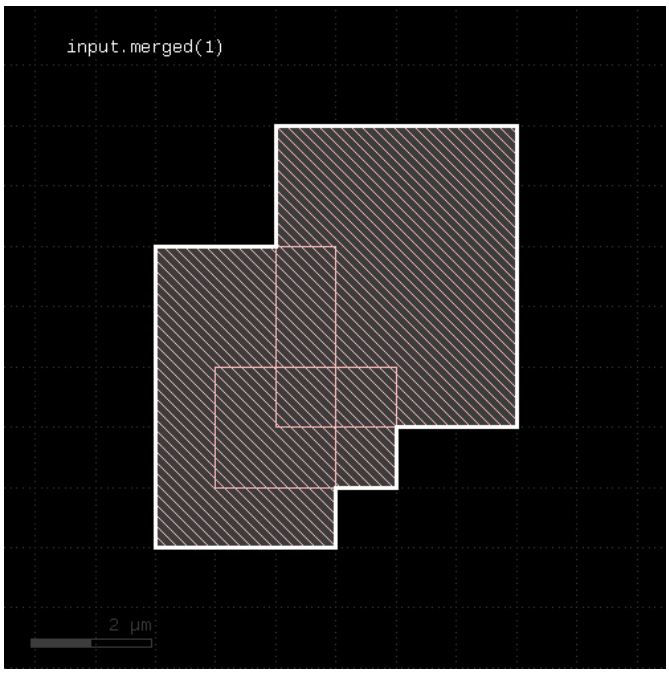
Returns the merged input. Usually, merging is done implicitly using the clean state (which is default). However, in raw state, merging can be enforced by using this method. In addition, this method allows specification of a minimum overlap count, i.e. only where at least the given number of polygons overlap, output is produced. See sized for an application of that.

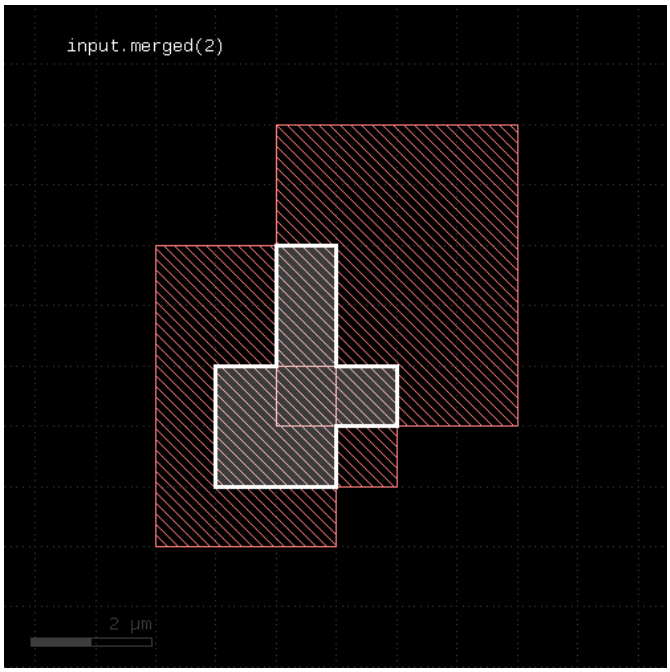
This method works both on edge or polygon layers. Edge merging forms single, continuous edges from coincident and connected individual edges.

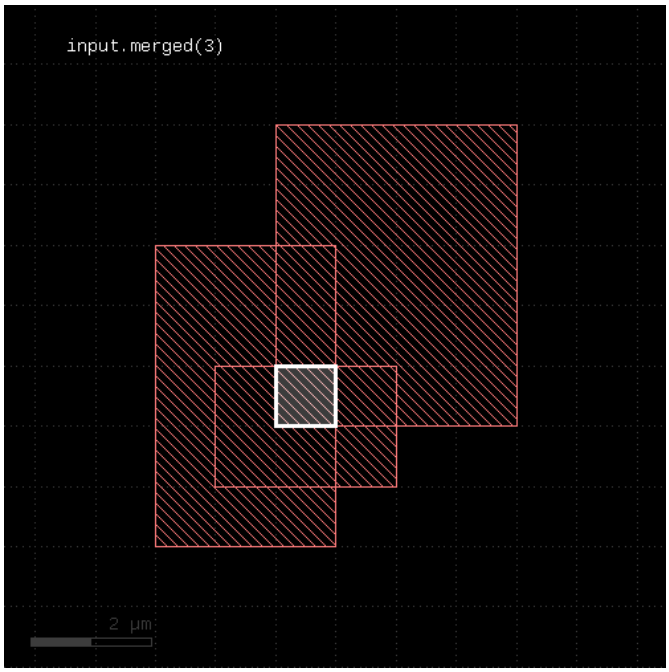
A version that modifies the input layer is merge.

The following images show the effect of various forms of the "merged" method:









"middle" - Returns the center points of the bounding boxes of the polygons

Usage:

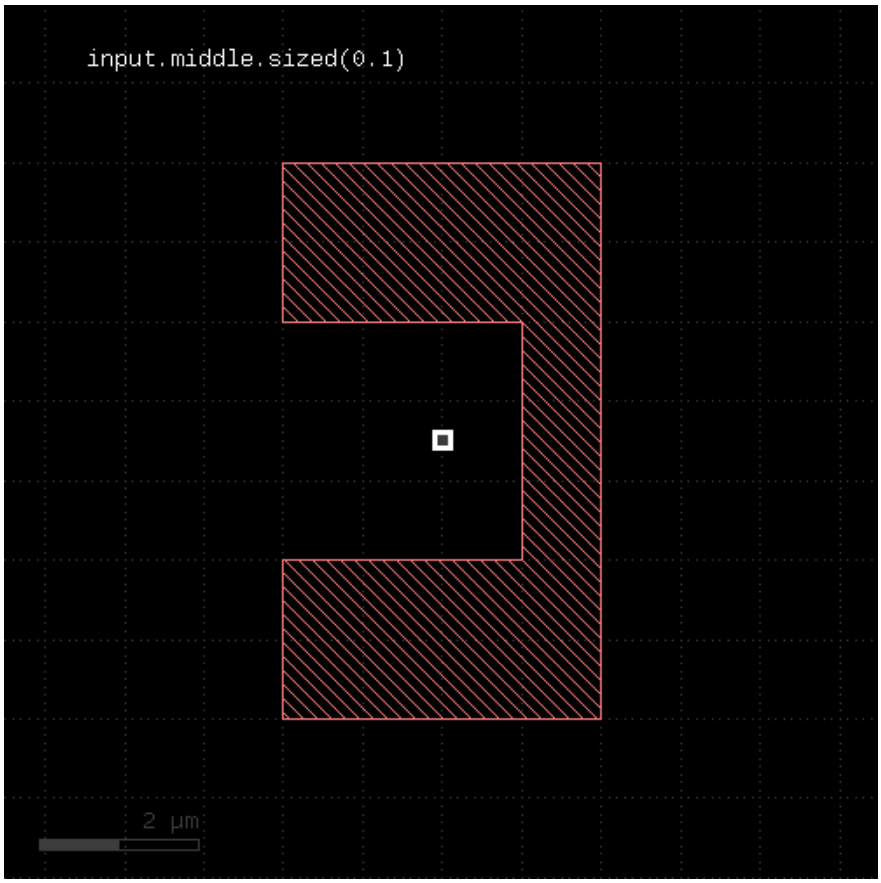
- `layer.middle([ options ])`

This method produces markers on the centers of the polygon's bounding box centers. These markers can be point-like edges or small 2x2 DBU boxes. The latter is the default. A more generic function is extent_refs. "middle" is basically a synonym for "extent_refs(:center)".

The options available are:

- **as_boxes** : with this option, small boxes will be produced as markers
- **as_dots** : with this option, point-like edges will be produced instead of small boxes

The following image shows the effect of this method



"move" - Moves (shifts, translates) a layer (modifies the layer)

Usage:

- `layer.move(dx, dy)`

Moved the input by the given distance. The layer that this method is called upon is modified and the modified version is returned for further processing.

Shift distances can be given as floating-point values (in micron) or integer values (in database units). To explicitly specify the unit, use the unit denominators.

"moved" - Moves (shifts, translates) a layer

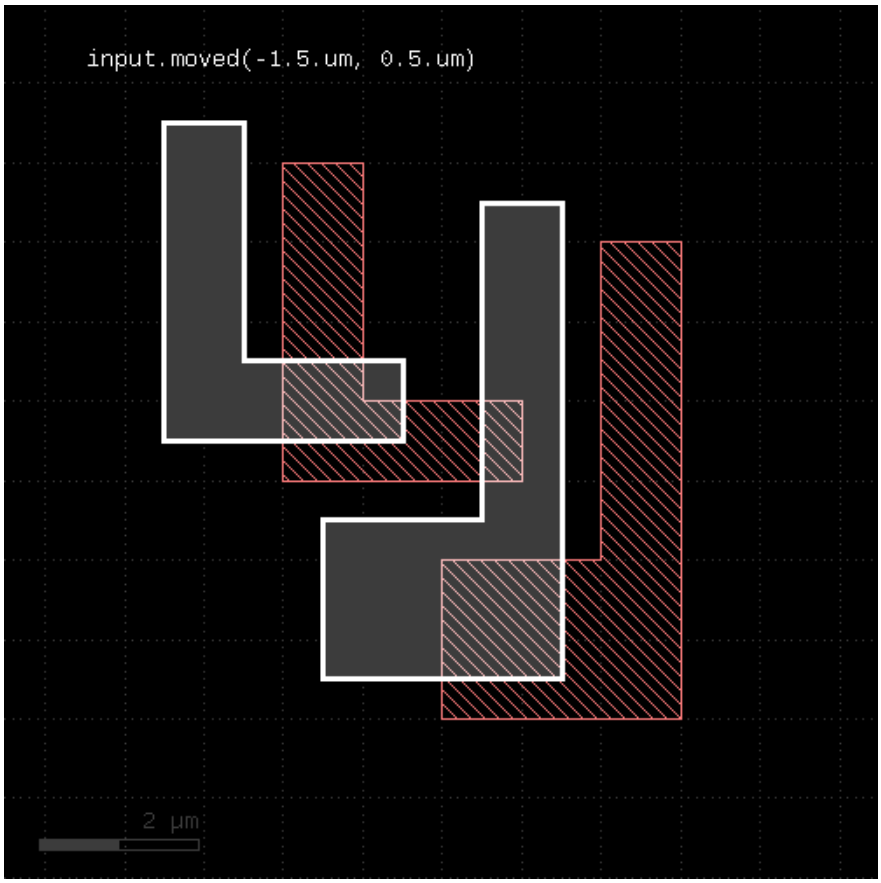
Usage:

- `layer.moved(dx, dy)`

Moves the input layer by the given distance (x, y) and returns the moved layer. The layer that this method is called upon is not modified.

Shift distances can be given as floating-point values (in micron) or integer values (in database units). To explicitly specify the unit, use the unit denominators.

The following images shows the effect of the "moved" method:



"nets" - Pulls net shapes from selected or all nets, optionally annotating nets with properties

Usage:

- `layer.nets`
- `layer.nets(net_filter)`
- `layer.nets(circuit_filter, net_filter)`
- `layer.nets(netter, ...)`
- `layer.nets(prop(key), ...)`
- `layer.nets(prop(key), ...)`

This method needs a layer that has been used in a connect statement. It will take the shapes corresponding to this layer for all or selected nets and attach the net identity in form of a user property.

This way, the resulting shapes can be used in property-constrained boolean operations or DRC checks to implement operations in connected or non-connected mode.

A glob-style name pattern can be supplied to filter nets. Nets are always complete - subnets from subcircuits are not selected. The net name is taken from the net's home circuit (to topmost location where all net connections are formed). You can specify a circuit filter to select nets from certain circuits only or give a Circuit object explicitly.

```
connect(metal1, via1)
```

```
connect(via1, metal2)

metal1_all_nets = metal1.nets
metal1_vdd      = metal1.nets("VDD")
metal1_vdd      = metal1.nets("TOPLEVEL", "VDD")
```

By default, the property key used for the net identity is numerical 0 (integer). You can change the key by giving a property key with the "prop" qualifier. Using "nil" for the key will disable properties:

```
metal1_vdd = metal1.nets("VDD", prop(1))
# disables properties:
metal1_vdd = metal1.nets("VDD", prop(nil))
```

If a custom netter object has been used for the construction of the connectivity, pass it to the "nets" method among the other arguments.

"non_rectangles" - Selects all polygons from the input which are not rectangles

Usage:

- `layer.non_rectangles`

This method is available for polygon layers. By default "merged" semantics applies, i.e. all polygons are merged before non-rectangles are selected (see clean and raw).

"non_rectilinear" - Selects all non-rectilinear polygons from the input

Usage:

- `layer.non_rectilinear`

This method is available for polygon layers. By default "merged" semantics applies, i.e. all polygons are merged before non-rectilinear polygons are selected (see clean and raw).

"non_squares" - Selects all polygons from the input which are not squares

Usage:

- `layer.non_rectangles`

This method is available for polygon layers. By default "merged" semantics applies, i.e. all polygons are merged before non-squares are selected (see clean and raw).

"non_strict" - Marks a layer for non-strict handling

Usage:

- `layer.non_strict`

See strict for details about this option.

This feature has been introduced in version 0.23.2.

"not" - Boolean NOT operation

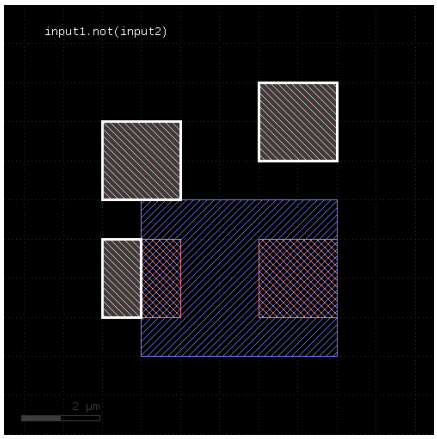
Usage:

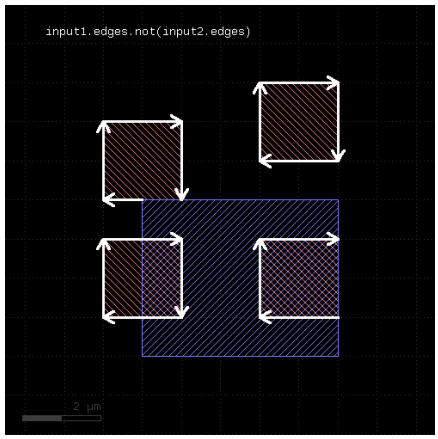
- `layer.not(other [, prop_constraint ])`

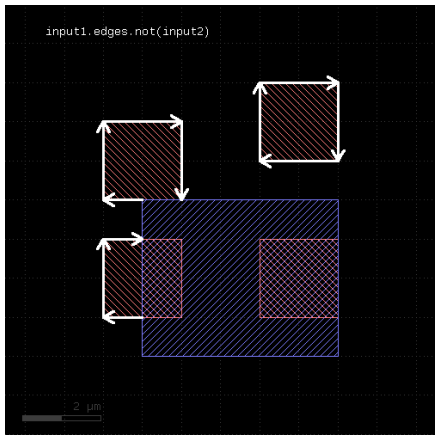
The method computes a boolean NOT between self and other. It is an alias for the "-" operator.

This method is available for polygon and edge layers. If the first operand is an edge layer and the second is an edge layer, the result will be the edges of the first operand which are outside the polygons of the second operand.

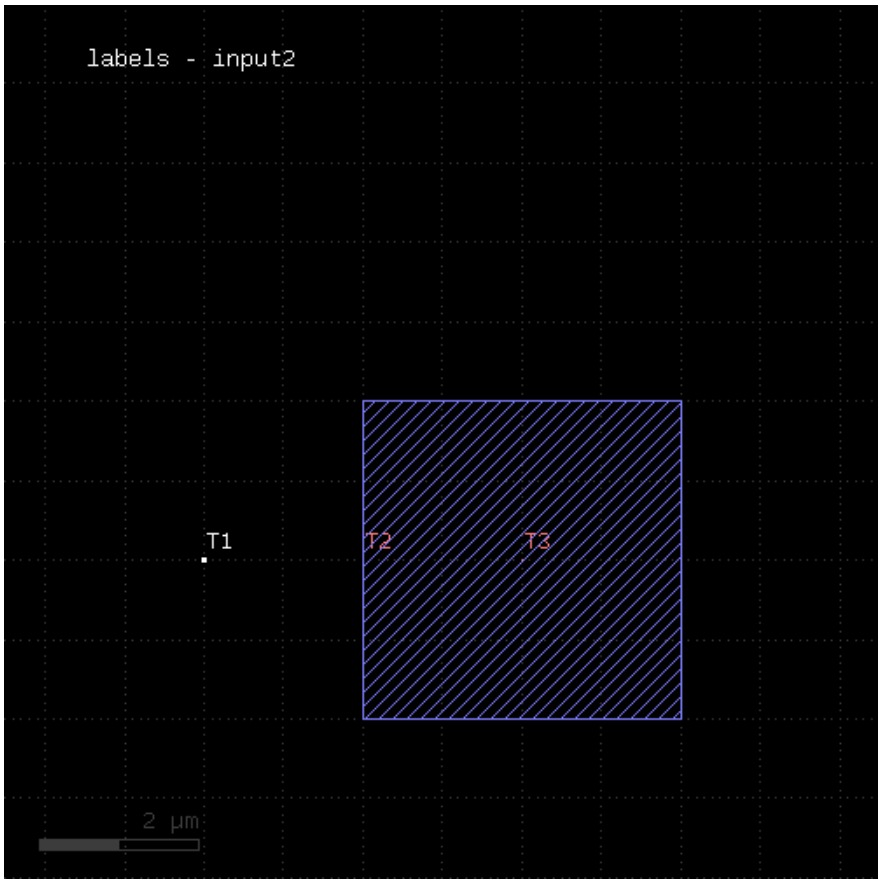
The following images show the effect of the "not" method on polygons and edges (input1: red, input2: blue):







The NOT operation can be applied between a text and a polygon layer. In this case, the texts outside the polygons will be written to the output (labels: red, input2: blue):



When a properties constraint is given, the operation is performed only between shapes with the given relation. Together with the ability to provide net-annotated shapes through the nets method, this allows constraining the boolean operation to shapes from the same or from different nets.

See prop_eq, prop_ne and prop_copy for details.

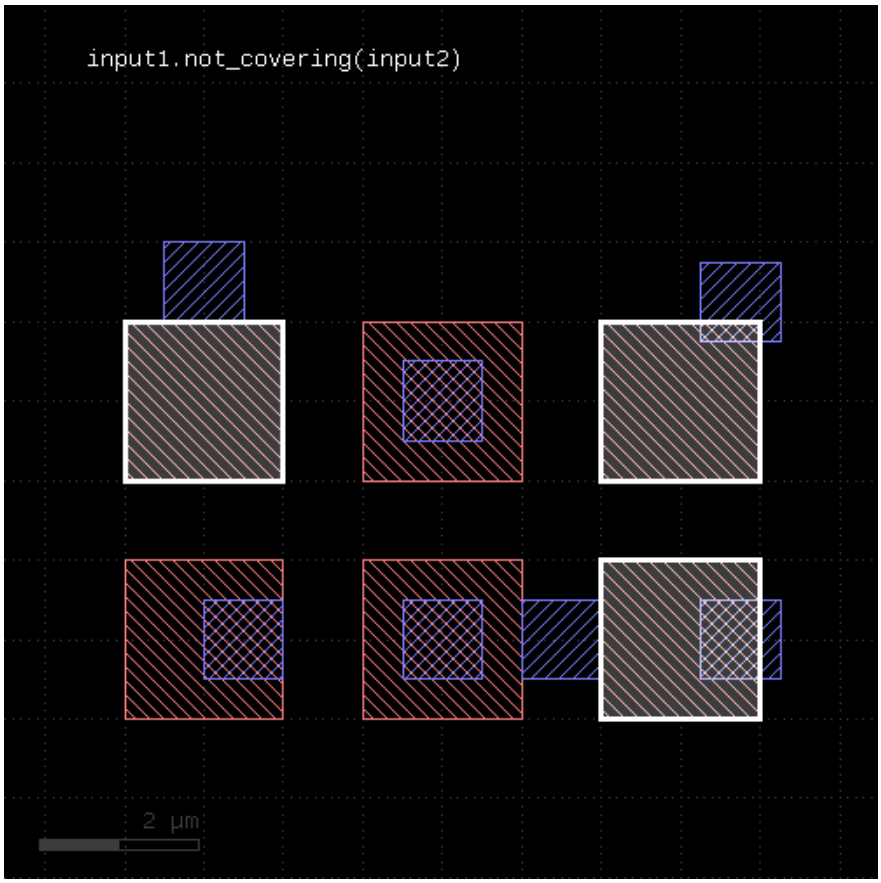
"not_covering" - Selects shapes or regions of self which do not cover (enclose) one or more shapes from the other region

Usage:

- `layer.not_covering(other)`
- `layer.not_covering(other, min_count)`
- `layer.not_covering(other, min_count, max_count)`
- `layer.not_covering(other, min_count .. max_count)`

This method selects all shapes or regions from self which do not cover shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. This method returns the inverse of covering and provides the same options.

The following image shows the effect of the "not_covering" method:



This method is available for polygons only. It returns a new layer containing the selected shapes. A version which modifies self is select_not_covering.

"not_in" - Selects shapes or regions of self which are not contained in the other layer

Usage:

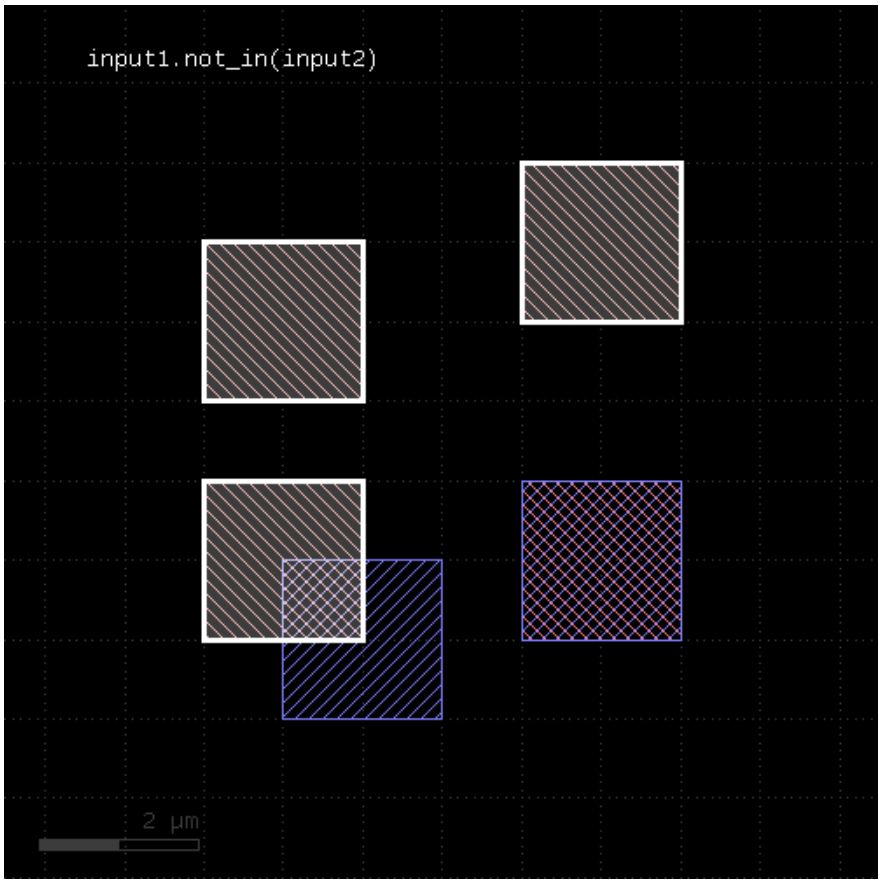
- `layer.not_in(other)`

This method selects all shapes or regions from self which are not contained the other region exactly. It will use individual shapes from self or other if the respective region is in raw mode. If not, it will use coherent regions or combined edges from self or other.

It will return a new layer containing the selected shapes. A method which selects all shapes contained in the other layer is in.

This method is available for polygon and edge layers.

The following image shows the effect of the "not_in" method (input1: red, input2: blue):



"not_inside" - Selects edges or polygons of self which are not inside edges or polygons from the other layer

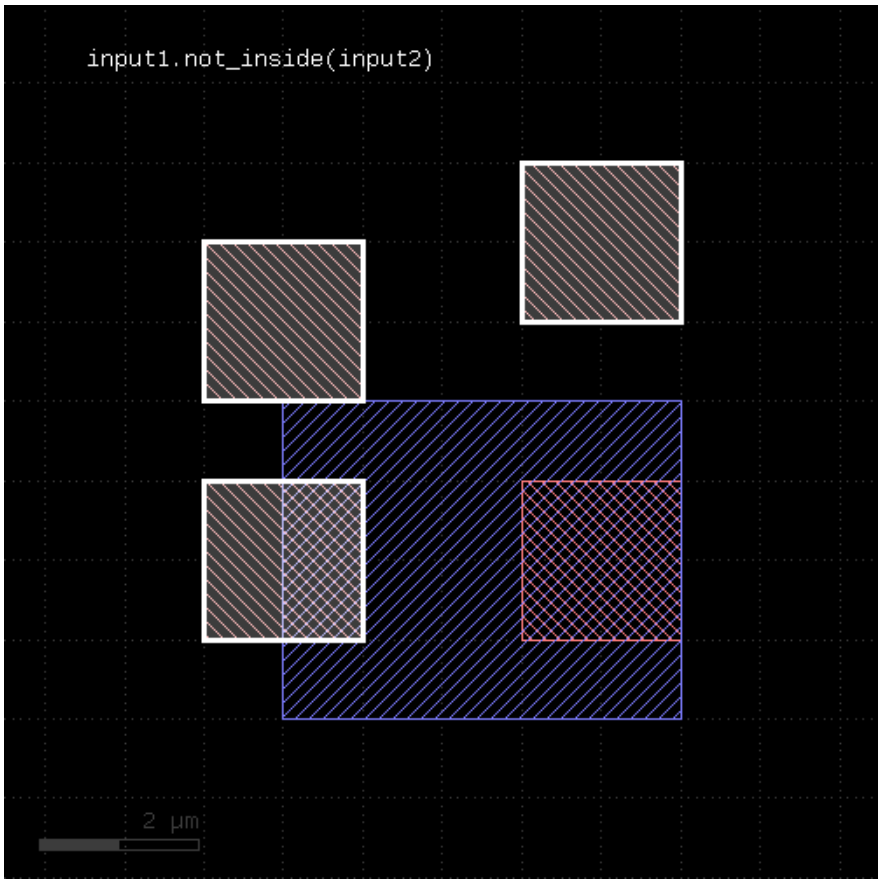
Usage:

- `layer.not_inside(other)`

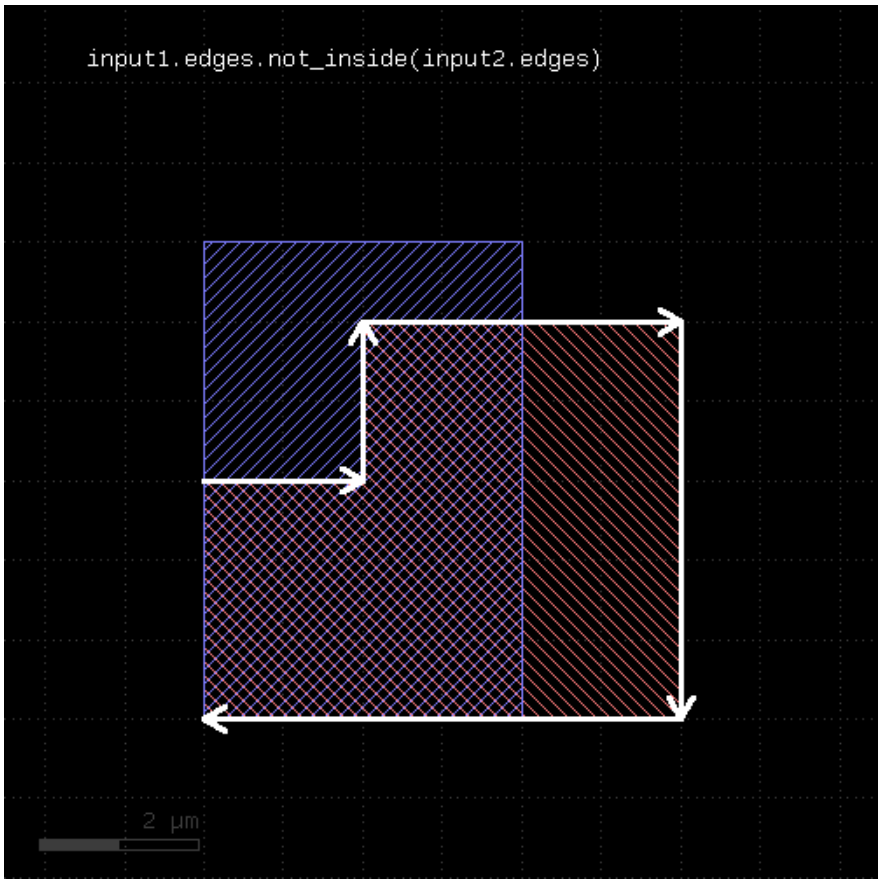
This method computes the inverse of inside - i.e. edges or polygons from the layer not being inside polygons or edges from the other layer.

This method returns a new layer containing the selected shapes. A version which modifies self is select_not_inside. split_inside is a function computing both results of inside and not_inside in a single call. outside is a similar function selecting edges or polygons outside other edges or polygons. Note that "outside" is not the same than "not inside".

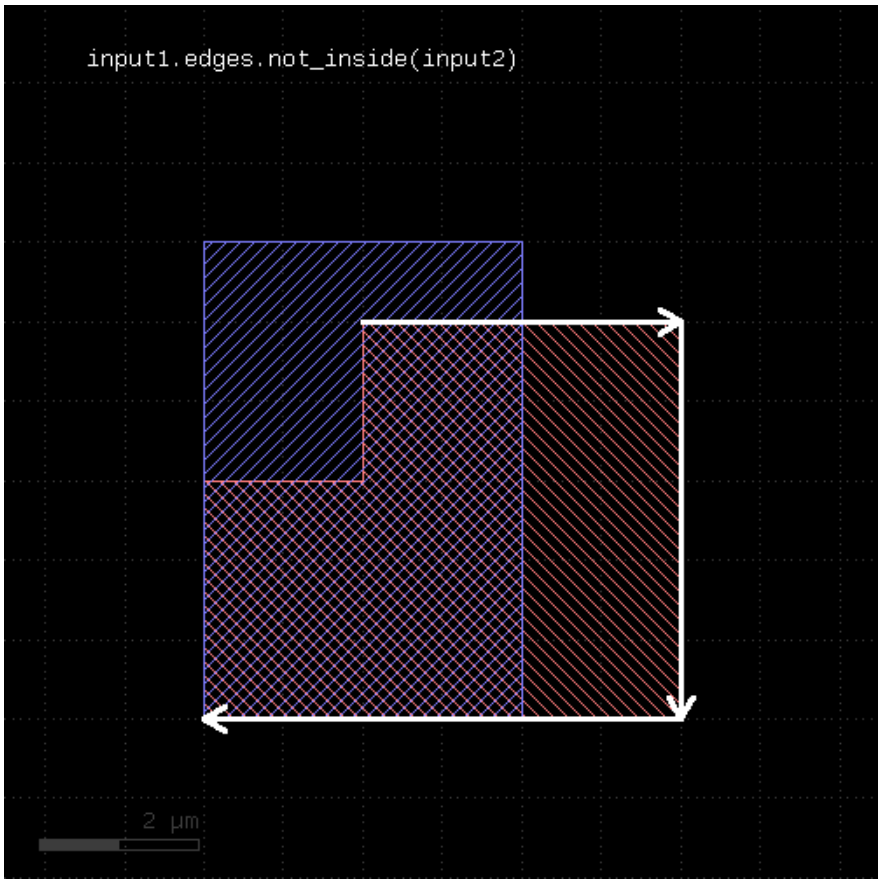
The following image shows the effect of the "not_inside" method for polygon layers (input1: red, input2: blue):



The following images show the effect of the "not_inside" method for edge layers and edge or polygon layers the second input. Note that the edges are computed from the polygons in this example (input1: red, input2: blue):



input1.edges.not_inside(input2.edges)
2 µm



"not_interacting" - Selects shapes or regions of self which do not touch or overlap shapes from the other region

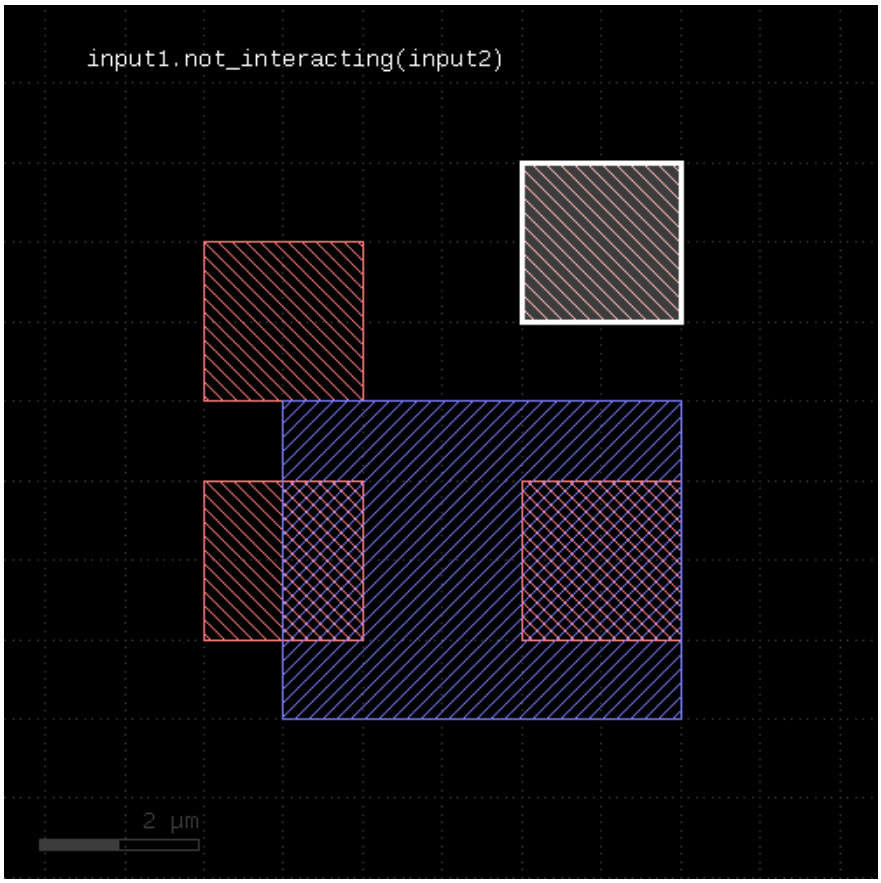
Usage:

- `layer.not_interacting(other)`
- `layer.not_interacting(other, min_count)`
- `layer.not_interacting(other, min_count, max_count)`
- `layer.not_interacting(other, min_count .. max_count)`

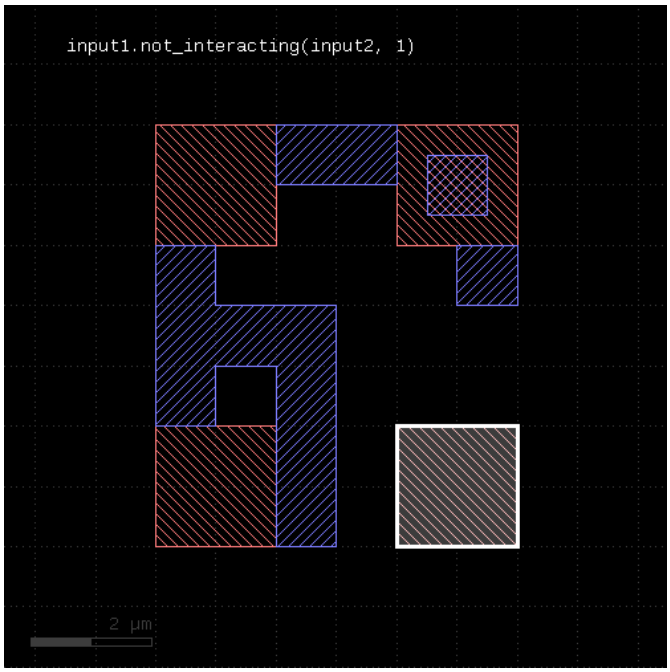
This method selects all shapes or regions from self which do not touch or overlap shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It returns a new layer containing the selected shapes. A version which modifies self is select_not_interacting.

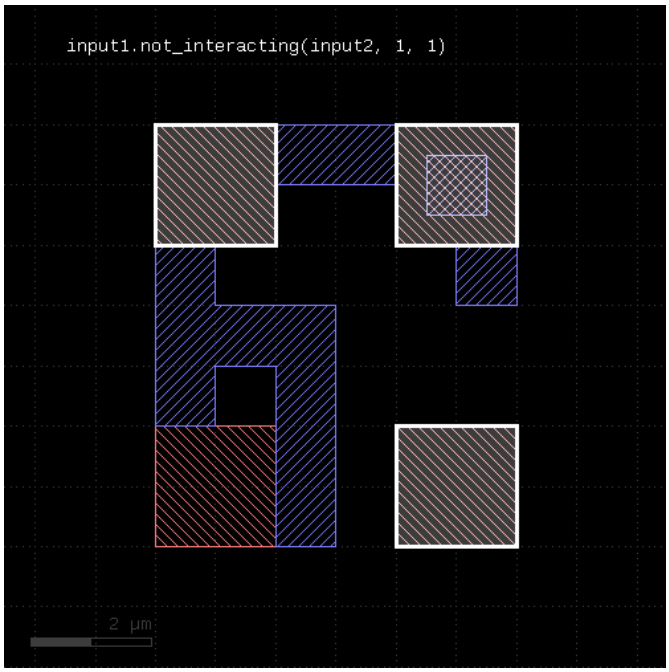
This method is available for polygon, text and edge layers. Edges can be selected with respect to other edges or polygons. Texts can be selected with respect to polygons. Polygons can be selected with respect to edges, texts and other polygons.

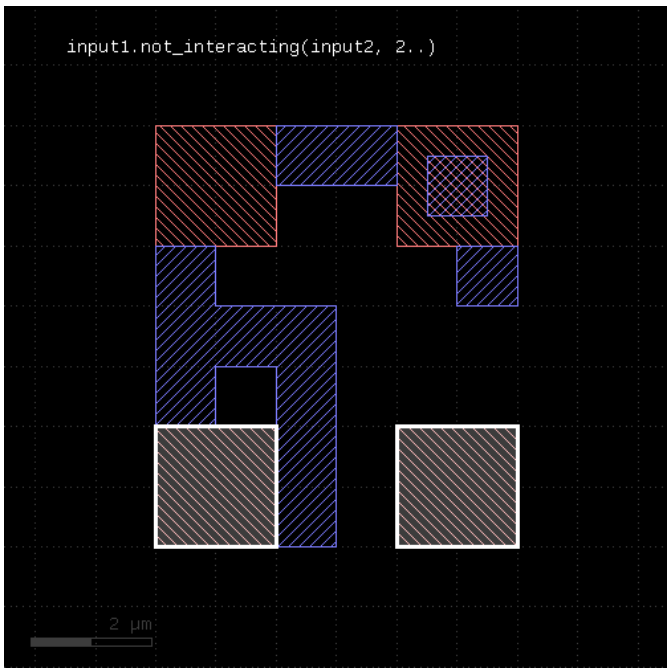
The following image shows the effect of the "not_interacting" method (input1: red, input2: blue):

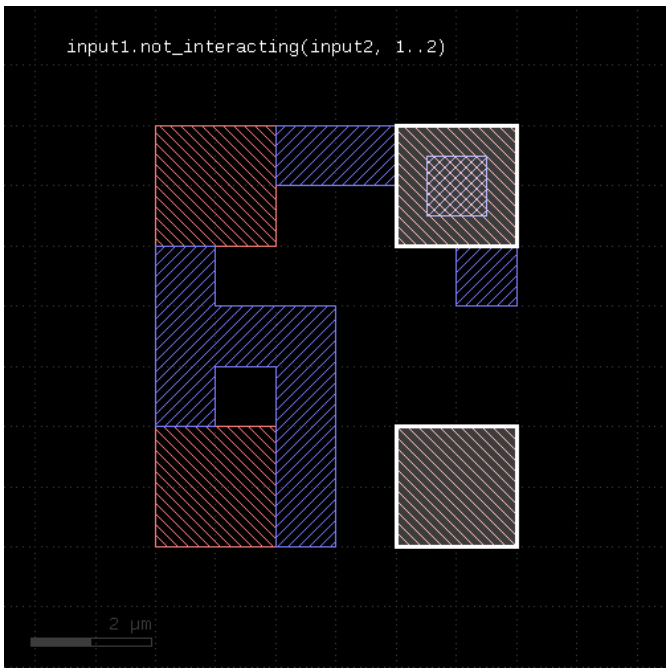


If a single count is given, shapes from self are selected only if they interact with less than the given number of (different) shapes from the other layer. If a min and max count is given, shapes from self are selected only if they interact with less than min_count or more than max_count different shapes from the other layer. Two polygons overlapping or touching at two locations are counted as single interactions.









"not_outside" - Selects edges or polygons of self which are not outside edges or polygons from the other layer

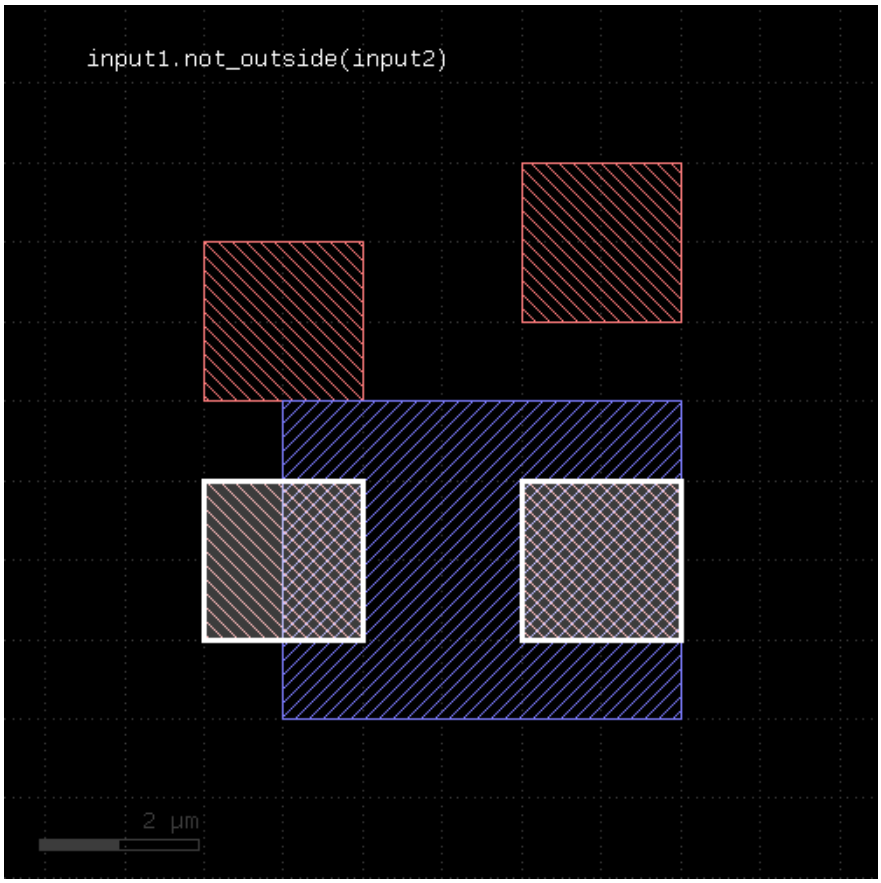
Usage:

- `layer.not_outside(other)`

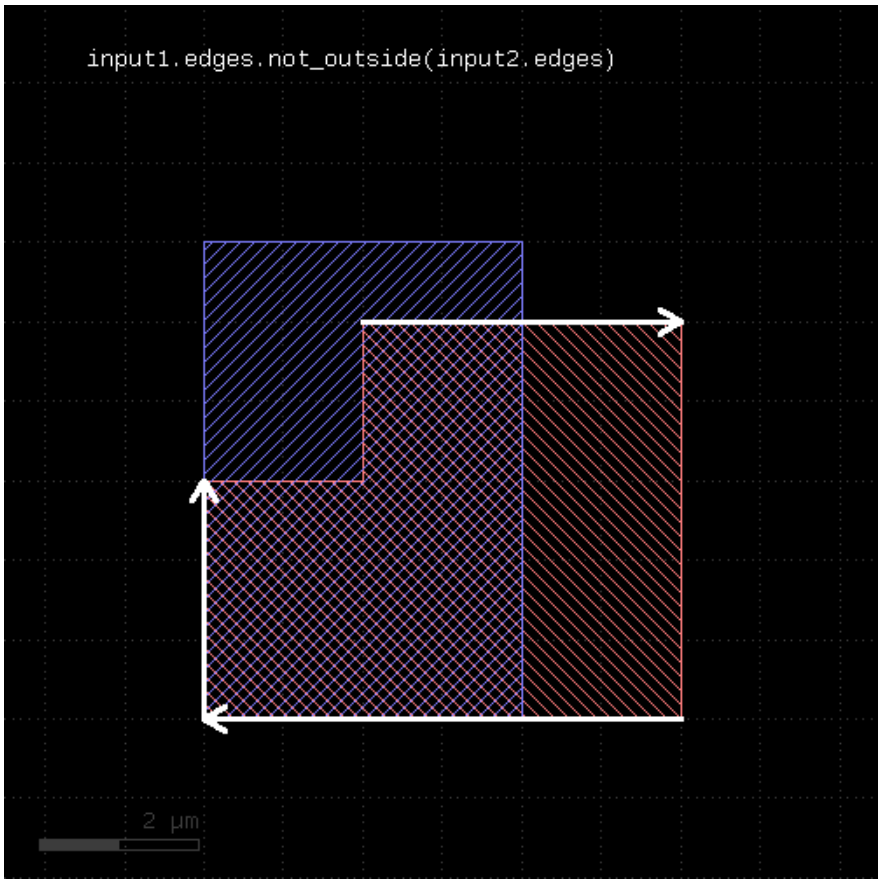
This method computes the inverse of outside - i.e. edges or polygons from the layer not being outside polygons or edges from the other layer.

This method returns a new layer containing the selected shapes. A version which modifies self is select_not_outside. split_outside is a function computing both results of outside and not_outside in a single call. outside is a similar function selecting edges or polygons outside other edges or polygons. Note that "outside" is not the same than "not outside".

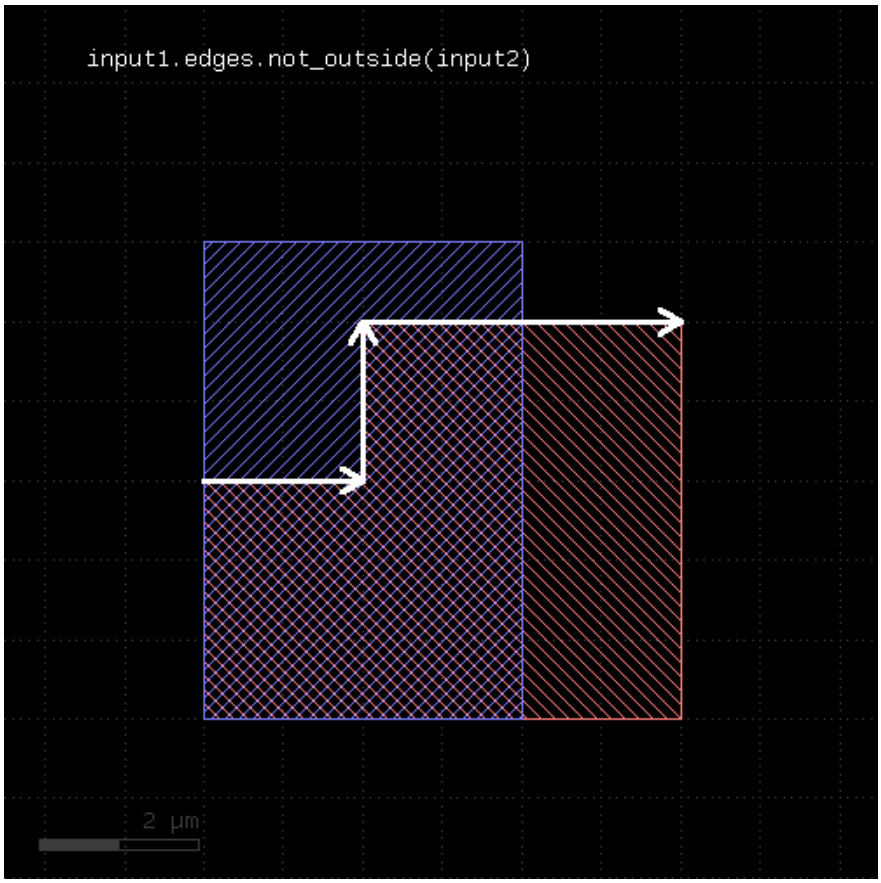
The following image shows the effect of the "not_outside" method for polygon layers (input1: red, input2: blue):



The following images show the effect of the "not_outside" method for edge layers and edge or polygon layers the second input. Note that the edges are computed from the polygons in this example (input1: red, input2: blue):



input1.edges.not_outside(input2.edges)
2 µm



"not_overlapping" - Selects shapes or regions of self which do not overlap shapes from the other region

Usage:

- `layer.not_overlapping(other)`
- `layer.not_overlapping(other, min_count)`
- `layer.not_overlapping(other, min_count, max_count)`
- `layer.not_overlapping(other, min_count .. max_count)`

This method selects all shapes or regions from self which do not overlap shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. This method will return the inverse of overlapping and provides the same options.

The "not_overlapping" method is similar to the outside method. However, "outside" does not provide the option to specify counts.

This method is available for polygons only. It returns a new layer containing the selected shapes. A version which modifies self is select_not_overlapping.

"notch" - An intra-polygon spacing check

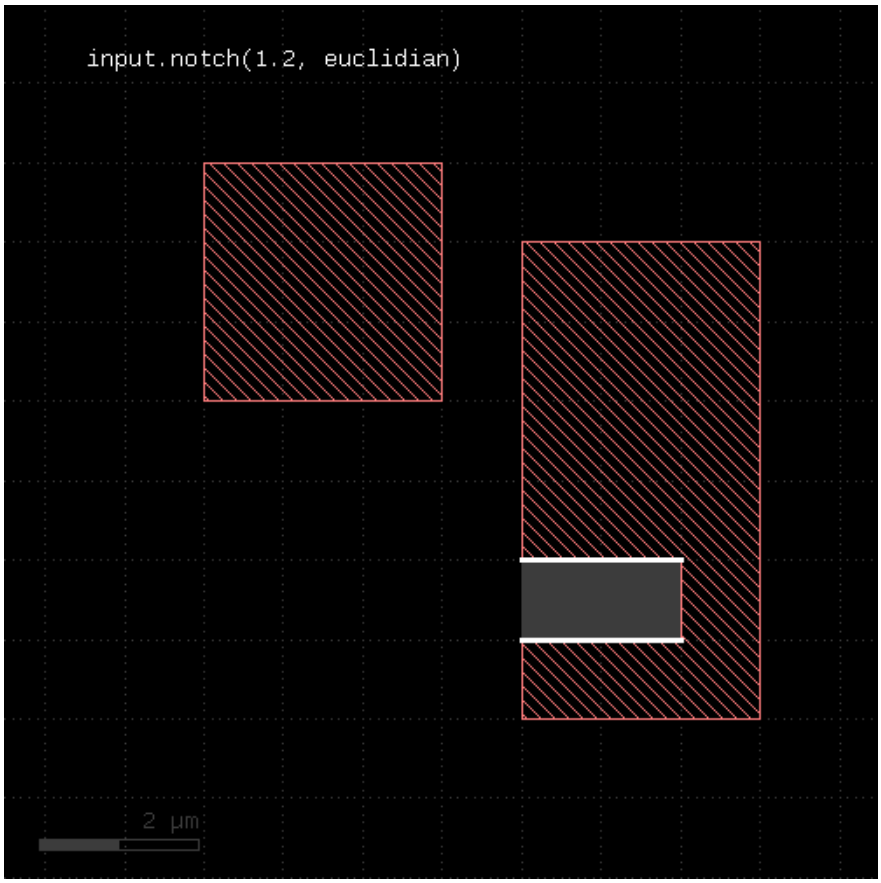
Usage:

- `layer.notch(value [, options])`

Note: "notch" is available as an operator for the "universal DRC" function Layer#drc within the DRC framework. This variant has more options and is more intuitive to use. See notch for more details.

See space for a description of this method. "notch" is the space check variant which finds space violations within a single polygon, but not against other polygons. In contrast to space, the "notch" method is available for polygon layers only, since only on such layers different polygons can be identified. Also, opposite and rectangle error filtering is not available for this method.

The following image shows the effect of the notch check:



"odd_polygons" - Checks for odd polygons (self-overlapping, non-orientable)

Usage:

- `layer.odd_polygons`

Returns the parts of the polygons which are not orientable (i.e. "8" configuration) or self-overlapping. Merged semantics does not apply for this method. Always the raw polygons are taken (see raw).

The odd_polygons check is not available in deep mode currently. See deep_reject_odd_polygons for an alternative.

"ongrid" - Checks for on-grid vertices

Usage:

- `layer.ongrid(g)`
- `layer.ongrid(gx, gy)`

Returns a single-vertex marker for each vertex whose x coordinate is not a multiple of g or gx or whose y coordinate is not a multiple of g or gy. The single-vertex markers are edge pair objects which describe a single point. When setting the grid to 0, no grid check is performed in that specific direction.

This method requires a polygon layer. Merged semantics applies (see raw and clean).

"or" - Boolean OR operation

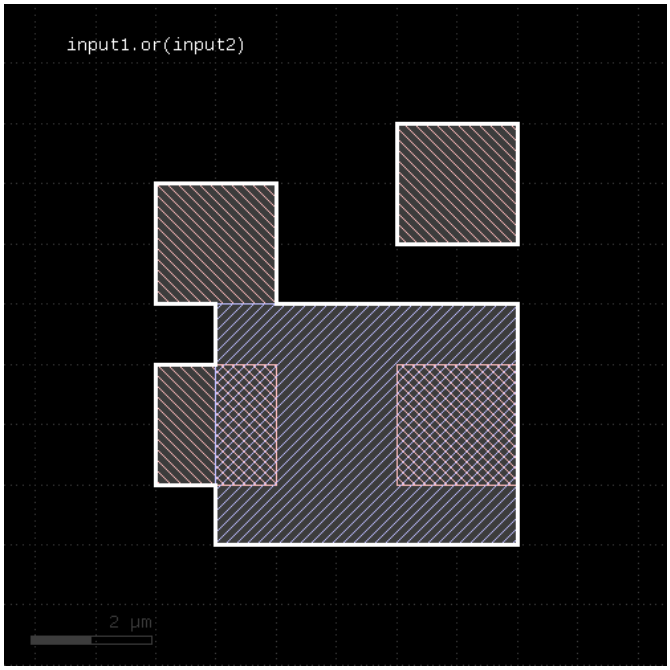
Usage:

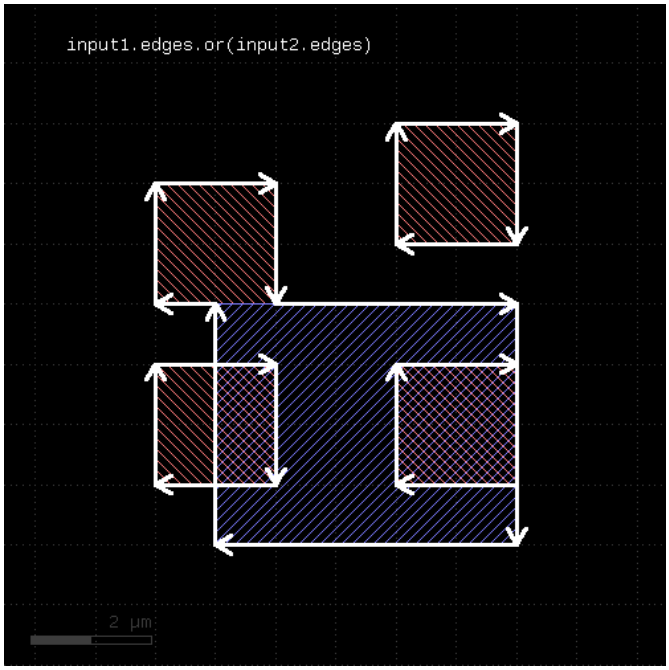
- `layer.or(other)`

The method computes a boolean OR between self and other. It is an alias for the "|" operator.

This method is available for polygon and edge layers.

The following images show the effect of the "or" method on polygons and edges (input1: red, input2: blue):





"output" - Outputs the content of the layer

Usage:

- `layer.output(specs)`

This method will copy the content of the layer to the specified output.

If a report database is selected for the output, the specification has to include a category name and optionally a category description.

If the layout is selected for the output, the specification can consist of one to three parameters: a layer number, a data type (optional, default is 0) and a layer name (optional). Alternatively, the output can be specified by a single LayerInfo object.

See report and target on how to configure output to a target layout or report database.

See also new_target and new_report on how to create additional targets for output. This allows saving certain layers to different files than the standard target or report. To do so, create a new target or report using one of these functions and pass that object to the corresponding "output" call as an additional argument.

Example:

```
check1 = ...
check2 = ...
check3 = ...

second_report = new_report("Only for check2", "check2.lyrdb")

check1.output("Check 1")
check2.output("Check 2", second_report)
check3.output("Check 3")
```

"outside" - Selects edges or polygons of self which are outside edges or polygons from the other layer

Usage:

- `layer.outside(other)`

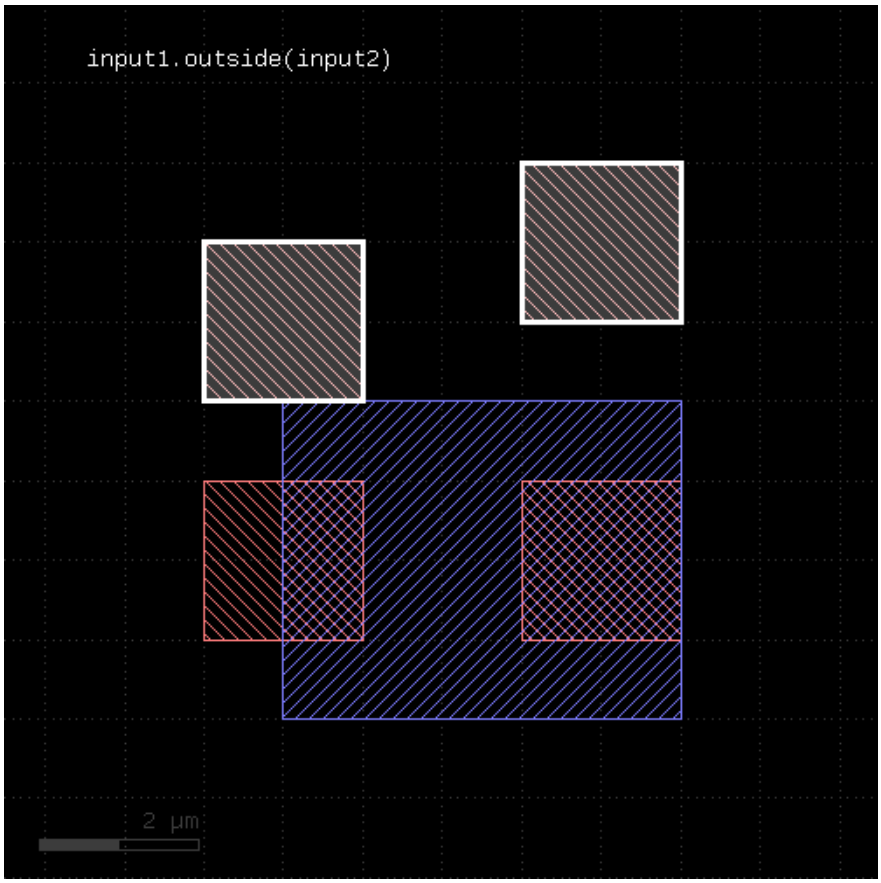
If layer is a polygon layer, the other layer needs to be a polygon layer too. In this case, this method selects all polygons which are entirely outside polygons from the other layer.

If layer is an edge layer, the other layer can be polygon or edge layer. In the first case, all edges entirely outside the polygons from the other layer are selected. If the other layer is an edge layer, all edges entirely outside of edges from the other layer are selected.

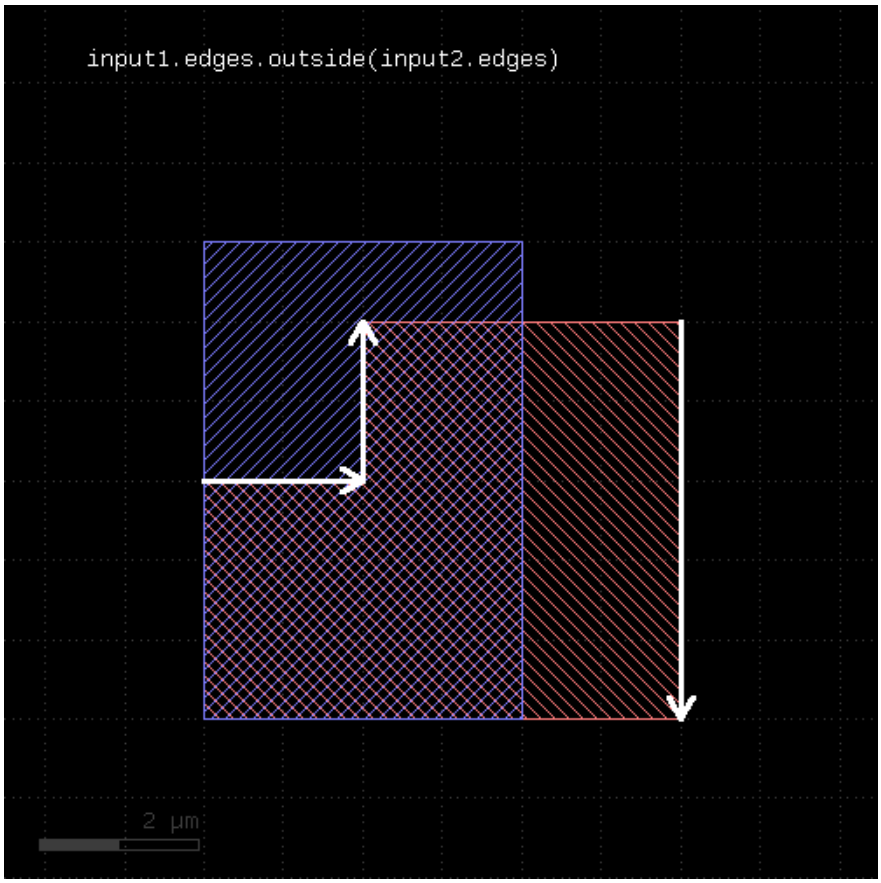
Merged semantics applies - i.e. edges or polygons are joined before the result is computed, unless the layers are in raw mode.

This method returns a new layer containing the selected shapes. A version which modifies self is select_outside. not_outside is a function computing the inverse of outside. split_outside is a function computing both results in a single call. outside is a similar function selecting edges or polygons outside other edges or polygons.

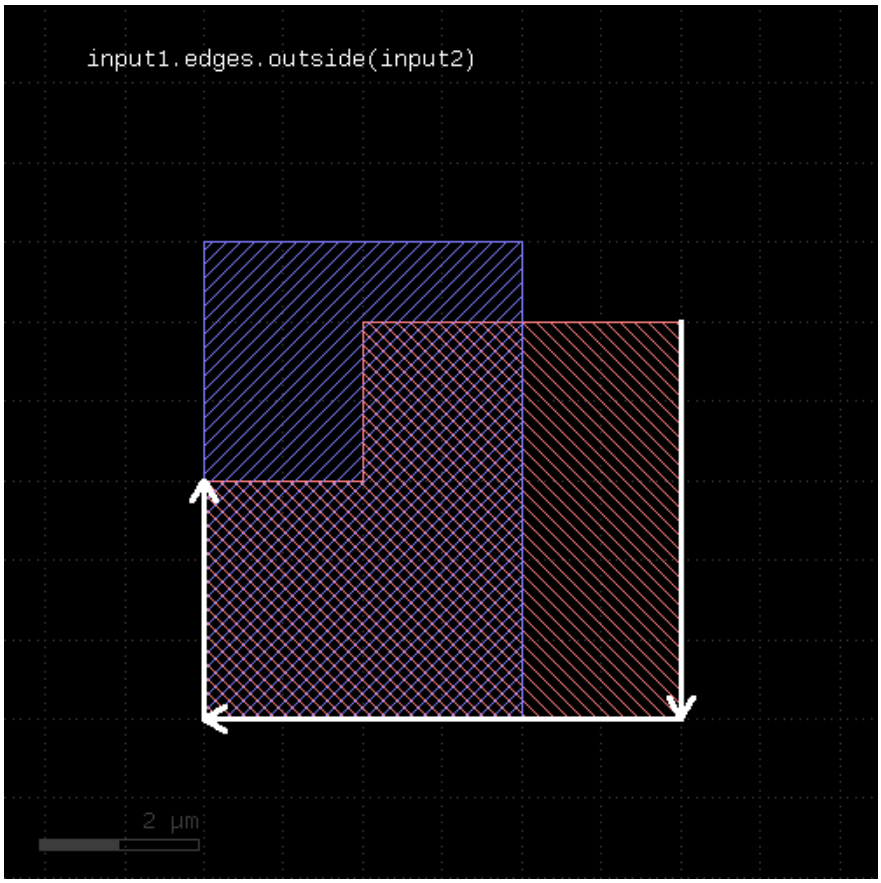
The following image shows the effect of the "outside" method for polygons (input1: red, input2: blue):



The following images show the effect of the "outside" method for edge layers and edge or polygon layers the second input. Note that the edges are computed from the polygons in this example (input1: red, input2: blue):



input1.edges.outside(input2.edges)
2 µm



"outside_part" - Returns the parts of the edges outside the given region

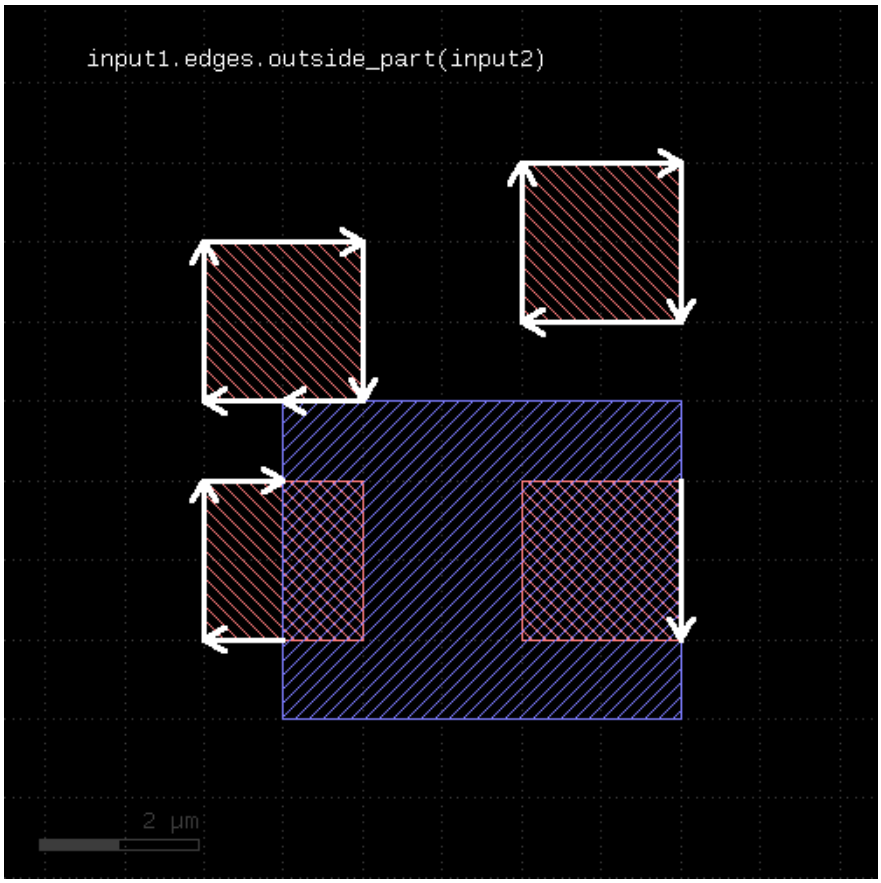
Usage:

- `layer.outside_part(region)`

This method returns the parts of the edges which are outside the given region. This is similar to the "&" operator, but this method does not remove edges that are exactly on the boundaries of the polygons of the region.

This method is available for edge layers. The argument must be a polygon layer.

inside_part is a method computing the opposite part. inside_outside_part is a method computing both inside and outside part in a single call.



"overlap" - An overlap check

Usage:

- `layer.overlap(other_layer, value [, options])`

Note: "overlap" is available as an operator for the "universal DRC" function drc within the DRC framework. This variant has more options and is more intuitive to use. See overlap for more details.

This method checks whether layer and other_layer overlap by at least the given length. Locations, where this is not the case will be reported in form of edge pair error markers. Locations, where both layers touch will be reported as errors as well. Formally such locations form an overlap with a value of 0. Locations, where both regions do not overlap or touch will not be reported. Such regions can be detected with outside or by a boolean "not".

The options are the same as for separation.

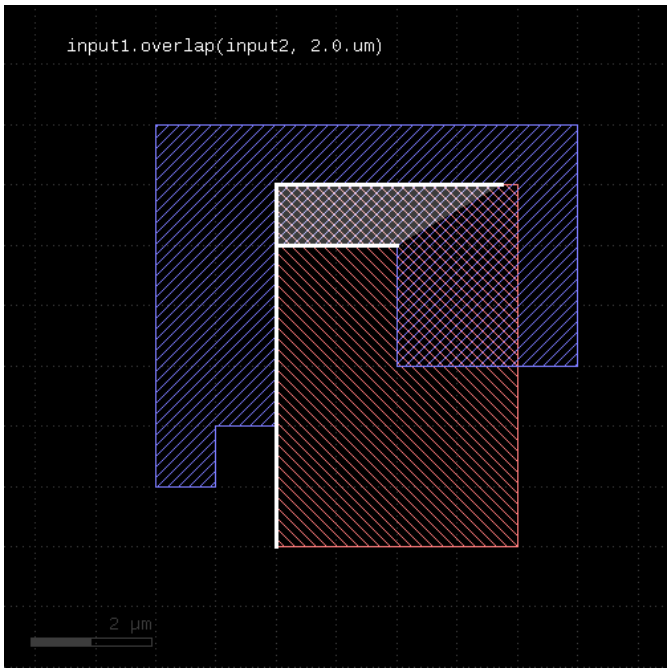
Formally, the overlap method is a two-layer width check. In contrast to the single- layer width method (width), the zero value also triggers an error and separate polygons are checked against each other, while for the single-layer width, only single polygons are considered.

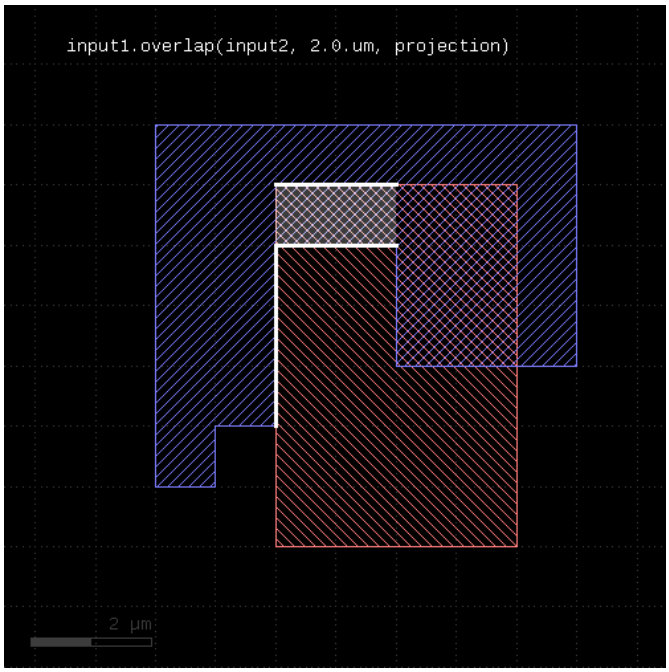
The overlap method can be applied to both edge or polygon layers. On edge layers the orientation of the edges matters: only edges which run back to back with their inside side pointing towards each other are checked for distance.

As for the other DRC methods, merged semantics applies.

Distance values can be given as floating-point values (in micron) or integer values (in database units). To explicitly specify the unit, use the unit denominators.

The following images show the effect of the overlap check (input1: red, input2: blue):





"overlapping" - Selects shapes or regions of self which overlap shapes from the other region

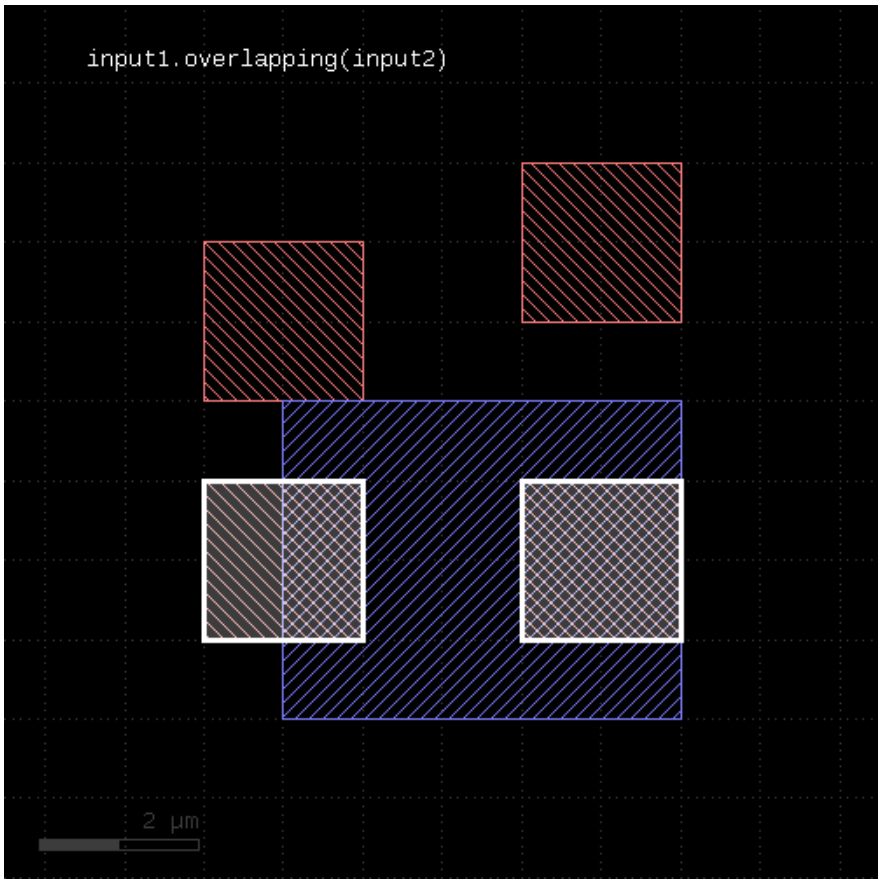
Usage:

- `layer.overlapping(other)`
- `layer.overlapping(other, min_count)`
- `layer.overlapping(other, min_count, max_count)`
- `layer.overlapping(other, min_count .. max_count)`

This method selects all shapes or regions from self which overlap shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It returns a new layer containing the selected shapes. A version which modifies self is select_overlapping.

This method is available for polygons only.

The following image shows the effect of the "overlapping" method:



A range of counts can be specified. If so, the shape from the primary layer is only selected when overlapping a given number of shapes from the other layer. For the interpretation of the count see interacting.

"perimeter" - Returns the total perimeter of the polygons in the region

Usage:

- `layer.perimeter`

This method requires a polygon layer. It returns the total perimeter of all polygons in micron. Merged semantics applies, i.e. before computing the perimeter, the polygons are merged unless raw mode is chosen (see raw).

The returned value gives the perimeter in micrometer units.

"polygons" - Returns polygons from edge pairs

Usage:

- `layer.polygons([ enlargement ])`

This method applies to edge pair collections. The edge pairs will be converted into polygons connecting the edges the edge pairs are made of. In order to properly handle special edge pairs (coincident edges, point-like edges etc.) an enlargement parameter can be specified which will make the resulting polygon somewhat larger than the original edge pair. If the enlargement parameter is 0, special edge pairs with an area of 0 will be dropped.

"polygons?" - Returns true, if the layer is a polygon layer

Usage:

- `layer.polygons?`

"pull_inside" - Selects shapes or regions of other which are inside polygons from the this region

Usage:

- `layer.pull_inside(other)`

This method selects all shapes or regions from other which are inside polygons from this region. Unless other is in raw mode (see raw), coherent regions are selected from other, otherwise individual shapes are selected.

The functionality is similar to select_inside, but chosing shapes from other rather than from self. Because in deep mode the hierarchy reference comes from self, this method provides a way to pull shapes from other to the hierarchy to self.

This method is available for polygon layers. Other needs to be a polygon layer too.

"pull_interacting" - Selects shapes or edges of other which touch or overlap shapes from the this region

Usage:

- `layer.pull_interacting(other)`

This method selects all shapes or regions from other which touch or overlap shapes from this region. Unless other is in raw mode (see raw), coherent regions are selected from other, otherwise individual shapes are selected.

The functionality is similar to select_interacting, but chosing shapes from other rather than from self. Because in deep mode the hierarchy reference comes from self, this method provides a way to pull shapes from other to the hierarchy to self.

This method will neither modify self nor other.

This method is available for polygon, edge and text layers, similar to interacting.

"pull_overlapping" - Selects shapes or regions of other which overlap shapes from the this region

Usage:

- `layer.pull_overlapping(other)`

This method selects all shapes or regions from other which overlap shapes from this region. Unless other is in raw mode (see raw), coherent regions are selected from other, otherwise individual shapes are selected.

The functionality is similar to select_overlapping, but chosing shapes from other rather than from self. Because in deep mode the hierarchy reference comes from self, this method provides a way to pull shapes from other to the hierarchy to self.

This method is available for polygon layers. Other needs to be a polygon layer too.

"raw" - Marks a layer as raw

Usage:

- `layer.raw`

A raw layer basically is the opposite of a "clean" layer (see clean). Polygons on a raw layer are considered "as is", i.e. overlapping polygons are not connected and inner edges may occur due to cut lines. Holes may not exists if the polygons are derived from a representation that does not allow holes (i.e. GDS2 files).

Note that this method will set the state of the layer. In combination with the fact, that copied layers are references to the original layer, this may lead to unexpected results:

```
l = ...
l2 = l1
... do something
l.raw
# now l2 is also a raw layer
```

To avoid that, use the dup method to create a real (deep) copy.

"rectangles" - Selects all rectangles from the input

Usage:

- `layer.rectangles`

This method is available for polygon layers. By default "merged" semantics applies, i.e. all polygons are merged before rectangles are selected (see clean and raw). non_rectangles will select all non-rectangles.

"rectilinear" - Selects all rectilinear polygons from the input

Usage:

- `layer.rectilinear`

This method is available for polygon layers. By default "merged" semantics applies, i.e. all polygons are merged before rectilinear polygons are selected (see clean and raw). non_rectilinear will select all non-rectangles.

"remove_props" - Returns a new layer with all properties removed

Usage:

- `layer.remove_props`

This method will drop all user properties from the layer. Note that a new layer without properties is returned. The original layer stays untouched.

See also select_props and map_props.

"rotate" - Rotates a layer (modifies the layer)

Usage:

- `layer.rotate(a)`

Rotates the input by the given angle (in degree). The layer that this method is called upon is modified and the modified version is returned for further processing.

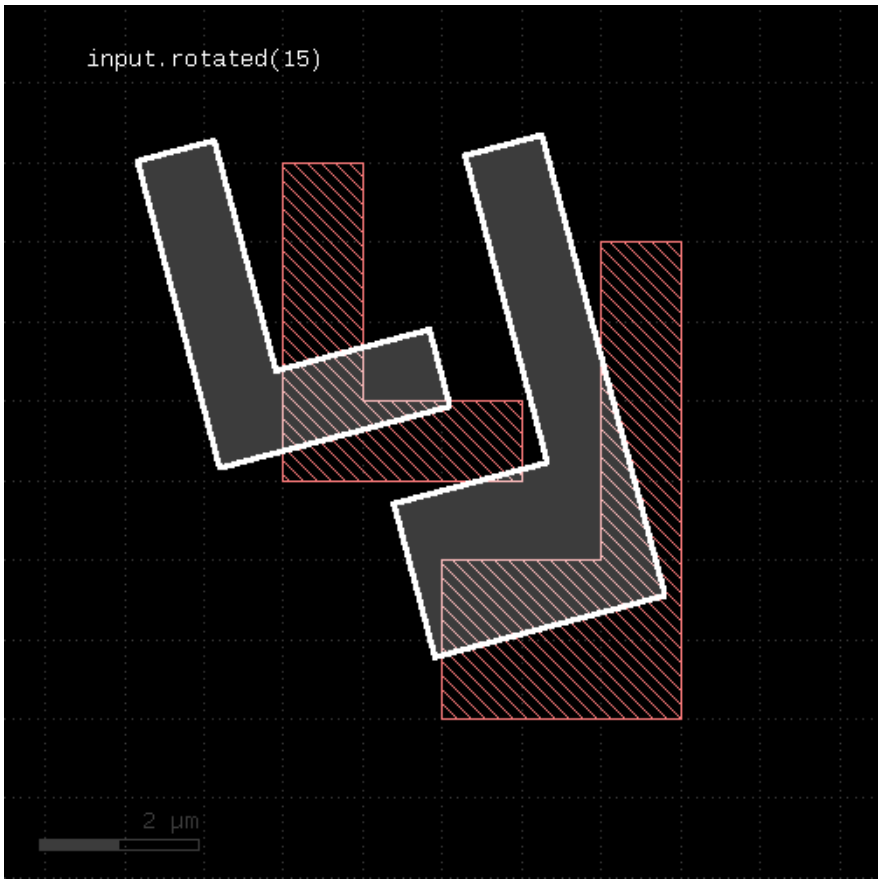
"rotated" - Rotates a layer

Usage:

- `layer.rotated(a)`

Rotates the input layer by the given angle (in degree) and returns the rotated layer. The layer that this method is called upon is not modified.

The following image shows the effect of the "rotated" method:



"rounded_corners" - Applies corner rounding to each corner of the polygon

Usage:

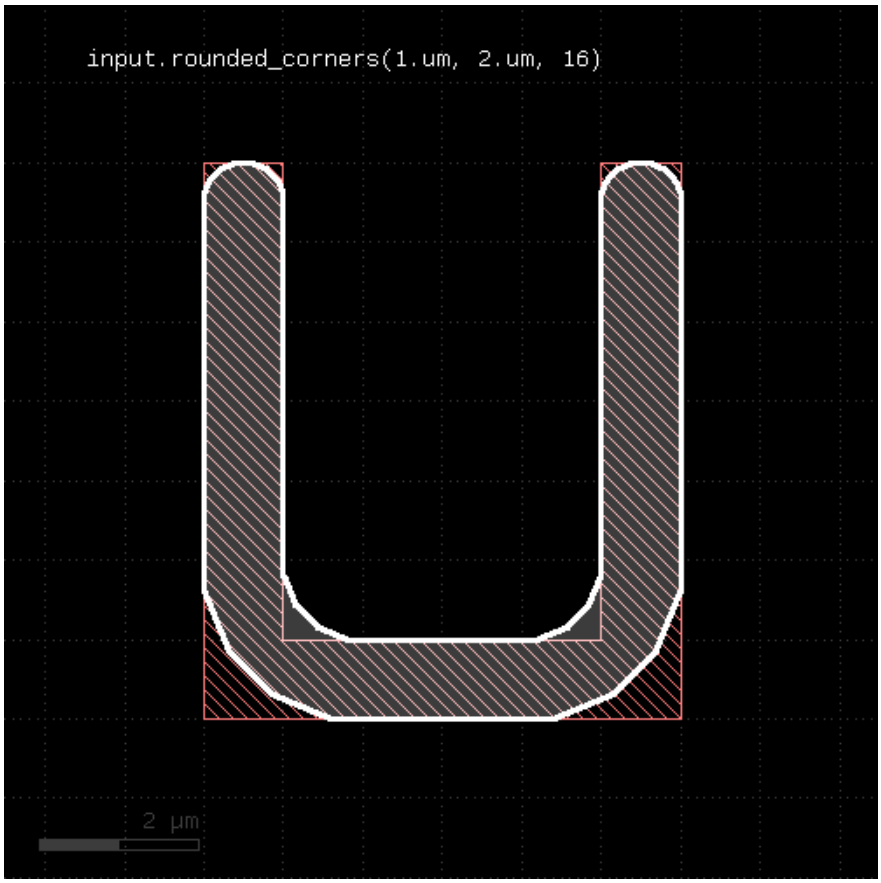
- `layer.rounded_corners(inner, outer, n)`

Inner (concave) corners are replaced by circle segments with a radius given by the "inner" parameter. Outer (convex) corners are relaced by circle segments with a radius given by the "outer" parameter.

The circles are approximated by polygons. "n" segments are used to approximate a full circle.

This method return a layer wit the modified polygons. Merged semantics applies for this method (see raw and clean). If used with tiling, the rounded_corners function may render invalid results because in tiling mode, not the whole merged region may be captured. In that case, inner edges may appear as outer ones and their corners will receive rounding.

The following image shows the effect of the "rounded_corners" method. The upper ends of the vertical bars are rounded with a smaller radius automatically because their width does not allow a larger radius.



"scale" - Scales a layer (modifies the layer)

Usage:

- `layer.scale(f)`

Scales the input. After scaling, features have a f times bigger dimension. The layer that this method is called upon is modified and the modified version is returned for further processing.

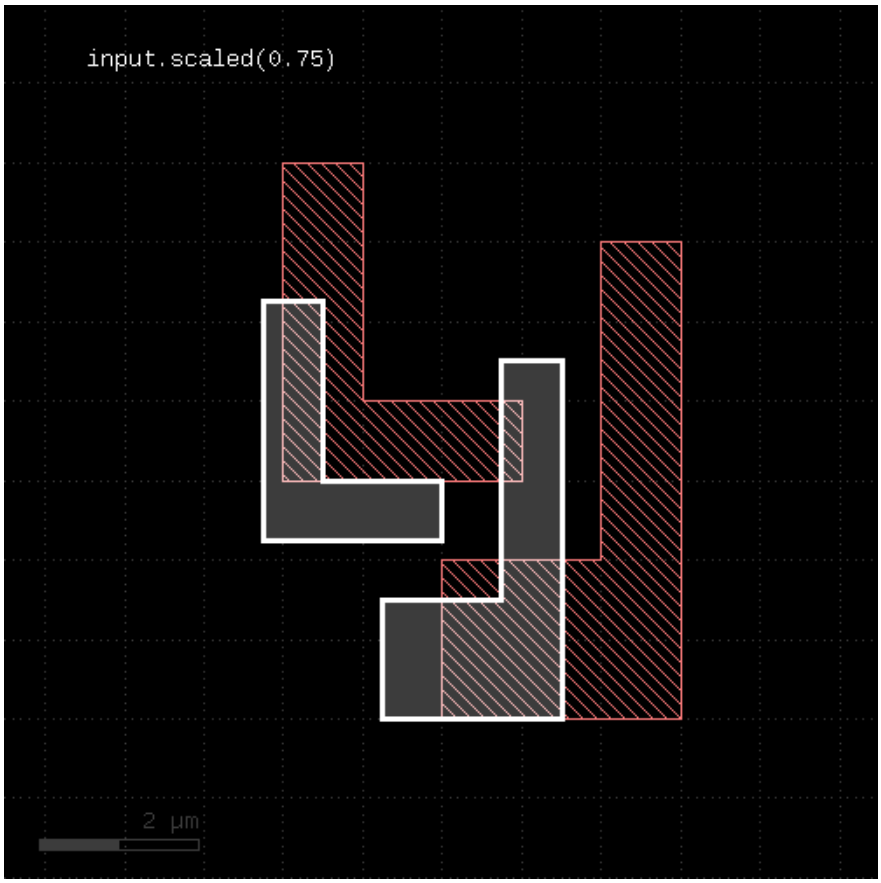
"scaled" - Scales a layer

Usage:

- `layer.scaled(f)`

Scales the input layer and returns a new layer whose features have a f times bigger dimension. The layer that this method is called upon is not modified.

The following images shows the effect of the "scaled" method:



"second_edges" - Returns the second edges of an edge pair collection

Usage:

- `layer.second_edges`

Applies to edge pair collections only. Returns the second edges of the edge pairs in the collection.

Some checks deliver symmetric edge pairs (e.g. space, width, etc.) for which the edges are commutable. "second_edges" will not deliver edges for such edge pairs. Instead, "first_edges" will deliver both.

"select" - Selects edges, edge pairs or polygons based on evaluation of a block

Usage:

- `layer.select { |object| ... }`

This method evaluates the block and returns a new container with those objects for which the block evaluates to true. It is available for edge, polygon and edge pair layers. The corresponding objects are DPolygon, DEdge or DEdgePair.

Because this method executes inside the interpreter, it's inherently slow. Tiling does not apply to this method.

Here is a (slow) equivalent of the area selection method:

```
new_layer = layer.select { |polygon| polygon.area >= 10.0 }
```

"select_covering" - Selects shapes or regions of self which completely cover (enclose) one or more shapes from the other region

Usage:

- `layer.select_covering(other)`
- `layer.select_covering(other, min_count)`
- `layer.select_covering(other, min_count, max_count)`
- `layer.select_covering(other, min_count .. max_count)`

This method selects all shapes or regions from self which cover shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It modifies self to contain the selected shapes. A version which does not modify self is covering.

This method is available for polygons only.

"select_inside" - Selects edges or polygons of self which are inside edges or polygons from the other layer

Usage:

- `layer.select_inside(other)`

This method is the in-place version of inside - i.e. it modifies the layer instead of returning a new layer and leaving the original layer untouched.

"select_interacting" - Selects shapes or regions of self which touch or overlap shapes from the other region

Usage:

- `layer.select_interacting(other)`
- `layer.select_interacting(other, min_count)`
- `layer.select_interacting(other, min_count, max_count)`
- `layer.select_interacting(other, min_count .. max_count)`

This method selects all shapes or regions from self which touch or overlap shapes from the other layer. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It modifies self to contain the selected shapes. A version which does not modify self is interacting.

This method is available for polygon, text and edge layers. Edges can be selected with respect to other edges or polygons. Texts can be selected with respect to polygons. Polygons can be selected with respect to edges, texts and other polygons.

If a single count is given, shapes from self are selected only if they do interact at least with the given number of (different) shapes from the other layer. If a min and max count is given, shapes from self are selected only if they interact with min_count or more, but a maximum of max_count different shapes from the other layer. Two polygons overlapping or touching at two locations are counted as single interactions.

"select_not_covering" - Selects shapes or regions of self which do not cover (enclose) one or more shapes from the other region

Usage:

- `layer.select_not_covering(other)`
- `layer.select_not_covering(other, min_count)`

- `layer.select_not_covering(other, min_count, max_count)`
- `layer.select_not_covering(other, min_count .. max_count)`

This method selects all shapes or regions from self which do not cover shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It modifies self to contain the selected shapes. A version which does not modify self is not_covering.

This method is available for polygons only.

"select_not_inside" - Selects edges or polygons of self which are not inside edges or polygons from the other layer

Usage:

- `layer.select_not_inside(other)`

This method is the in-place version of inside - i.e. it modifies the layer instead of returning a new layer and leaving the original layer untouched.

"select_not_interacting" - Selects shapes or regions of self which do not touch or overlap shapes from the other region

Usage:

- `layer.select_not_interacting(other)`
- `layer.select_not_interacting(other, min_count)`
- `layer.select_not_interacting(other, min_count, max_count)`
- `layer.select_not_interacting(other, min_count .. max_count)`

This method selects all shapes or regions from self which do not touch or overlap shapes from the other layer. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It modifies self to contain the selected shapes. A version which does not modify self is not_interacting.

This method is available for polygon, text and edge layers. Edges can be selected with respect to other edges or polygons. Texts can be selected with respect to polygons. Polygons can be selected with respect to edges, texts and other polygons.

If a single count is given, shapes from self are selected only if they interact with less than the given number of (different) shapes from the other layer. If a min and max count is given, shapes from self are selected only if they interact with less than min_count or more than max_count different shapes from the other layer. Two polygons overlapping or touching at two locations are counted as single interactions.

"select_not_outside" - Selects edges or polygons of self which are not outside edges or polygons from the other layer

Usage:

- `layer.select_not_outside(other)`

This method is the in-place version of outside - i.e. it modifies the layer instead of returning a new layer and leaving the original layer untouched.

"select_not_overlapping" - Selects shapes or regions of self which do not overlap shapes from the other region

Usage:

- `layer.select_not_overlapping(other)`
- `layer.select_not_overlapping(other, min_count)`
- `layer.select_not_overlapping(other, min_count, max_count)`
- `layer.select_not_overlapping(other, min_count .. max_count)`

This method selects all shapes or regions from self which do not overlap shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It modifies self to contain the selected shapes. A version which does not modify self is not_overlapping.

This method is available for polygons only.

"select_outside" - Selects edges or polygons of self which are outside edges or polygons from the other layer

Usage:

- `layer.select_outside(other)`

This method is the in-place version of outside - i.e. it modifies the layer instead of returning a new layer and leaving the original layer untouched.

"select_overlapping" - Selects shapes or regions of self which overlap shapes from the other region

Usage:

- `layer.select_overlapping(other)`
- `layer.select_overlapping(other, min_count)`
- `layer.select_overlapping(other, min_count, max_count)`
- `layer.select_overlapping(other, min_count .. max_count)`

This method selects all shapes or regions from self which overlap shapes from the other region. Unless self is in raw mode (see raw), coherent regions are selected from self, otherwise individual shapes are selected. It modifies self to contain the selected shapes. A version which does not modify self is overlapping.

This method is available for polygons only.

"select_props" - Enables or selects properties from a property-annotated layer

Usage:

- `layer.select_props(keys)`

This method will select specific property keys from layers. It returns a new layer with the new properties. The original layer is not modified.

You can specify the user property keys (names) to use. As user properties in general are a set of key/value pairs and may carry multiple values under different keys, this feature can be handy to filter out a specific aspect. To get only the values from key 1 (integer), use:

```
layer1 = input(1, 0, enable_properties)
layer1_filtered = layer1.select_props(1)
```

To get the combined key 1 and 2 properties, use:

```
layer1 = input(1, 0, enable_properties)
```

```
layer1_filtered = layer1.select_props(1, 2)
```

Without any arguments, this method will remove all properties. Note that you can directly filter or map properties on input which is more efficient than first loading all and then selecting some properties. See DRCSource#input for details.

map_props is a way to change property keys and remove_props will entirely remove all user properties.

"sep" - An alias for "separation"

Usage:

- `layer.sep(value [, options])`

See separation for a description of that method

"separation" - A two-layer spacing check

Usage:

- `layer.separation(other_layer, value [, options])`
- `layer.sep(other_layer, value [, options])`

Note: "separation" and "sep" are available as operators for the "universal DRC" function drc within the DRC framework. These variants have more options and are more intuitive to use. See separation for more details.

This method performs a two-layer spacing check. Like space, this method can be applied to edge or polygon layers. Locations where edges of the layer are closer than the specified distance to the other layer are reported as edge pair error markers.

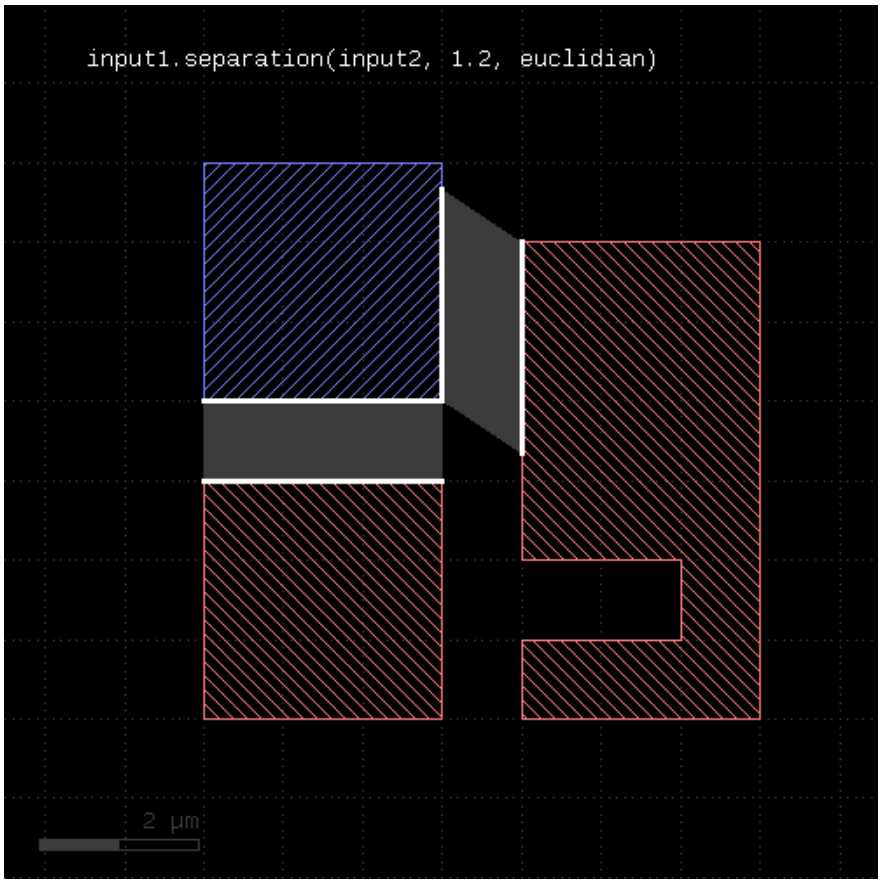
"sep" is the short form of this method.

In contrast to the space and related methods, locations where both layers touch are also reported. More specifically, the case of zero spacing will also trigger an error while for space it will not.

As for the other DRC methods, merged semantics applies.

Distance values can be given as floating-point values (in micron) or integer values (in database units). To explicitly specify the unit, use the unit denominators.

The following image shows the effect of the separation check (input1: red, input2: blue):

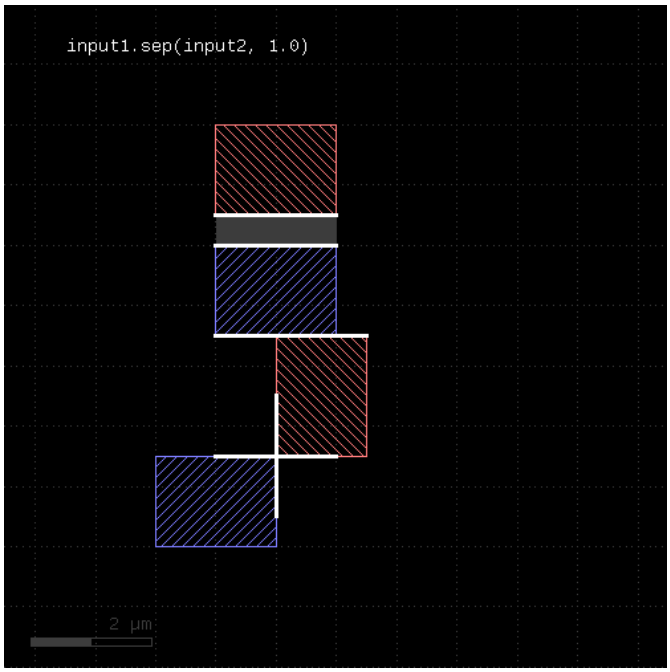


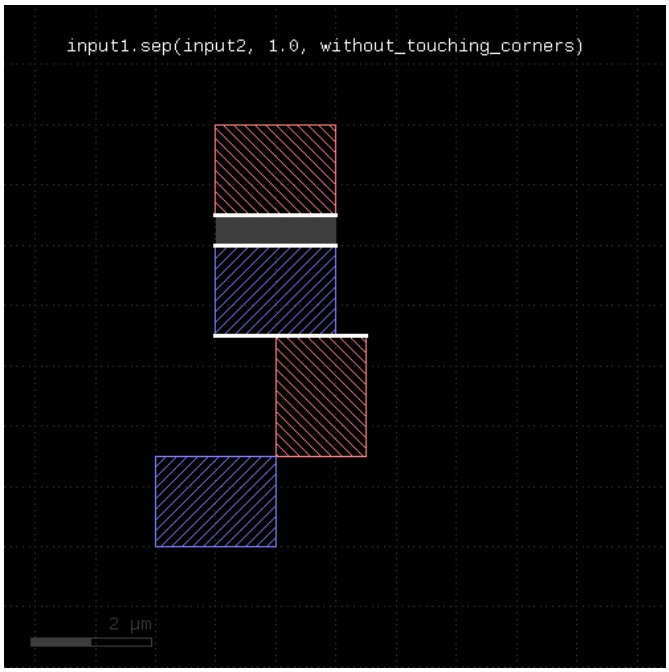
Touching shapes

Like width and space, the separation check also supports the "without_touching_corners" option.

This option will turn off errors that arise due to edges touching in one corner (the "kissing corners" configuration). By default, such edges will yield an error, as they form a zero-distance situation. With this option in place, no errors will be reported.

The following images illustrate the effect of the "without_touching_corners" option. The white line at the top of the bottom red shape is actually an edge pair indicating the zero-distance violation of the separation check:

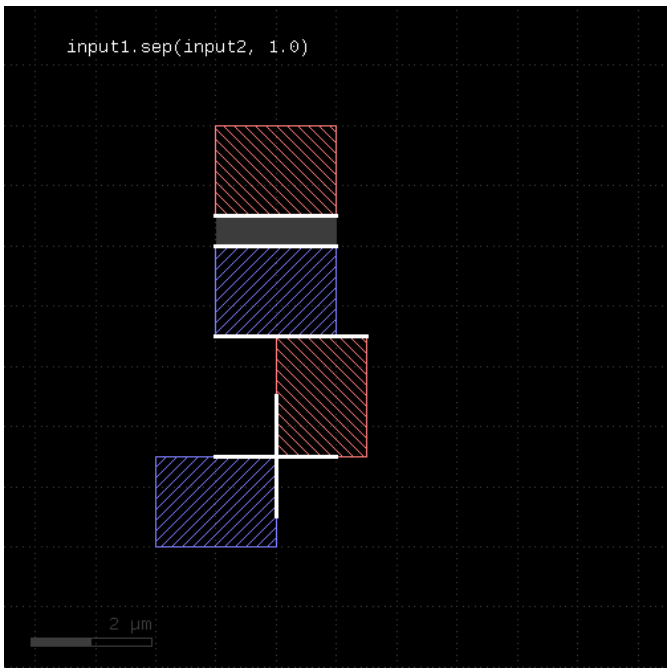


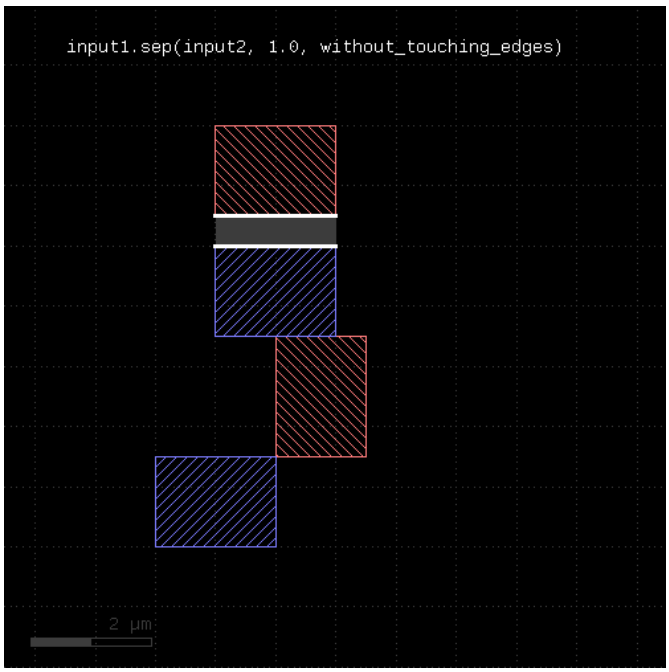


Another option is "without_touching_edges" which turns off errors that arise at coincident edges. Formally such edges represent a zero-distance situation, hence are flagged by default. Turning off the check in this case can be helpful when separating a layer into two parts (e.g. thin/wide metal separation) and an error between touching regions is not desired.

The "without_touching_edges" option is a stronger version of "without_touching_corners" and makes sense only for two-layer checks.

The following images illustrate the effect of the "without_touching_edges" option:





Opposite and rectangle error filtering

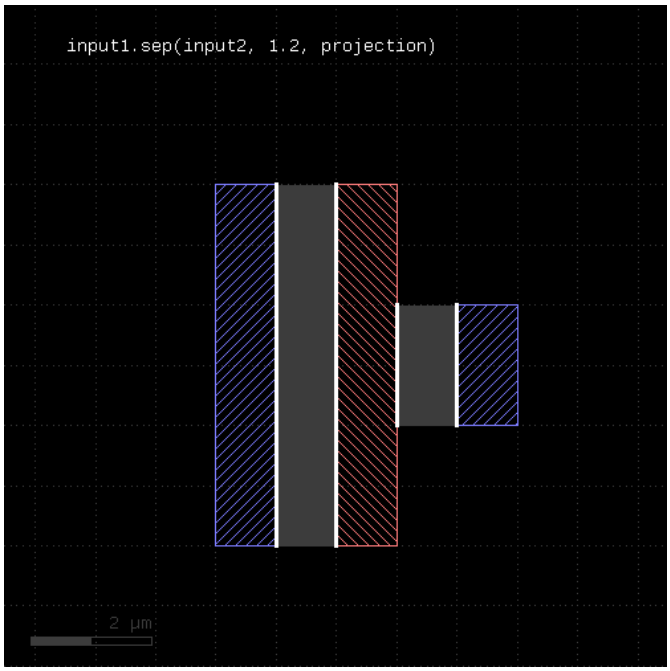
The options for the separation check are those available for the width or space method plus opposite and rectangle error filtering.

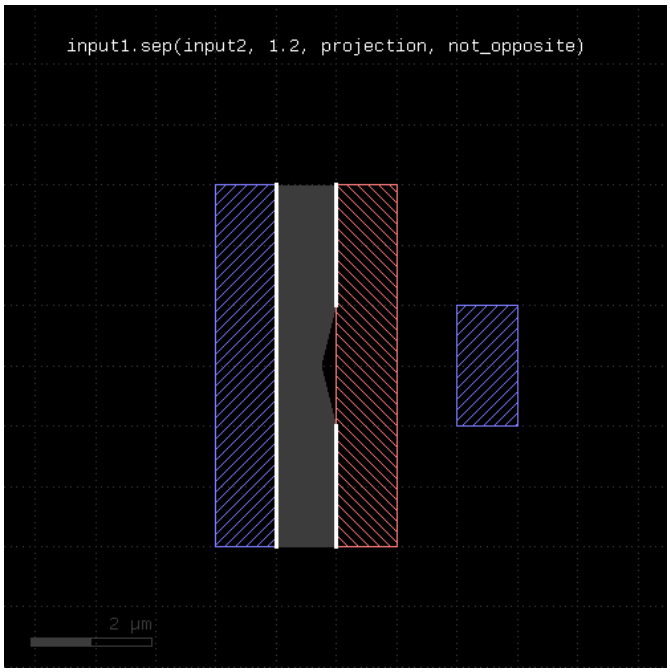
Opposite error filtering will waive errors that are on opposite sides of the original figure. The inverse is selection of errors only when there is an error present on the opposite side of the original figure. Opposite error waiving or selection is achieved through these options inside the DRC function call:

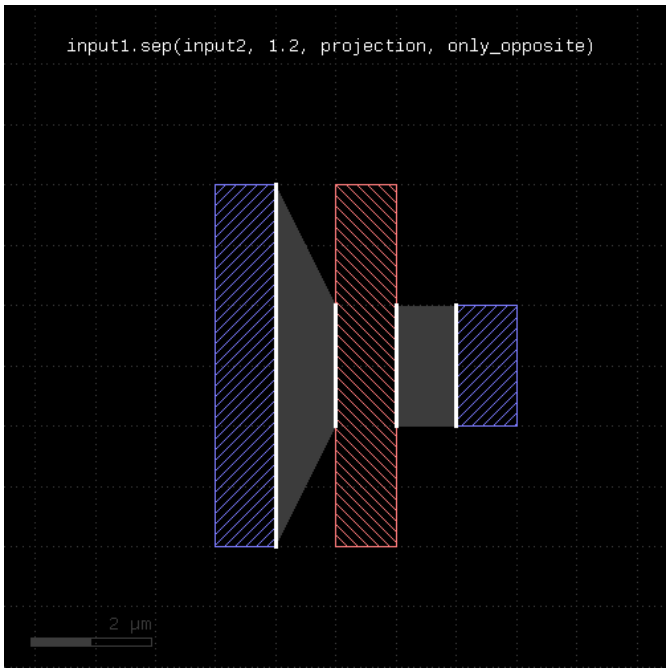
- **not_opposite** will waive opposite errors
- **only_opposite** will select errors only if there is an opposite one

These modes imply partial waiving or selection if "opposite" only applies to a section of an error.

The following images shows the effect of these options:







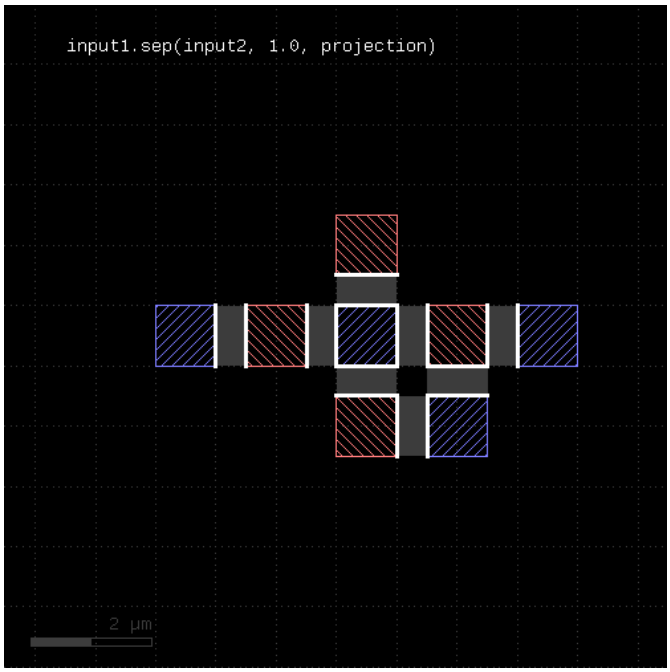
Rectangle error filtering allows waiving errors based on how they cover the sides of an original rectangular figure. This selection only applies to errors covering the full edge of the rectangle. Errors covering parts of the rectangle edges are not considered in this scheme.

The rectangle filter option is enabled by these modes:

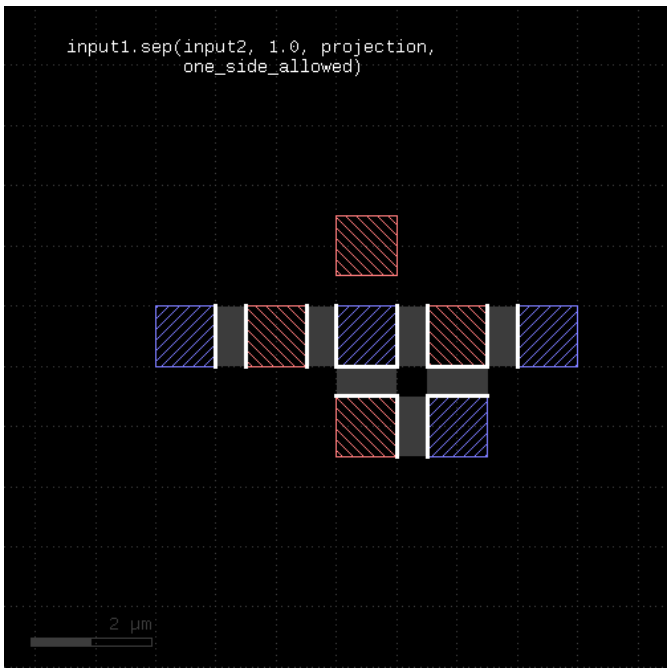
- **one_side_allowed** will waive errors when they appear on one side of the rectangle only
- **two_sides_allowed** will waive errors when they appear on two sides of the rectangle
- **two_connected_sides_allowed** will waive errors when they appear on two connected sides of the rectangle ("L" configuration)
- **two_opposite_sides_allowed** will waive errors when they appear on two opposite sides of the rectangle
- **three_sides_allowed** will waive errors when they appear on three sides of the rectangle
- **four_sides_allowed** will waive errors when they appear on four sides of the rectangle

Multiple of these options can be given, which will make errors waived if one of these conditions is met.

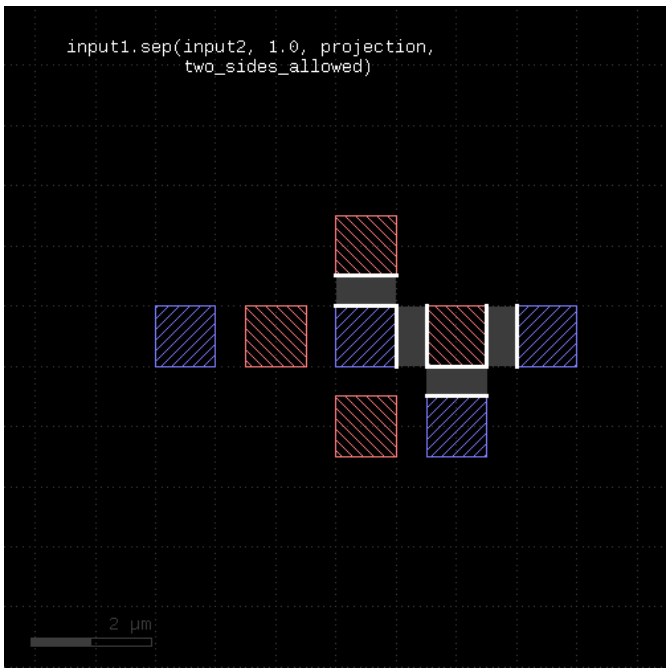
The following images shows the effect of some rectangle filter modes:



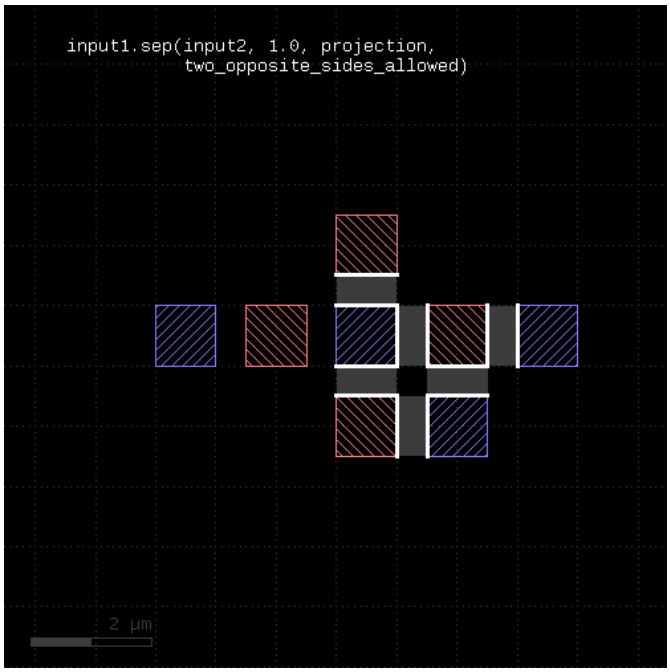
input1.sep(input2, 1.0, projection)
2 µm

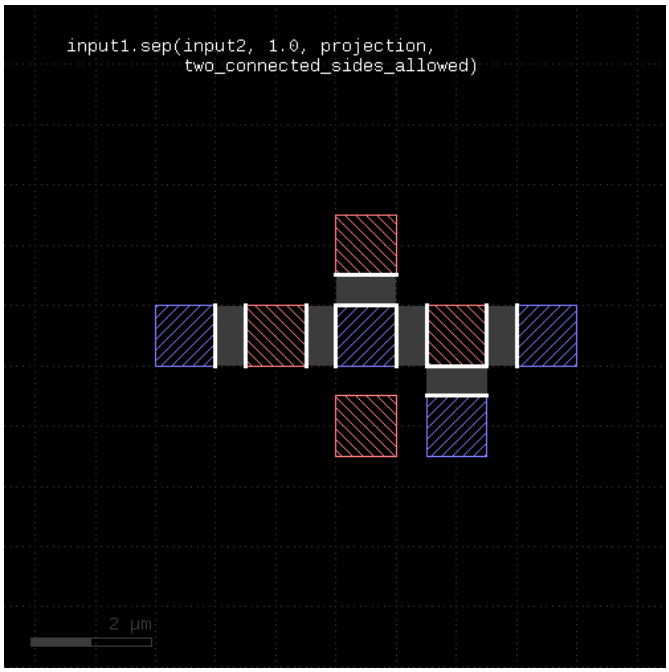


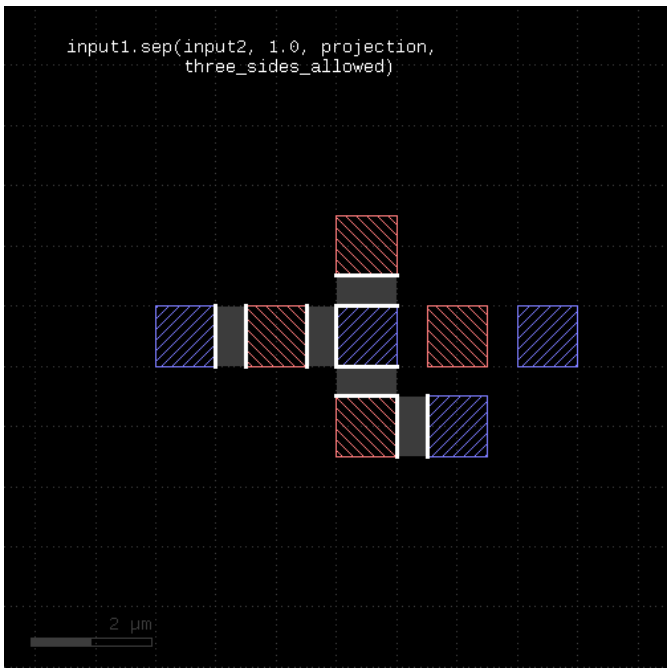
input1.sep(input2, 1.0, projection,
one_side_allowed)
2 µm

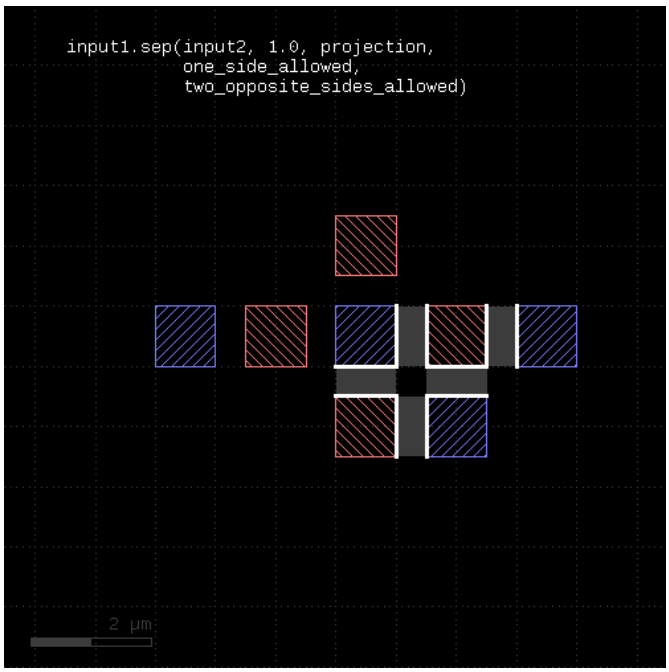


input1.sep(input2, 1.0, projection,
two_sides_allowed)
2 µm









"size" - Polygon sizing (per-edge biasing, modifies the layer)

Usage:

- `layer.size(d [, mode])`

- `layer.size(dx, dy [, mode]))`

See sized. The size method basically does the same but modifies the layer it is called on. The input layer is returned and available for further processing.

"sized" - Polygon sizing (per-edge biasing)

Usage:

- `layer.sized(d [, mode])`
- `layer.sized(dx, dy [, mode]))`

This method requires a polygon layer. It will apply a bias per edge of the polygons and return the biased layer. The layer that this method is called on is not modified.

In the single-value form, that bias is applied both in horizontal or vertical direction. In the two-value form, the horizontal and vertical bias can be specified separately.

The mode defines how to handle corners. The following modes are available:

- **diamond_limit** : This mode will connect the shifted edges without corner interpolation
- **octagon_limit** : This mode will create octagon-shaped corners
- **square_limit** : This mode will leave 90 degree corners untouched but cut off corners with a sharper angle. This is the default mode.
- **acute_limit** : This mode will leave 45 degree corners untouched but cut off corners with a sharper angle
- **no_limit** : This mode will not cut off (only at extremely sharp angles

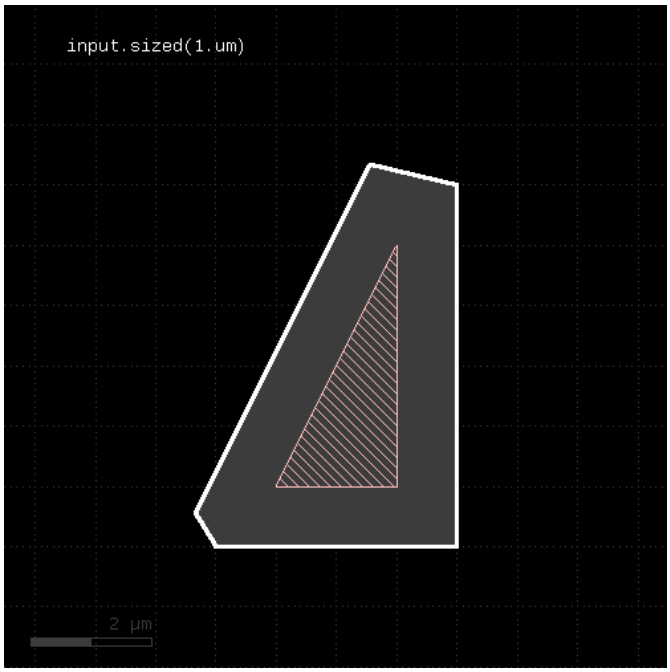
Merged semantics applies, i.e. polygons will be merged before the sizing is applied unless the layer was put into raw mode (see raw).
On output, the polygons are not merged immediately, so it is possible to detect overlapping regions after a positive sizing using raw and merged with an overlap count, for example:

```
layer.sized(300.nm).raw.merged(2)
```

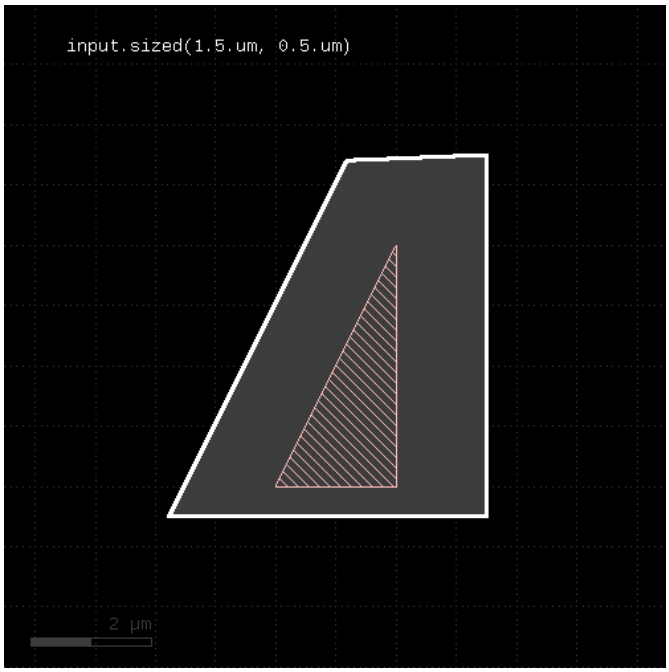
Bias values can be given as floating-point values (in micron) or integer values (in database units). To explicitly specify the unit, use the unit denominators.

size is working like sized but modifies the layer it is called on.

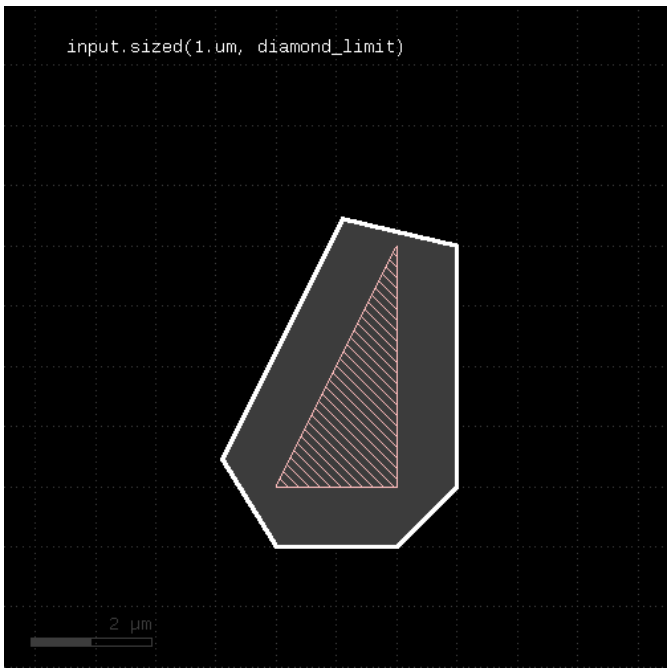
The following images show the effect of various forms of the "sized" method:



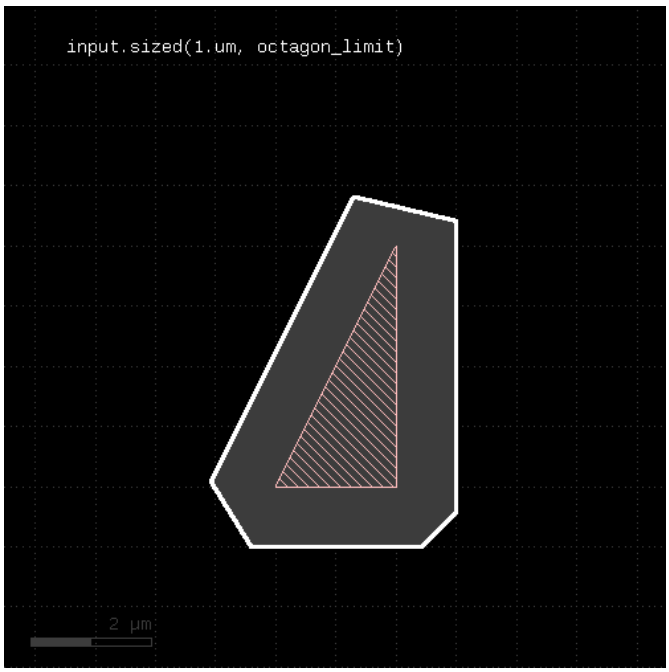
input.sized(1.um)
2 µm



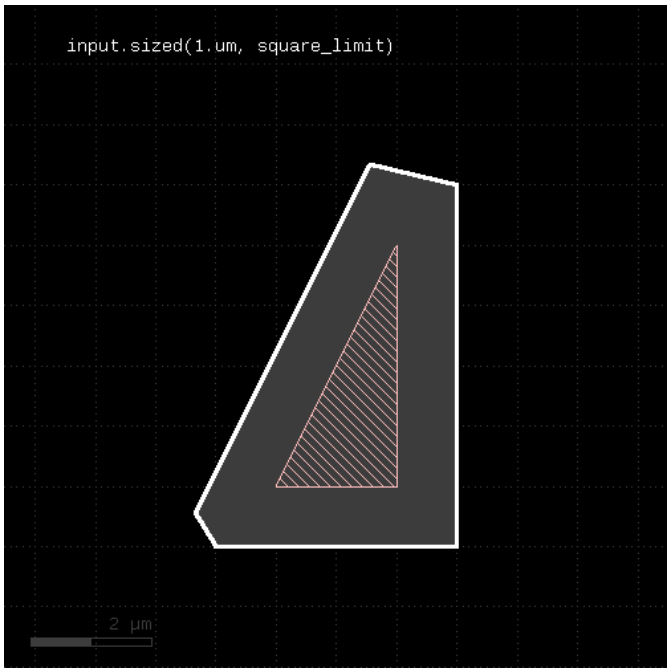
input.sized(1.5.um, 0.5.um)
2 µm

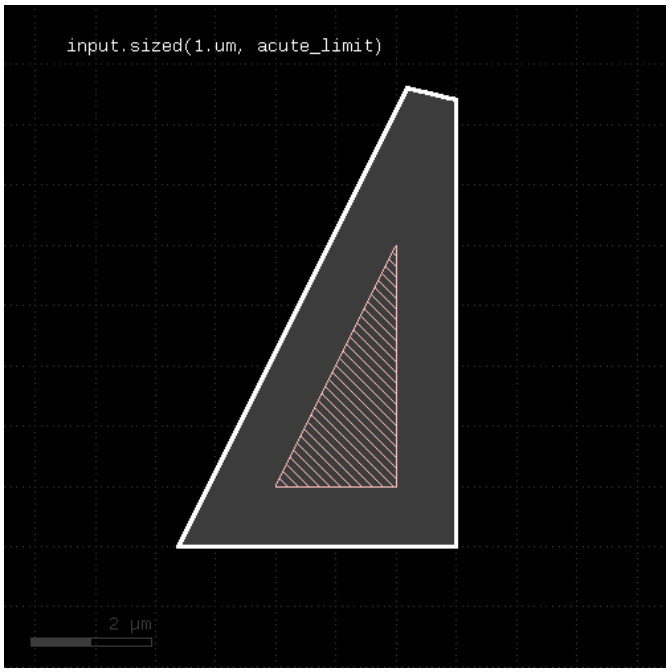


input.sized(1.um, diamond_limit)
2 µm



input.sized(1.um, octagon_limit)
2 µm





"smoothed" - Smoothes the polygons of the region

Usage:

- `layer.smoothed(d)`
- `layer.smoothed(d, hv_keep)`

"Smoothing" returns a simplified version of the polygons. Simplification is achieved by removing vertices unless the resulting polygon deviates by more than the given distance d from the original polygon.

"hv_keep" is a boolean parameter which makes the smoothing function maintain horizontal or vertical edges. The default is false, meaning horizontal or vertical edges may be changed into tilted ones.

This method return a layer wit the modified polygons. Merged semantics applies for this method (see raw and clean).

"snap" - Brings each vertex on the given grid (g or gx/gy for x or y direction)

Usage:

- `layer.snap(g)`
- `layer.snap(gx, gy)`

Shifts each off-grid vertex to the nearest on-grid location. If one grid is given, this grid is applied to x and y coordinates. If two grids are given, gx is applied to the x coordinates and gy is applied to the y coordinates. If 0 is given as a grid, no snapping is performed in that direction.

This method modifies the layer. A version that returns a snapped version of the layer without modifying the layer is snapped.

This method requires a polygon layer. Merged semantics applies (see raw and clean).

"snapped" - Returns a snapped version of the layer

Usage:

- `layer.snapped(g)`
- `layer.snapped(gx, gy)`

See snap for a description of the functionality. In contrast to snap, this method does not modify the layer but returns a snapped copy.

"space" - A space check

Usage:

- `layer.space(value [, options])`

Note: "space" is available as an operator for the "universal DRC" function Layer#drc within the DRC framework. This variant has more options and is more intuitive to use. See space for more details.

This method performs a space check and returns a collection of edge pairs. A space check can be performed on polygon and edge layers. On edge layers, all edges are checked against all other edges. If two edges form a "face to face" relation (i.e. their outer sides face each other) and their distance is less than the specified value, an error shape is generated for that edge pair. On polygon layers, the polygons on each layer are checked for space against other polygons for locations where their space is less than the specified value. In that case, an edge pair error shape is generated. The space check will also check the polygons for space violations against themselves, i.e. notches violating the space condition are reported.

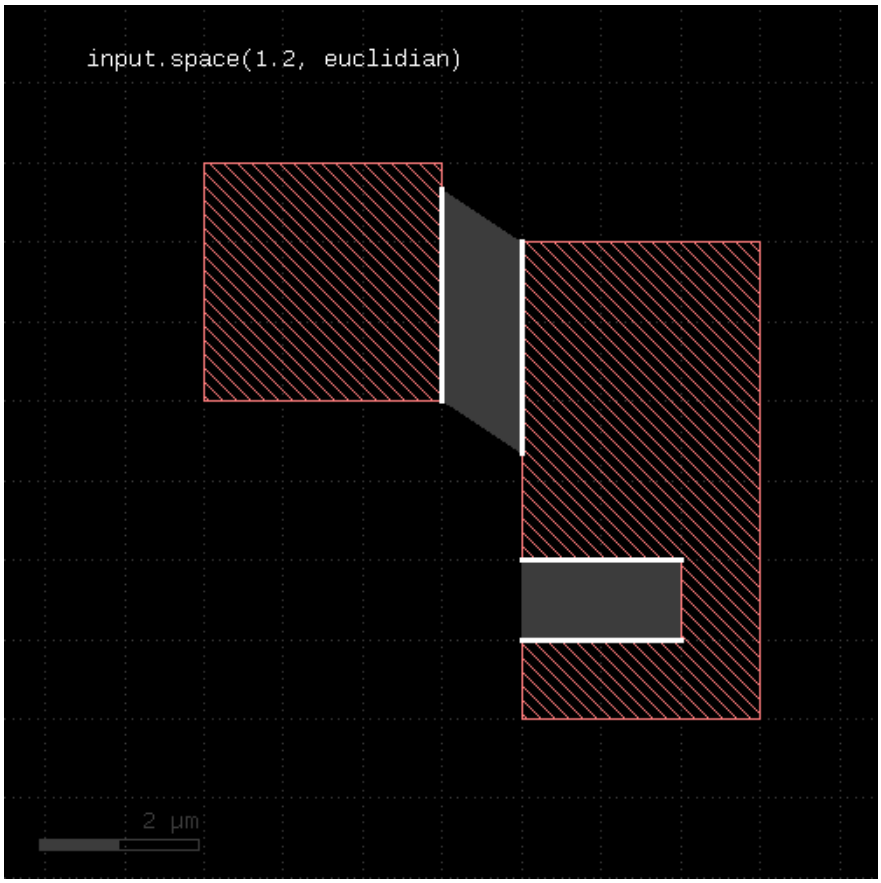
The notch method is similar, but will only report self-space violations. The isolated method will only report space violations to other polygons. separation is a two-layer space check where space is checked against polygons of another layer.

As for the other DRC methods, merged semantics applies.

Distance values can be given as floating-point values (in micron) or integer values (in database units). To explicitly specify the unit, use the unit denominators.

For the manifold options of this function see the width method description.

The following image shows the effect of the space check:



"split_covering" - Returns the results of covering and not_covering at the same time

Usage:

- `(a, b) = layer.split_covering(other [, options ])`

This method returns the polygons covering polygons from the other layer in one layer and all others in a second layer. This method is equivalent to calling covering and not_covering, but is faster than doing this in separate steps:

```
(covering, not_covering) = l1.split_covering(l2)
```

The options of this method are the same than covering.

"split_inside" - Returns the results of inside and not_inside at the same time

Usage:

- `(a, b) = layer.split_inside(other)`

This method returns the polygons or edges inside of polygons or edges from the other layer in one layer and all others in a second layer. This method is equivalent to calling inside and not_inside, but is faster than doing this in separate steps:

```
(inside, not_inside) = l1.split_inside(l2)
```

"split_interacting" - Returns the results of interacting and not_interacting at the same time

Usage:

- `(a, b) = layer.split_interacting(other [, options ])`

This method returns the polygons or edges interacting with objects from the other container in one layer and all others in a second layer. This method is equivalent to calling interacting and not_interacting, but is faster than doing this in separate steps:

```
(interacting, not_interacting) = l1.split_interacting(l2)
```

The options of this method are the same than interacting.

"split_outside" - Returns the results of outside and not_outside at the same time

Usage:

- `(a, b) = layer.split_outside(other)`

This method returns the polygons or edges outside of polygons or edges from the other layer in one layer and all others in a second layer. This method is equivalent to calling outside and not_outside, but is faster than doing this in separate steps:

```
(outside, not_outside) = l1.split_outside(l2)
```

"split_overlapping" - Returns the results of overlapping and not_overlapping at the same time

Usage:

- `(a, b) = layer.split_overlapping(other [, options ])`

This method returns the polygons overlapping polygons from the other layer in one layer and all others in a second layer. This method is equivalent to calling overlapping and not_overlapping, but is faster than doing this in separate steps:

```
(overlapping, not_overlapping) = l1.split_overlapping(l2)
```

The options of this method are the same than overlapping.

"squares" - Selects all squares from the input

Usage:

- `layer.squares`

This method is available for polygon layers. By default "merged" semantics applies, i.e. all polygons are merged before squares are selected (see clean and raw). non_squares will select all non-rectangles.

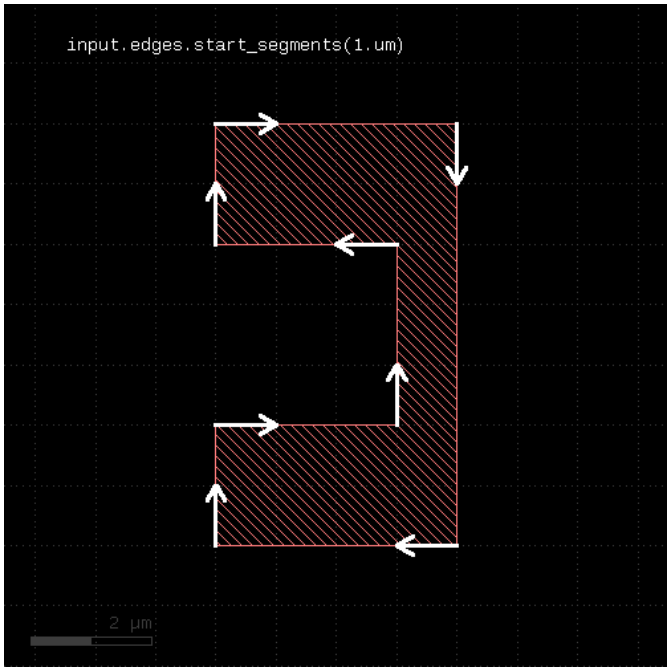
"start_segments" - Returns the part at the beginning of each edge

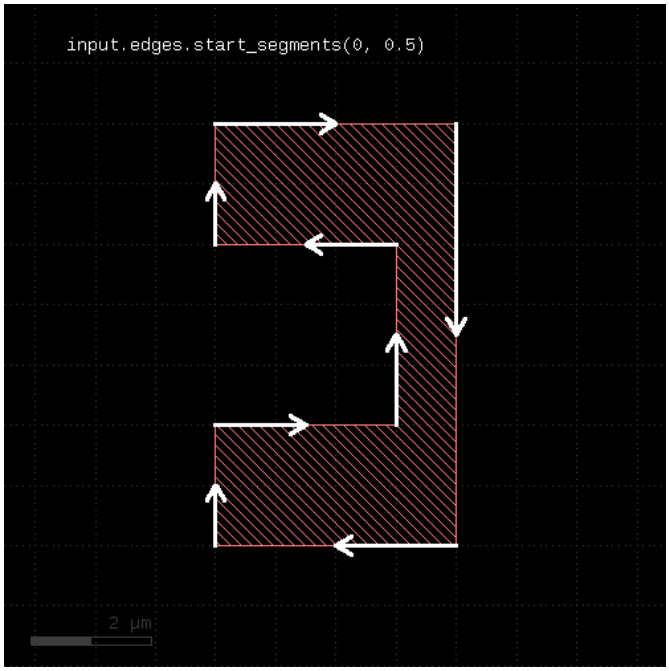
Usage:

- `layer.start_segments(length)`
- `layer.start_segments(length, fraction)`

This method will return a partial edge for each edge in the input, located and the end of the original edge. The new edges will share the start point with the original edges, but not necessarily their end points. For further details about the orientation of edges and the parameters of this method, see end_segments.

The following images show the effect of the method:





"strict" - Marks a layer for strict handling

Usage:

- `layer.strict`

If a layer is marked for strict handling, some optimizations are disabled. Specifically for boolean operations, the results will also be merged if one input is empty. For boolean operations, strict handling should be enabled for both inputs. Strict handling is disabled by default.

See non_strict about how to reset this mode.

This feature has been introduced in version 0.23.2.

"strict?" - Returns true, if strict handling is enabled for this layer

Usage:

- `layer.is_strict?`

See strict for a discussion of strict handling.

This feature has been introduced in version 0.23.2.

"texts" - Selects texts from an original layer

Usage:

- `layer.texts`
- `layer.texts(p)`
- `layer.texts([ options ])`

This method can be applied to original layers - i.e. ones that have been created with input. By default, a small box (2x2 DBU) will be produced on each selected text. By using the "as_dots" option, degenerated point-like edges will be produced.

The preferred method however is to use true text layers created with labels. In this case, without specifying "as_dots" or "as_boxes" retains the text objects as such a text filtering is applied. In contrast to this, layers generated with input cannot maintain the text nature of the selected objects and produce dots or small polygon boxes in the texts method.

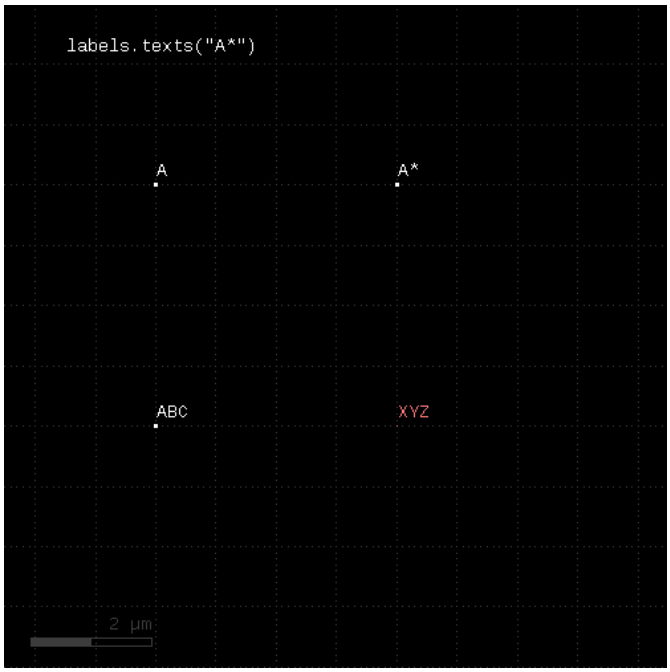
Texts can be selected either by exact match string or a pattern match with a glob-style pattern. By default, glob-style pattern are used. The options available are:

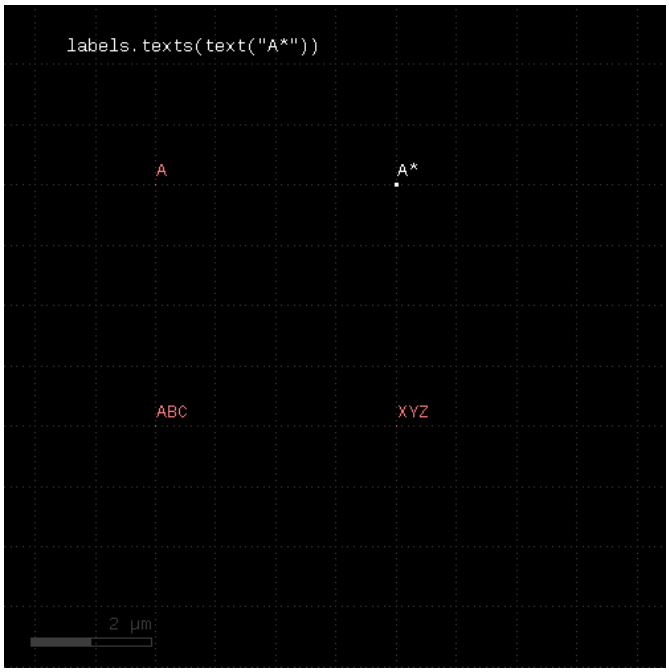
- **pattern(p)** : Use a pattern to match the string (this is the default)
- **text(s)** : Select the texts that exactly match the given string
- **as_boxes** : with this option, small boxes will be produced as markers
- **as_dots** : with this option, point-like edges will be produced instead of small boxes

Here are some examples:

```
# Selects all texts
t = labels(1, 0).texts
# Selects all texts beginning with an "A"
t = labels(1, 0).texts("A*")
t = labels(1, 0).texts(pattern("A*"))
# Selects all texts whose string is "ABC"
t = labels(1, 0).texts(text("ABC"))
```

The effect of the operation is shown in these examples:





"texts?" - Returns true, if the layer is a text collection

Usage:

- `layer.texts?`

"texts_not" - Selects texts from an original layer not matching a specific selection

Usage:

- `layer.texts_not`
- `layer.texts_not(p)`
- `layer.texts_not([ options ])`

This method can be applied to true text layers obtained with labels. In this case, without specifying "as_dots" or "as_boxes" retains the text objects as such. Only text filtering is applied.

Beside that this method acts like texts, but will select the text objects not matching the filter.

"transform" - Transforms a layer (modifies the layer)

Usage:

- `layer.transform(t)`

Like transform, but modifies the input and returns a reference to it for further processing.

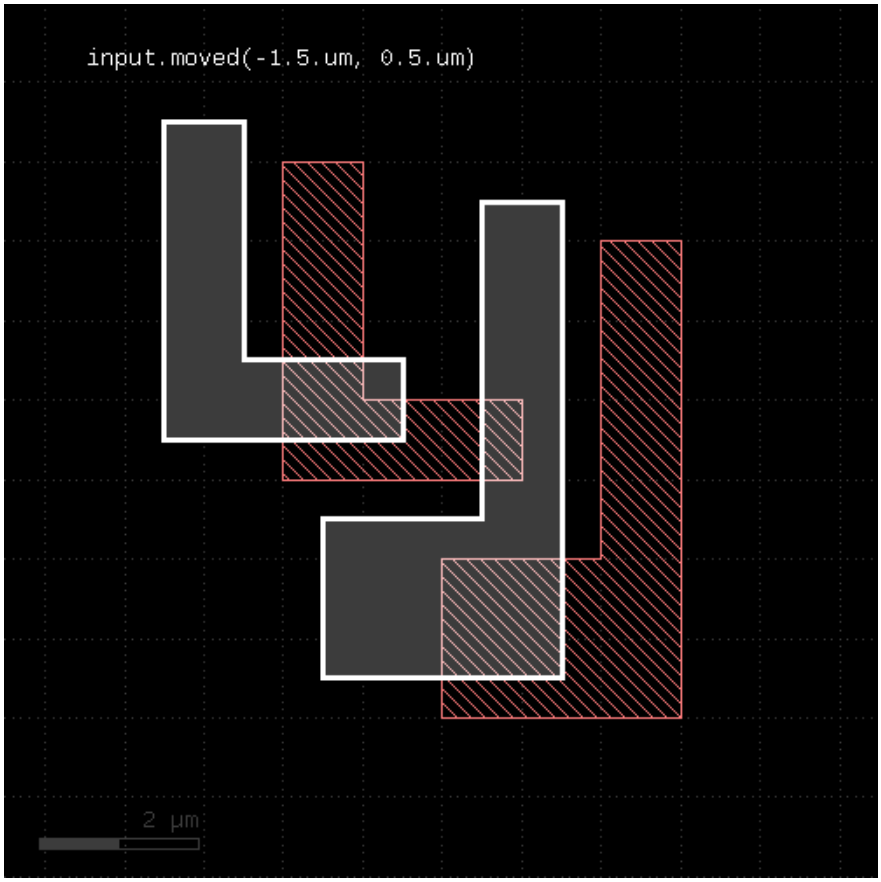
"transformed" - Transforms a layer

Usage:

- `layer.transformed(t)`

Transforms the input layer by the given transformation and returns the moved layer. The layer that this method is called upon is not modified. This is the most generic method is transform a layer. The transformation is a DCplxTrans object which describes many different kinds of affine transformations except shear and anisotropic magnification.

The following image shows the effect of the "moved" method:



"width" - A width check

Usage:

- `layer.width(value [, options])`

Note: "width" is available as an operator for the "universal DRC" function Layer#drc within the DRC framework. This variant has more options and is more intuitive to use. See width for more details.

This method performs a width check and returns a collection of edge pairs. A width check can be performed on polygon and edge layers. On edge layers, all edges are checked against all other edges. If two edges form a "back to back" relation (i.e. their inner sides face each other) and their distance is less than the specified value, an error shape is generated for that edge pair. On polygon layers, the polygons on each layer are checked for locations where their width is less than the specified value. In that case, an edge pair error shape is generated.

Options

The options available are:

- **euclidian** : perform the check using Euclidian metrics (this is the default)

- **square** : perform the check using Square metrics
- **projection** : perform the check using projection metrics
- **whole_edges** : With this option, the check will return all of the edges, even if the criterion is violated only over a part of the edge
- **angle_limit(a)** : Specifies the angle above or equal to which no check is performed. The default value is 90, which means that for edges having an angle of 90 degree or more, no check is performed. Setting this value to 45 will make the check only consider edges enclosing angles of less than 45 degree.
- **projection_limits(min, max) or projection_limits(min .. max)** : this option makes the check only consider edge pairs whose projected length on each other is more or equal than min and less than max
- **projecting (in condition)** : This specification is equivalent to "projection_limits" but is more intuitive, as "projecting" is written with a condition, like "projecting < 2.um". Available operators are: "==", "<", "<=", ">" and ">=". Double-bounded ranges are also available, like: "0.5 <= projecting < 2.0".
- **without_touching_corners** : With this option present, touching corners (aka "kissing corners") will not yield errors. The default is to produce errors in these cases.
- **without_touching_edges** : With this option present, coincident edges will not yield errors. This is a stronger version of "without_touching_corners" and makes sense only for two-layer checks or raw-mode input layers. It is listed here for completeness.
- **transparent** : Performs the check without shielding (polygon layers only)
- **shielded** : Performs the check with shielding (polygon layers only)
- **props_eq** , **props_ne** , **props_copy** : (only props_copy applies to width check) - See "Properties constraints" below.

Note that without the angle_limit, acute corners will always be reported, since two connected edges always violate the width in the corner. By adjusting the angle_limit, an acute corner check can be implemented.

Merge semantics applies to this method, i.e. disconnected polygons are merged before the width is checked unless "raw" mode is chosen.

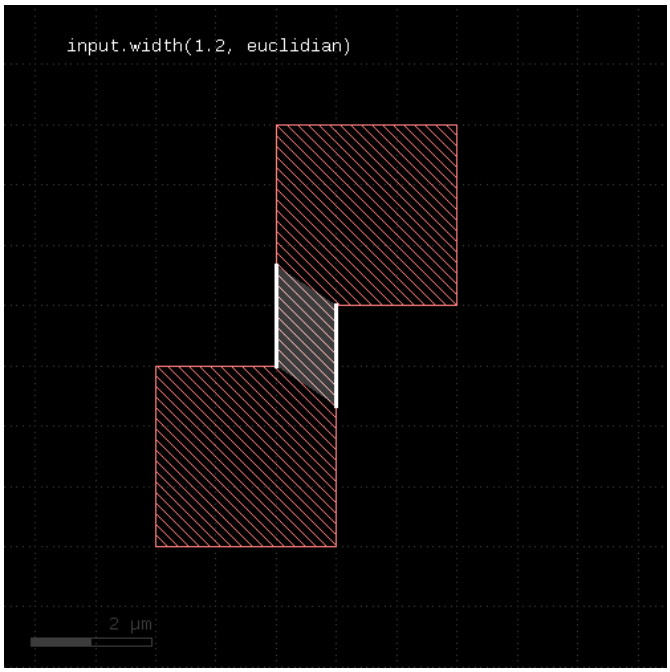
The resulting edge pairs can be converted to polygons using the polygons method.

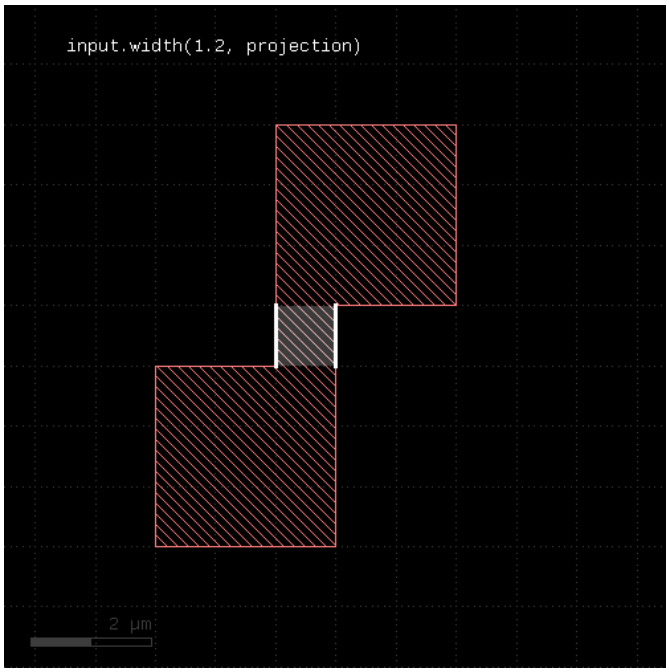
Distance values can be given as floating-point values (in micron) or integer values (in database units). To explicitly specify the unit, use the unit denominators, i.e.

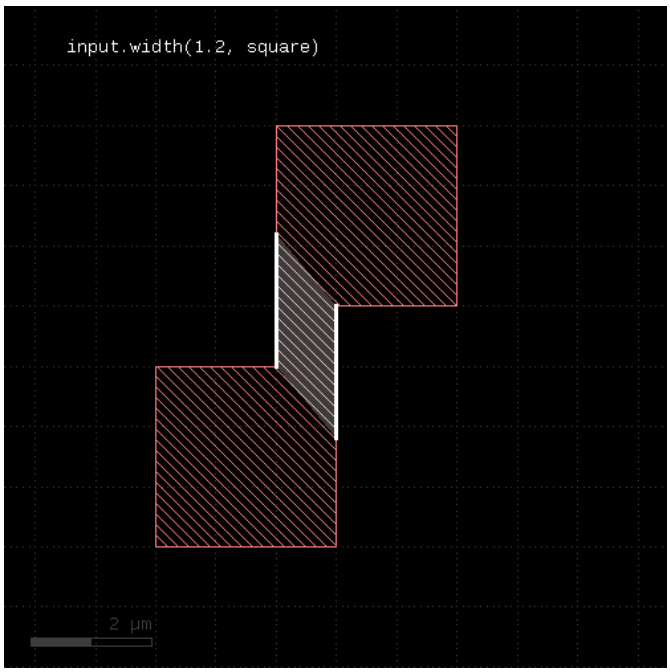
```
# width check for 1.5 micron:
markers = in.width(1.5)
# width check for 2 database units:
markers = in.width(2)
# width check for 2 micron:
markers = in.width(2.um)
# width check for 20 nanometers:
markers = in.width(20.nm)
```

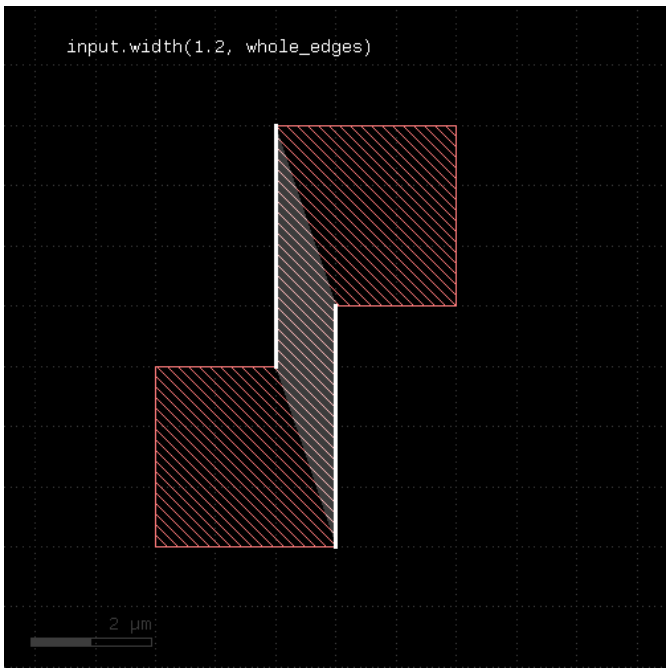
Examples

The following images show the effect of various forms of the width check:









Universal DRC function

There is an alternative notation for the check using the "universal DRC" function ("Layer#drc"). This notation is more intuitive and allows checking for widths bigger than a certain value or within a certain range. See "width" for details.

Apart from that it provides the same options than the plain width check. Follow this link for the documentation of this feature: width.

Shielding

"shielding" is a concept where an internal or external distance is measured only if the opposite edge is not blocked by other edges between. Shielded mode makes a difference if very large distances are to be checked and the minimum distance is much smaller: in this case, a large distance violation may be blocked by features located between the edges which are checked. With shielding, large distance violations are not reported in this case. Shielding is also effective at zero distance which has an adverse effect: Consider a case, where one layer A is a subset of another layer B. If you try to check the distance between features of B vs. A, you cannot use shielding, because B features which are identical to A features will shield those entirely.

Shielding is enabled by default, but can be switched off with the "transparent" option.

Properties constraints (available on intra-polygon checks such as space, sep etc.)

This feature is listed here, because this documentation is generic and used for other checks as well. props_eq and props_ne are not available on 'width' or 'notch' as these apply to intra-polygon checks - when pairs of different polygons are involved - something that 'width' or 'notch' does need.

With properties constraints, the check is performed between shapes with the same or different properties. "properties" refers to the full set of key/value pairs attached to a shape.

Property constraints are specified by adding props_eq or props_ne to the arguments. If these literals are present, only shapes with same of different properties are involved in the check. In connection with the net annotation feature this allows checking space between connected or disconnected shapes for example:

```
connect(metal1, via1)
...

# attaches net identity as properties
metal1_nets = metal1.nets

space_not_connected = metal1_nets.space(0.4.um, props_ne)
space_connected     = metal1_nets.space(0.4.um, props_eq)
```

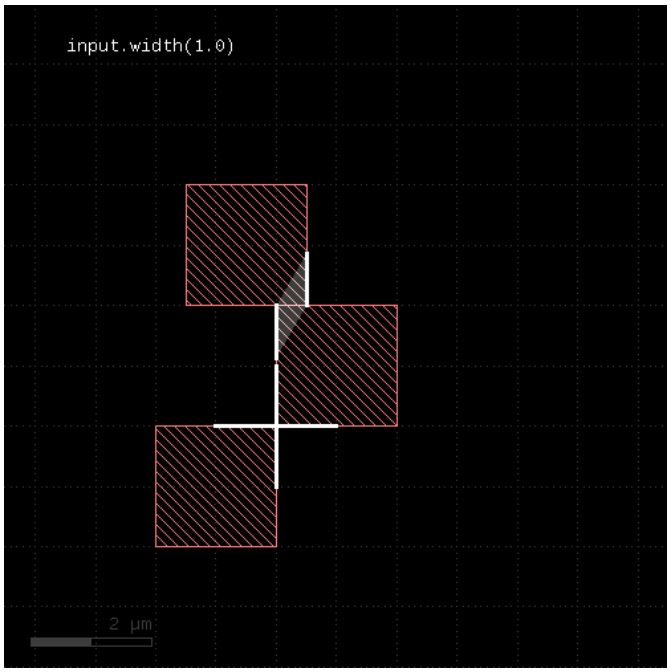
props_copy is a special properties constraint that does not alter the behaviour of the checks, but copies the primary shape's properties to the output markers. This constraint is applicable to width and notch checks too. The effect is that the original polygon's properties are copied to the error markers. props_copy can be combined with props_eq and props_ne to copy the original shape's properties to the output too:

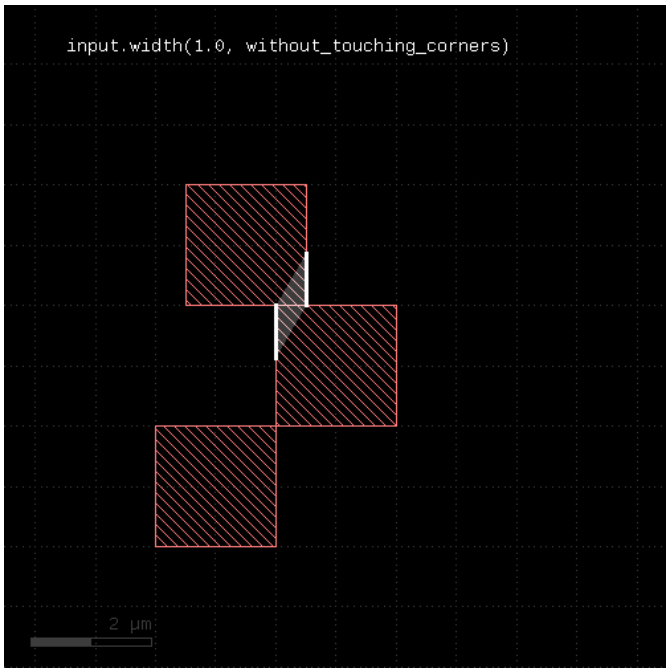
```
space_not_connected = metal1_nets.space(0.4.um, props_ne + props_copy)
space_connected     = metal1_nets.space(0.4.um, props_eq + props_copy)
```

Touching shapes

The "without_touching_corners" option will turn off errors that arise due to the "kissing corner" configuration (or "checkerboard pattern"). Formally this is a width violation across the diagonal, but when considering this configuration as disconnected boxes, no error should be reported.

The following images illustrate the effect of the "without_touching_corners" option:





"with_angle" - Selects edges by their angle

Usage:

- `layer.with_angle(min .. max)`
- `layer.with_angle(value)`
- `layer.with_angle(min, max)`
- `layer.with_angle(ortho)`
- `layer.with_angle(diagonal)`
- `layer.with_angle(diagonal_only)`
- `edge_pair_layer.with_angle(... [, both])`

When called on an edge layer, the method selects edges by their angle, measured against the horizontal axis in the mathematical sense.

For this measurement edges are considered without their direction and straight lines. A horizontal edge has an angle of zero degree. A vertical one has an angle of 90 degee. The angle range is from -90 (exclusive) to 90 degree (inclusive).

The first version of this method selects edges with a angle larger or equal to min and less than max (but not equal). The second version selects edges with exactly the given angle. The third version is identical to the first one.

When called on an edge pair layer, this method selects edge pairs with one or both edges meeting the angle criterion. In this case an additional argument is accepted which can be either "both" (plain word) to indicate that both edges have to be within the given interval. Without this argument, it is sufficient for one edge to meet the criterion.

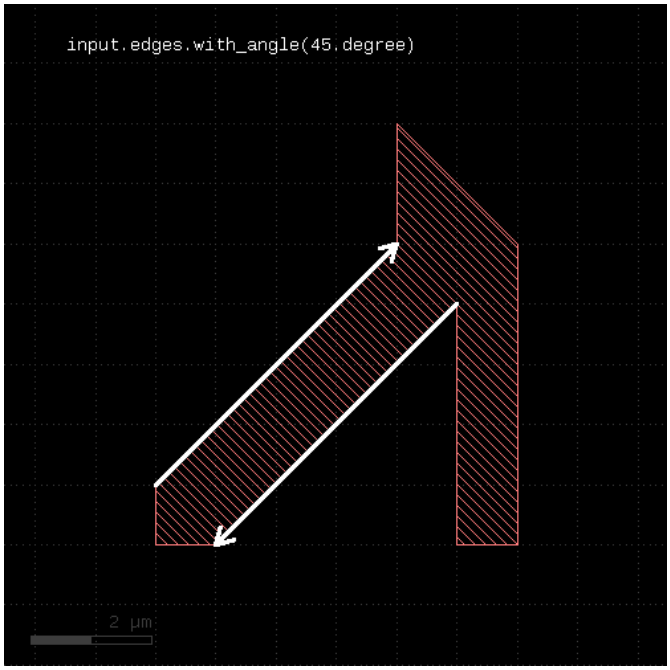
Here are examples for "with_angle" on edge pair layers:

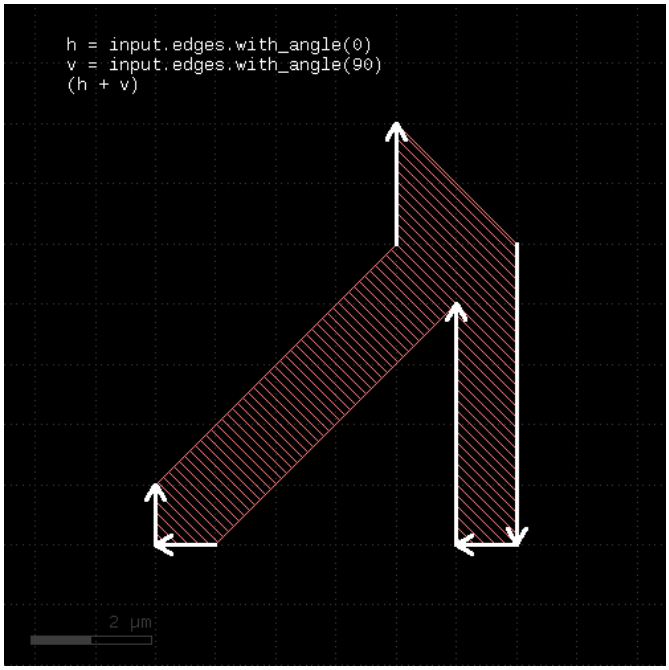
```
# at least one edge needs to be horizontal
ep1 = edge_pairs.with_angle(0)
# both edges need to vertical
```

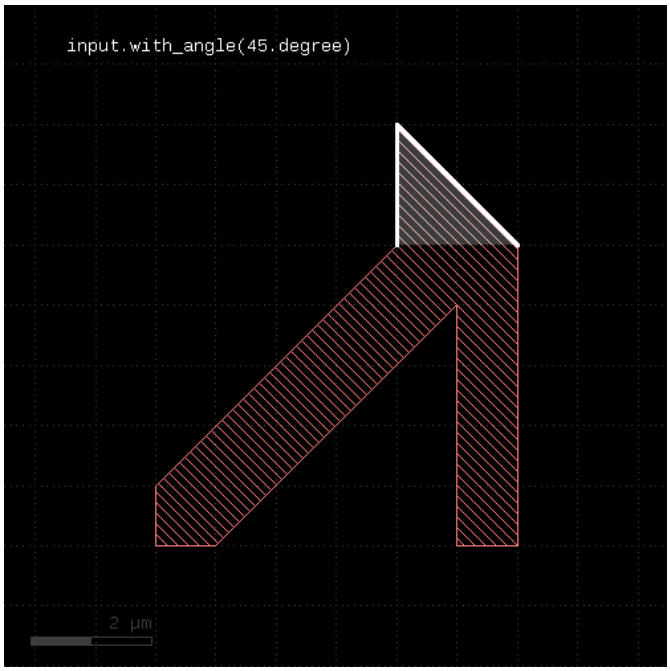
```
ep2 = edge_pairs.with_angle(90, both)
```

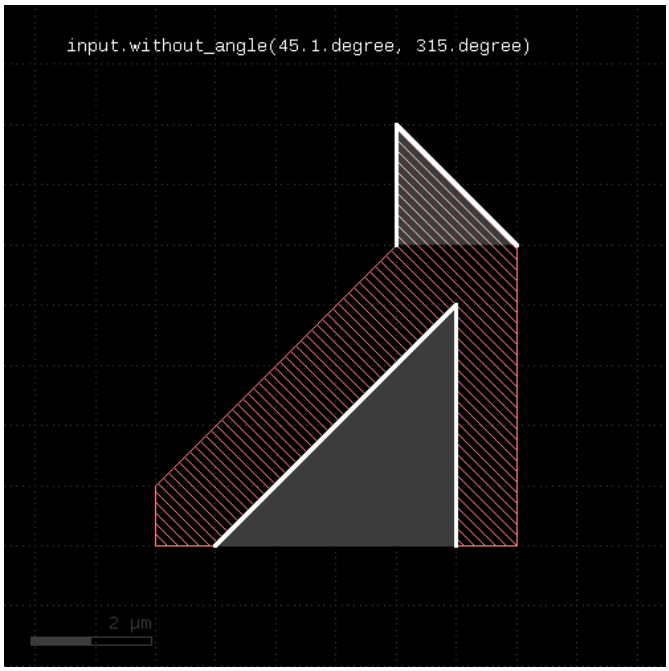
A method delivering all objects not matching the angle criterion is without_angle. Note that for edge pairs, in order to get the inverse result, you have to add or drop "both" on without_angle. This is because without_angle without both returns edge pairs where one edge does not match the criterion. The logical opposite of "one edge matches" however is "both edges do not match".

The following images demonstrate some use cases of with_angle and without_angle :









Specifying "ortho", "diagonal" or "diagonal_only" instead of the angle values will select 0 and 90 degree edges (ortho), -45 and 45 degree edges (diagonal_only) and both types (diagonal). This simplifies the implementation of selectors for manhattan or half-manhattan features:

```
ortho_edges = edges.with_angle(ortho)

# which is equivalent to, but more efficient as:
ortho_edges = edges.with_angle(0) + edges.with_angle(90)
```

Note that in former versions, with_angle could be used on polygon layers selecting corners with specific angles. This feature has been deprecated. Use corners instead.

"with_area" - Selects polygons or edge pairs by area

Usage:

- `layer.with_area(min .. max)`
- `layer.with_area(value)`
- `layer.with_area(min, max)`

The first form will select all polygons or edge pairs with an area larger or equal to min and less (but not equal to) max. The second form will select the polygons or edge pairs with exactly the given area. The third form basically is equivalent to the first form, but allows specification of nil for min or max indicating no lower or upper limit.

This method is available for polygon or edge pair layers.

"with_area_ratio" - Selects polygons by the ratio of the bounding box area vs. polygon area

Usage:

- `layer.with_area_ratio(min .. max)`
- `layer.with_area_ratio(value)`
- `layer.with_area_ratio(min, max)`

The area ratio is a measure how far a polygon is approximated by its bounding box. The value is always larger or equal to 1. Boxes have a area ratio of 1. Larger values mean more empty area inside the bounding box.

This method is available for polygon layers only.

"with_bbox_aspect_ratio" - Selects polygons by the aspect ratio of their bounding box

Usage:

- `layer.with_bbox_aspect_ratio(min .. max)`
- `layer.with_bbox_aspect_ratio(value)`
- `layer.with_bbox_aspect_ratio(min, max)`

The method selects polygons similar to with_area or with_perimeter. However, the measured value is the aspect ratio of the bounding box. It is the larger dimensions divided by the smaller one. The "thinner" the polygon, the larger the aspect ratio. A square bounding box gives an aspect ratio of 1.

This method is available for polygon layers only.

"with_bbox_height" - Selects polygons by the height of the bounding box

Usage:

- `layer.with_bbox_height(min .. max)`
- `layer.with_bbox_height(value)`
- `layer.with_bbox_height(min, max)`

The method selects polygons similar to with_area or with_perimeter. However, the measured dimension is the width of the bounding box.

This method is available for polygon layers only.

"with_bbox_max" - Selects polygons by the maximum dimension of the bounding box

Usage:

- `layer.with_bbox_max(min .. max)`
- `layer.with_bbox_max(value)`
- `layer.with_bbox_max(min, max)`

The method selects polygons similar to with_area or with_perimeter. However, the measured dimension is the maximum dimension of the bounding box. The maximum dimension is either the width or height of the bounding box, whichever is larger.

This method is available for polygon layers only.

"with_bbox_min" - Selects polygons by the minimum dimension of the bounding box

Usage:

- `layer.with_bbox_min(min .. max)`
- `layer.with_bbox_min(value)`
- `layer.with_bbox_min(min, max)`

The method selects polygons similar to with_area or with_perimeter. However, the measured dimension is the minimum dimension of the bounding box. The minimum dimension is either the width or height of the bounding box, whichever is smaller.

This method is available for polygon layers only.

"with_bbox_width" - Selects polygons by the width of the bounding box

Usage:

- `layer.with_bbox_width(min .. max)`
- `layer.with_bbox_width(value)`
- `layer.with_bbox_width(min, max)`

The method selects polygons similar to with_area or with_perimeter. However, the measured dimension is the width of the bounding box.

This method is available for polygon layers only.

"with_density" - Returns tiles whose density is within a given range

Usage:

- `layer.with_density(min_value, max_value [, options ])`
- `layer.with_density(min_value .. max_value [, options ])`

This method runs a tiled analysis over the current layout. It reports the tiles whose density is between "min_value" and "max_value". "min_value" and "max_value" are given in relative units, i.e. within the range of 0 to 1.0 corresponding to a density of 0 to 100%.

"min_value" or "max_value" can be nil or omitted in the ".." range notation. In this case, they are taken as "0" and "100%".

The tile size must be specified with the "tile_size" option:

```
# reports areas where layer 1/0 density is below 10% on 20x20 um tiles
low_density = input(1, 0).with_density(0.0 .. 0.1, tile_size(20.um))
```

Anisotropic tiles can be specified by giving two values, like "tile_size(10.um, 20.um)". The first value is the horizontal tile dimension, the second value is the vertical tile dimension.

A tile overlap can be specified using "tile_step". If the tile step is less than the tile size, the tiles will overlap. The layout window given by "tile_size" is moved in increments of the tile step:

```
# reports areas where layer 1/0 density is below 10% on 30x30 um tiles
# with a tile step of 20x20 um:
low_density = input(1, 0).with_density(0.0 .. 0.1, tile_size(30.um), tile_step(20.um))
```

For "tile_step", anisotropic values can be given as well by using two values: the first for the horizontal and the second for the vertical tile step.

Another option is "tile_origin" which specifies the location of the first tile's position. This is the lower left tile's lower left corner. If no origin is given, the tiles are centered over the area investigated.

By default, the tiles will cover the bounding box of the input layer. A separate layer can be used in addition. This way, the layout's dimensions can be derived from some drawn boundary layer. To specify a separate, additional layer included in the bounding box, use the "tile_boundary" option:

```
# reports density of layer 1/0 below 10% on 20x20 um tiles. The layout's boundary is taken from
# layer 0/0:
cell_frame = input(0, 0)
low_density = input(1, 0).with_density(0.0 .. 0.1, tile_size(20.um), tile_boundary(cell_frame))
```

Note that the layer given in "tile_boundary" adds to the input layer for computing the bounding box. The computed area is at least the area of the input layer.

Computation of the area can be skipped by explicitly giving a tile count in horizontal and vertical direction. With the "tile_origin" option this allows full control over the area covered:

```
# reports density of layer 1/0 below 10% on 20x20 um tiles in the region 0,0 .. 2000,3000
# (100 and 150 tiles of 20 um each are used in horizontal and vertical direction):
low_density = input(1, 0).with_density(0.0 .. 0.1, tile_size(20.um), tile_origin(0.0, 0.0), tile_count(100,
 150))
```

The "padding mode" indicates how the area outside the layout's bounding box is considered. There are two modes:

- **padding_zero** : the outside area is considered zero density. This is the default mode.
- **padding_ignore** : the outside area is ignored for the density computation.

Example:

```
low_density = input(1, 0).with_density(0.0 .. 0.1, tile_size(20.um), padding_ignore)
```

The complementary version of "with_density" is without_density.

"with_distance" - Selects edge pairs by the distance of the edges

Usage:

- `layer.with_distance(min .. max)`
- `layer.with_distance(value)`
- `layer.with_distance(min, max)`

The method selects edge pairs by the distance of their edges. The first version selects edge pairs with a distance larger or equal to min and less than max (but not equal). The second version selects edge pairs with exactly the given distance. The third version is similar to the first one, but allows specification of nil for min or max indicating that there is no lower or upper limit.

The distance of the edges is defined by the minimum distance of all points from the edges involved. For edge pairs generated in geometrical checks this is equivalent to the actual distance of the original edges.

This method is available for edge pair layers only.

"with_holes" - Selects all polygons with the specified number of holes

Usage:

- `layer.with_holes`
- `layer.with_holes(count)`
- `layer.with_holes(min_count, max_count)`
- `layer.with_holes(min_count .. max_count)`

This method is available for polygon layers. It will select all polygons from the input layer which have the specified number of holes. Without any argument, all polygons with holes are selected.

"with_internal_angle" - Selects edge pairs by their internal angle

Usage:

- `edge_pair_layer.with_internal_angle(min .. max)`
- `edge_pair_layer.with_internal_angle(value)`
- `edge_pair_layer.with_internal_angle(min, max)`

This method selects edge pairs by the angle enclosed by their edges. The angle is between 0 (parallel or anti-parallel edges) and 90 degree (perpendicular edges). If an interval or two values are given, the angle is checked to be within the given range.

Here are examples for "with_internal_angle" on edge pair layers:

```
# selects edge pairs with parallel edges
ep1 = edge_pairs.with_internal_angle(0)
# selects edge pairs with perpendicular edges
```

```
ep2 = edge_pairs.with_internal_angle(90)
```

"with_length" - Selects edges by their length

Usage:

- `layer.with_length(min .. max)`
- `layer.with_length(value)`
- `layer.with_length(min, max)`
- `edge_pairlayer.with_length(min, max [, both])`

The method selects edges by their length. The first version selects edges with a length larger or equal to min and less than max (but not equal). The second version selects edges with exactly the given length. The third version is similar to the first one, but allows specification of nil for min or max indicating that there is no lower or upper limit.

This method is available for edge and edge pair layers.

When called on an edge pair layer, this method will select edge pairs if one or both of the edges meet the length criterion. Use the additional argument and pass "both" (plain word) to specify that both edges need to be within the given interval. By default, it's sufficient for one edge to meet the criterion.

Here are examples for "with_length" on edge pair layers:

```
# at least one edge needs to have a length of 1.0 <= l < 2.0
ep1 = edge_pairs.with_length(1.um .. 2.um)
# both edges need to have a length of exactly 2 um
ep2 = edge_pairs.with_length(2.um, both)
```

"with_perimeter" - Selects polygons by perimeter

Usage:

- `layer.with_perimeter(min .. max)`
- `layer.with_perimeter(value)`
- `layer.with_perimeter(min, max)`

The first form will select all polygons with an perimeter larger or equal to min and less (but not equal to) max. The second form will select the polygons with exactly the given perimeter. The third form basically is equivalent to the first form, but allows specification of nil for min or max indicating no lower or upper limit.

This method is available for polygon layers only.

"with_relative_height" - Selects polygons by the ratio of the height vs. width of its bounding box

Usage:

- `layer.with_relative_height(min .. max)`
- `layer.with_relative_height(value)`
- `layer.with_relative_height(min, max)`

The relative height is a measure how tall a polygon is. Tall polygons have values larger than 1, wide polygons have a value smaller than 1. Squares have a value of 1.

Don't use this method when you can use with_area_ratio, which provides a similar measure but is isotropic.

This method is available for polygon layers only.

"without_angle" - Selects edges by the their angle

Usage:

- `layer.without_angle(min .. max)`
- `layer.without_angle(value)`
- `layer.without_angle(min, max)`
- `layer.without_angle(ortho)`
- `layer.without_angle(diagonal)`
- `layer.without_angle(diagonal_only)`
- `edge_pair_layer.without_angle(... [, both])`

The method basically is the inverse of with_angle. It selects all edges of the edge layer or corners of the polygons which do not have the given angle (second form) or whose angle is not inside the given interval (first and third form) or of the given type (other forms).

When called on edge pairs, it selects edge pairs by the angles of their edges.

A note on the "both" modifier (without_angle called on edge pairs): "both" means that both edges need to be "without_angle". For example

```
# both edges are not horizontal or:
# the edge pair is skipped if one edge is horizontal
ep = edge_pairs.without_angle(0, both)
```

See with_internal_angle and without_internal_angle to select edge pairs by the angle between the edges.

"without_area" - Selects polygons or edge pairs by area

Usage:

- `layer.without_area(min .. max)`
- `layer.without_area(value)`
- `layer.without_area(min, max)`

This method is the inverse of "with_area". It will select polygons or edge pairs without an area equal to the given one or outside the given interval.

This method is available for polygon or edge pair layers.

"without_area_ratio" - Selects polygons by the aspect ratio of their bounding box

Usage:

- `layer.without_area_ratio(min .. max)`
- `layer.without_area_ratio(value)`
- `layer.without_area_ratio(min, max)`

The method provides the opposite filter for with_area_ratio.

This method is available for polygon layers only.

"without_bbox_height" - Selects polygons by the aspect ratio of their bounding box

Usage:

- `layer.without_bbox_aspect_ratio(min .. max)`
- `layer.without_bbox_aspect_ratio(value)`
- `layer.without_bbox_aspect_ratio(min, max)`

The method provides the opposite filter for with_bbox_aspect_ratio.

This method is available for polygon layers only.

"without_bbox_max" - Selects polygons by the maximum dimension of the bounding box

Usage:

- `layer.without_bbox_max(min .. max)`
- `layer.without_bbox_max(value)`
- `layer.without_bbox_max(min, max)`

The method selects polygons similar to without_area or without_perimeter. However, the measured dimension is the maximum dimension of the bounding box. The minimum dimension is either the width or height of the bounding box, whichever is larger.

This method is available for polygon layers only.

"without_bbox_min" - Selects polygons by the minimum dimension of the bounding box

Usage:

- `layer.without_bbox_min(min .. max)`
- `layer.without_bbox_min(value)`
- `layer.without_bbox_min(min, max)`

The method selects polygons similar to without_area or without_perimeter. However, the measured dimension is the minimum dimension of the bounding box. The minimum dimension is either the width or height of the bounding box, whichever is smaller.

This method is available for polygon layers only.

"without_bbox_width" - Selects polygons by the width of the bounding box

Usage:

- `layer.without_bbox_width(min .. max)`
- `layer.without_bbox_width(value)`
- `layer.without_bbox_width(min, max)`

The method selects polygons similar to without_area or without_perimeter. However, the measured dimension is the width of the bounding box.

This method is available for polygon layers only.

"without_density" - Returns tiles whose density is not within a given range

Usage:

- `layer.without_density(min_value, max_value [, options ])`
- `layer.without_density(min_value .. max_value [, options ])`

For details about the operations and the operation see with_density. This version will return the tiles where the density is not within the given range.

"without_distance" - Selects edge pairs by the distance of the edges

Usage:

- `layer.without_distance(min .. max)`
- `layer.without_distance(value)`
- `layer.without_distance(min, max)`

The method basically is the inverse of with_distance. It selects all edge pairs of the edge pair layer which do not have the given distance (second form) or are not inside the given interval (first and third form).

This method is available for edge pair layers only.

"without_holes" - Selects all polygons with the specified number of holes

Usage:

- `layer.without_holes`
- `layer.without_holes(count)`
- `layer.without_holes(min_count, max_count)`
- `layer.without_holes(min_count .. max_count)`

This method is available for polygon layers. It will select all polygons from the input layer which do not have the specified number of holes. Without any arguments, all polygons without holes are selected.

"without_internal_angle" - Selects edge pairs by their internal angle

Usage:

- `edge_pair_layer.without_internal_angle(min .. max)`
- `edge_pair_layer.without_internal_angle(value)`
- `edge_pair_layer.without_internal_angle(min, max)`

The method basically is the inverse of with_internal_angle. It selects all edge pairs by the angle enclosed by their edges, applying the opposite criterion than with_internal_angle.

"without_length" - Selects edges by the their length

Usage:

- `layer.without_length(min .. max)`

- `layer.without_length(value)`
- `layer.without_length(min, max)`
- `edge_pairlayer.with_length(min, max [, both])`

The method basically is the inverse of with_length. It selects all edges of the edge layer which do not have the given length (second form) or are not inside the given interval (first and third form).

This method is available for edge and edge pair layers.

A note on the "both" modifier (without_length called on edge pairs): "both" means that both edges need to be "without_length". For example

```
# both edges are not exactly 1 um in length, or:
# the edge pair is skipped if one edge has a length of exactly 1 um
ep = edge_pairs.without_length(1.um, both)
```

"without_perimeter" - Selects polygons by perimeter

Usage:

- `layer.without_perimeter(min .. max)`
- `layer.without_perimeter(value)`
- `layer.without_perimeter(min, max)`

This method is the inverse of "with_perimeter". It will select polygons without a perimeter equal to the given one or outside the given interval.

This method is available for polygon layers only.

"without_relative_height" - Selects polygons by the ratio of the height vs. width

Usage:

- `layer.without_relative_height(min .. max)`
- `layer.without_relative_height(value)`
- `layer.without_relative_height(min, max)`

The method provides the opposite filter for with_relative_height.

This method is available for polygon layers only.

"xor" - Boolean XOR operation

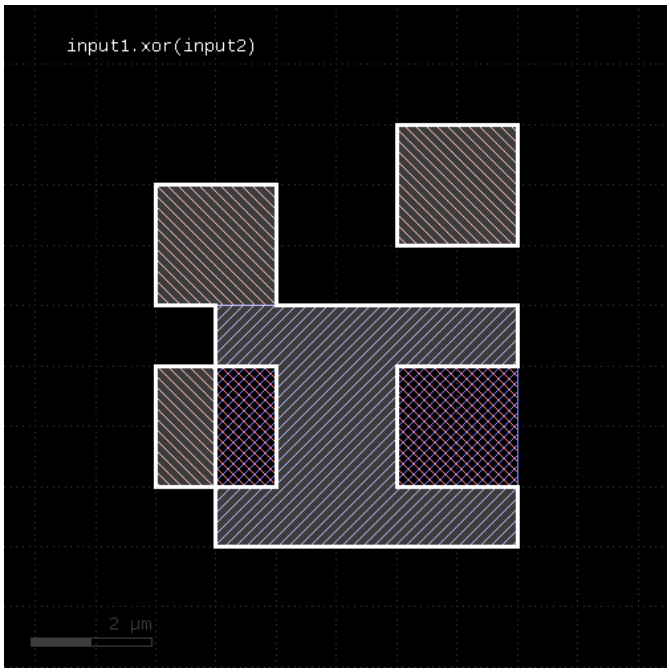
Usage:

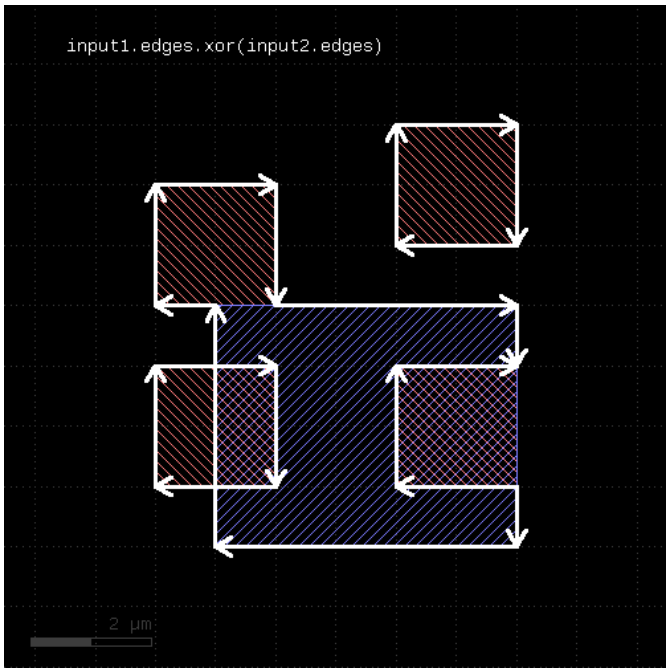
- `layer.xor(other)`

The method computes a boolean XOR between self and other. It is an alias for the "^" operator.

This method is available for polygon and edge layers.

The following images show the effect of the "xor" method on polygons and edges (input1: red, input2: blue):





"|" - Boolean OR operation

Usage:

- `self | other`

The method computes a boolean OR between self and other. A similar operation is join which will basically gives the same result but won't merge the shapes.

This method is available for polygon and edge layers. An alias is "or". See there for a description of the function.

2.20.3. DRC Reference: Netter object

The Netter object provides services related to network extraction from a layout. The relevant methods of this object are available as global functions too where they act on a default incarnation of the netter. Usually it's not required to instantiate a Netter object, but it serves as a container for this functionality.

```
# create a new Netter object:
nx = netter
nx.connect(poly, contact)
...
```

Network formation:

A basic service the Netter object provides is the formation of connected networks of conductive shapes (netting). To do so, the Netter must be given a connection specification. This happens by calling "connect" with two polygon layers. The Netter will then regard all overlaps of shapes on these layers as connections between the respective materials. Networks are the basis for netlist extraction, network geometry deduction and the antenna check.

Connections can be cleared with "clear_connections". If not, connections add atop of the already defined ones. Here is an example for the antenna check:

```
# build connction of poly+gate to metal1
connect(gate, poly)
connect(poly, contact)
connect(contact, metal1)

# runs an antenna check for metal1 with a ratio of 50
m1_antenna_errors = antenna_check(gate, metal1, 50.0)

# add connections to metal2
connect(metal1, via1)
connect(via1, metal2)

# runs an antenna check for metal2 with a ratio of 70.0
m2_antenna_errors = antenna_check(gate, metal2, 70.0)

# this will remove all connections made
clear_connections
...
```

Further functionality of the Netter object:

More methods will be added in the future to support network-related features.

"antenna_check" - Performs an antenna check

Usage:

- `antenna_check(gate, metal, ratio, [ diode_specs ... ] [, texts ])`

The antenna check is used to avoid plasma induced damage. Physically, the damage happes if during the manufacturing of a metal layer with plasma etching charge accumulates on the metal islands. On reaching a certain threshold, this charge may discarge over gate oxide attached of devices attached to such metal areas hence damaging it.

Antenna checks are performed by collecting all connected nets up to a certain metal layer and then computing the area of all metal shapes and all connected gates of a certain kind (e.g. thin and thick oxide gates). The ratio of metal area divided by the gate area must not exceed a certain threshold.

A simple antenna check is this:

```
poly = ... # poly layer
diff = ... # diffusion layer
contact = ... # contact layer
metal1 = ... # metal layer

# compute gate area
gate = poly & diff

# note that gate and poly have to be included - gate is
# a subset of poly, but forms the sensitive area
connect(gate, poly)
connect(poly, contact)
connect(contact, metal1)
errors = antenna_check(gate, metal1, 50.0)
```

Usually antenna checks apply to multiple metal layers. In this case, the connectivity needs to be extended after the first check to include the next metal layers. This can be achieved with incremental connects:

```
# provide connections up to metal1
connect(gate, poly)
connect(poly, contact)
connect(contact, metal1)
metal1_errors = antenna_check(gate, metal1, 50.0)

# now *add* connections up to metal2
connect(metal1, via1)
connect(via1, metal2)
metal2_errors = antenna_check(gate, metal2, 50.0)

... continue this scheme with further metal layers ...
```

Plasma induced damage can be rectified by including diodes which create a safe current path for discharging the metal islands. Such diodes can be identified with a recognition layer (usually the diffusion area of a certain kind). You can include such diode recognition layers in the antenna check. If a connection is detected to a diode, the respective network is skipped:

```
...
diode = ... # diode recognition layer

connect(diode, contact)
errors = antenna_check(gate, metal1, 50.0, diode)
```

You can also make diode connections decreases the sensitivity of the antenna check depending on the size of the diode. The following specification makes diode connections increase the ratio threshold by 10 per square micrometer of diode area:

```
...
diode = ... # diode recognition layer

connect(diode, contact)
# each square micrometer of diode area connected to a network
# will add 10 to the ratio:
errors = antenna_check(gate, metal1, 50.0, [ diode, 10.0 ])
```

Multiple diode specifications are allowed. Just add them to the antenna_check call.

You can include the perimeter into the area computation for the gate or metal layer or both. The physical picture is this: the side walls of the material contribute to the surface too. As the side wall area can be estimated by taking the perimeter times some material thickness, the effective area is:

```
A(eff) = A + P * t
```

Here A is the area of the polygons and P is their perimeter. t is the "thickness" in micrometer units. To specify such a condition, use the following notation:

```
errors = antenna_check(area_and_perimeter(gate, 0.5), ...)
```

"area_and_perimeter" takes the polygon layer and the thickness (0.5 micrometers in this case). This notation can be applied to both gate and metal layers. A detailed notation for the usual, area-only case is available as well for completeness:

```
errors = antenna_check(area_only(gate), ...)

# this is equivalent to a zero thickness:
errors = antenna_check(area_and_perimeter(gate, 0.0), ...)
# or the standard case:
errors = antenna_check(gate, ...)
```

Finally there is also "perimeter_only". When using this specification with a thickness value, the area is computed from the perimeter alone:

```
A(eff) = P * t
```

```
errors = antenna_check(perimeter_only(gate, 0.5), ...)
```

The error shapes produced by the antenna check are copies of the metal shapes on the metal layers of each network violating the antenna rule.

You can specify a text layer (use "labels" to create one). It will receive error labels describing the measured values and computation parameters for debugging the layout. This option has been introduced in version 0.27.11.

"clear_connections" - Clears all connections stored so far

Usage:

- `clear_connections`

See connect for more details.

"connect" - Specifies a connection between two layers

Usage:

- `connect(a, b)`

a and b must be polygon or text layers. After calling this function, the Netter regards all overlapping or touching shapes on these layers to form an electrical connection between the materials formed by these layers. This also implies intra-layer connections: shapes on these layers touching or overlapping other shapes on these layers will form bigger, electrically connected areas.

Texts will be used to assign net names to the nets. The preferred method is to use labels to create a text layer from a design layer. When using input, text labels are carried implicitly with the polygons but at the cost of small dummy shapes (2x2 DBU marker polygons) and limited functionality.

Multiple connect calls must be made to form larger connectivity stacks across multiple layers. Such stacks may include forks and joins.

Connections are accumulated. The connections defined so far can be cleared with clear_connections.

"connect_explicit" - Specifies a list of net names for nets to connect ("must connect" nets)

Usage:

- `connect_explicit(net_names)`
- `connect_explicit(cell_pattern, net_names)`

Use this method to explicitly connect nets even if there is no physical connection. The concept is similar to implicit connection (see connect_implicit). The method gets a list of nets which are connected virtually, even if there is no physical connection. The first version applies this scheme to all cells, the second version to cells matching the cell name pattern. The cell name pattern follows the usual glob style form (e.g. "A*" applies the connection in all cells whose name starts with "A").

This method is useful to establish a logical connection which is made later up on the next level of hierarchy. For example, a standard cell my not contain substrate or well taps as these may be made by tap or spare cells. Logically however, the cell only has one power or ground pin for the devices and substrate or well. In order to match both representations - for example for the purpose of LVS - the dual power or ground pins have to be connected. Assuming that there is a global net "BULK" for the substrate and a net "VSS" for the sources of the NMOS devices, the following statement will create this connection for all cell names beginning with "INV":

```
connect_global(bulk, "BULK")
...
connect_explicit("INV*", [ "BULK", "VSS" ])
```

The resulting net and pin will carry a name made from the combination of the connected nets. In this case it will be "BULK,VSS".

The virtual connection in general bears the risk of missing a physical connection. The "connect_explicit" feature therefore checks whether the connection is made physically on the next hierarchy level ("must connect" nets), except for top-level cells for which it is assumed that this connection is made later. A warning is raised instead for top level cells.

Explicit connections also imply implicit connections between different parts of one of the nets. In the example before, "VSS" pieces without a physical connection will also be connected.

The explicit connections are applied on the next net extraction and cleared on "clear_connections".

"connect_global" - Connects a layer with a global net

Usage:

- `connect_global(l, name)`

Connects the shapes from the given layer l to a global net with the given name. Global nets are common to all cells. Global nets automatically connect to parent cells throughs implied pins. An example is the substrate (bulk) net which connects to shapes belonging to tie-down diodes. "l" can be a polygon or text layer.

"connect_implicit" - Specifies a search pattern for implicit net connections ("must connect" nets)

Usage:

- `connect_implicit(label_pattern)`
- `connect_implicit(cell_pattern, label_pattern)`

This method specifies a net name search pattern, either for all cells or for certain cells, given by a name search pattern. Search pattern follow the usual glob form (e.g. "A*" for all cells or nets with names starting with "A").

Then, for nets matching the net name pattern and for which there is more than one subnet, the subnets are connected. "Subnets" are physically disconnected parts of a net which carry the same name.

This feature is useful for example for power nets which are complete in a cell, but are supposed to be connected upwards in the hierarchy ("must connect" nets). Physically there are multiple nets, logically - and specifically in the schematic for the purpose of LVS - there is only one net. "connect_implicit" now creates a virtual, combined physical net that matches the logical net.

This is general bears the risk of missing a physical connection. The "connect_implicit" feature therefore checks whether the connection is made physically on the next hierarchy level, except for top-level cells for which it is assumed that this connection is made later. A warning is raised instead for top level cells.

The implicit connections are applied on the next net extraction and cleared on "clear_connections". Another feature is connect_explicit which allows connecting differently named subnets in a similar fashion.

"device_scaling" - Specifies a dimension scale factor for the geometrical device properties

Usage:

- `device_scaling(factor)`

Specifying a factor of 2 will make all devices being extracted as if the geometries were two times larger. This feature is useful when the drawn layout does not correspond to the physical dimensions.

"extract_devices" - Extracts devices based on the given extractor class, name and device layer selection

Usage:

- `extract_devices(extractor, layer_hash)`
- `extract_devices(extractor_class, name, layer_hash)`

Runs the device extraction for given device extractor class. In the first form, the extractor object is given. In the second form, the extractor's class object and the new extractor's name is given.

The device extractor is either an instance of one of the predefined extractor classes (e.g. obtained from the utility methods such as mos4) or a custom class. It provides the algorithms for deriving the device parameters from the device geometry. It needs several device recognition layers which are passed in the layer hash.

Predefined device extractors are:

- mos3 - A three-terminal MOS transistor
- mos4 - A four-terminal MOS transistor
- dmos3 - A three-terminal MOS asymmetric transistor
- dmos4 - A four-terminal MOS asymmetric transistor
- bjt3 - A three-terminal bipolar transistor
- bjt4 - A four-terminal bipolar transistor
- diode - A planar diode
- resistor - A resistor
- resistor_with_bulk - A resistor with a separate bulk terminal
- capacitor - A capacitor
- capacitor_with_bulk - A capacitor with a separate bulk terminal

Each device class (e.g. n-MOS/p-MOS or high Vt/low Vt) needs its own instance of device extractor. The device extractor beside the algorithm and specific extraction settings defines the name of the device to be built.

The layer hash is a map of device type specific functional names (key) and polygon layers (value). Here is an example:

```
deep

nwell   = input(1, 0)
active  = input(2, 0)
poly    = input(3, 0)
bulk    = make_layer   # renders an empty layer used for putting the terminals on

nactive = active - nwell  # active area of NMOS
nsd     = nactive - poly  # source/drain area
gate    = nactive & poly  # gate area

extract_devices(mos4("NMOS4"), { :SD => nsd, :G => gate, :P => poly, :W => bulk })
```

The return value of this method will be the device class of the devices generated in the extraction step (see DeviceClass).

"ignore_extraction_errors" - Specifies whether to ignore extraction errors

Usage:

- `ignore_extraction_errors(value)`

With this value set to false (the default), "extract_netlist" will raise an exception upon extraction errors. Otherwise, extraction errors will be logged but no error is raised.

"l2n_data" - Gets the internal LayoutToNetlist object

Usage:

- `l2n_data`

The LayoutToNetlist object provides access to the internal details of the netter object.

"netlist" - Gets the extracted netlist or triggers extraction if not done yet

Usage:

- `netlist`

If no extraction has been performed yet, this method will start the layout analysis. Hence, all connect, connect_global and connect_implicit calls must have been made before this method is used. Further connect statements will clear the netlist and re-extract it again.

"soft_connect" - Specifies a soft connection between two layers

Usage:

- `soft_connect(a, b)`

a and b must be polygon or text layers. After calling this function, the Netter considers shapes from layer a and b connected in "soft mode". Typically, b is a high-ohmic layer such as diffusion, implant for substate material, also called the "lower" layer.

A soft connection between shapes from layer a and b forms a directional connection like an ideal diode: current can flow down, but now up (not meant in the physical sense, this is a concept).

Hence, two nets are disconnected, if they both connect to the same lower layer, but do not have a connection between them.

The netlist extractor will use this scheme to identify nets that are connected only via such a high-ohmic region. Such a case is typically bad for the functionality of a device and reported as an error. Once, the check has been made and no error is found, soft-connected nets are joined the same way than hard connections are made.

Beside this, soft connections follow the same rules than hard connections (see connect).

"soft_connect_global" - Soft-connects a layer with a global net

Usage:

- `soft-connect_global(l, name)`

Connects the shapes from the given layer l to a global net with the given name in "soft mode".

See connect_global for details about the concepts of global nets. See soft_connect for details about the concept of soft connections. In global net soft connections, the global net (typically a substrate) is always the "lower" layer.

"top_level" - Specifies top level mode

Usage:

- `top_level(value)`

With this value set to false (the default), it is assumed that the circuit is not used as a top level chip circuit. In that case, for example must-connect nets which are not connected are reported as as warnings. If top level mode is set to true, such disconnected nets are reported as errors as this indicates a missing physical connection.

2.20.4. DRC Reference: Source Object

The layer object represents a collection of polygons, edges or edge pairs. A source specifies where to take layout from. That includes the actual layout, the top cell and options such as clip/query boxes, cell filters etc.

"cell" - Specifies input from a specific cell

Usage:

- `source.cell(name)`

This method will create a new source that delivers shapes from the specified cell.

"cell_name" - Returns the name of the currently selected cell

Usage:

- `cell_name`

"cell_obj" - Returns the Cell object of the currently selected cell

Usage:

- `cell_obj`

"clip" - Specifies clipped input

Usage:

- `source.clip(box)`
- `source.clip(p1, p2)`
- `source.clip(l, b, r, t)`

Creates a source which represents a rectangular part of the original input. Three ways are provided to specify the rectangular region: a single DBox object (micron units), two DPoint objects (lower/left and upper/right coordinate in micron units) or four coordinates: left, bottom, right and top coordinate.

This method will create a new source which delivers the shapes from that region clipped to the rectangle. A method doing the same but without clipping is touching or overlapping.

"edge_pairs" - Gets the edge pairs from an input layer

Usage:

- `source.edge_pairs`
- `source.edge_pairs(layer)`
- `source.edge_pairs(layer, datatype)`
- `source.edge_pairs(layer_into)`
- `source.edge_pairs(filter, ...)`

Creates a layer with the edge_pairs from the given layer of the source. Edge pairs are not supported by layout formats so far. So except if the source is a custom-built layout object, this method has little use. It is provided for future extensions which may include edge pairs in file streams.

This method is identical to input with respect to the options supported.

Use the global version of "edge_pairs" without a source object to address the default source.

"edge_pairs" without any arguments will create a new, empty original layer.

This method has been introduced in version 0.27.

"edges" - Gets the edge shapes (or shapes that can be converted edges) from an input layer

Usage:

- `source.edges`
- `source.edges(layer)`
- `source.edges(layer, datatype)`
- `source.edges(layer_into)`
- `source.edges(filter, ...)`

Creates a layer with the edges from the given layer of the source. Edge layers are formed from shapes by decomposing the shapes into edges: polygons for example are decomposed into their outline edges. Some file formats support egdes as native objects.

This method is identical to input with respect to the options supported.

Use the global version of "edges" without a source object to address the default source.

"edges" without any arguments will create a new, empty original layer.

This method has been introduced in version 0.27.

"extent" - Returns a layer with the bounding box of the selected layout or cells

Usage:

- `source.extent`
- `source.extent(cell_filter)`

Without an argument, the extent method returns a layer with the bounding box of the top cell. With a cell filter argument, the method returns a layer with the bounding boxes of the selected cells. The cell filter is a glob pattern.

The extent function is useful to invert a layer:

```
inverse_1 = extent.sized(100.0) - input(1, 0)
```

The following example returns the bounding boxes of all cells whose names start with "A":

```
a_cells = extent("A*")
```

"global_transform" - Gets or sets a global transformation

Usage:

- `global_transform`
- `global_transform([ transformations ])`

This method returns a new source representing the transformed layout. It is provided in the spritit of Source#clip and similar methods.

The transformation is either given as a DTrans, DVector or DCplxTrans object or as one of the following specifications:

- "shift(x, y)": shifts the input layout horizontally by x and vertically by y micrometers
- "rotate(a)": rotates the input layout by a degree counter-clockwise
- "magnify(m)": magnifies the input layout by the factor m (NOTE: using fractional scale factors may result in small gaps due to grid snapping)
- "mirror_x": mirrors the input layout at the x axis
- "mirror_y": mirrors the input layout at the y axis

Multiple transformation specs can be given. In that case the transformations are applied right to left. Using "global_transform" will reset any global transformation present already. Without an argument, the global transformation is reset.

The following example rotates the layout by 90 degree at the origin (0, 0) and then shifts it up by 100 micrometers:

```
source.global_transform(shift(0, 100.um), rotate(90.0))
```

"input" - Specifies input from a source

Usage:

- `source.input`
- `source.input(layer)`
- `source.input(layer, datatype)`
- `source.input(layer_into)`
- `source.input(filter, ...)`
- `source.input(props_spec, ...)`

Creates a layer with the shapes from the given layer of the source. The layer can be specified by layer and optionally datatype, by a LayerInfo object or by a sequence of filters. Filters are expressions describing ranges of layers and/or datatype numbers or layer names. Multiple filters can be given and all layers matching at least one of these filter expressions are joined to render the input layer for the DRC engine.

Some filter expressions are:

- `1/0-255` : Datatypes 0 to 255 for layer 1
- `1-10` : Layers 1 to 10, datatype 0
- `METAL` : A layer named "METAL"
- `METAL (17/0)` : A layer named "METAL" or layer 17, datatype 0 (for GDS, which does not have names)

Layers created with "input" may contain both texts (labels) and polygons. There is a subtle difference between flat and deep mode: in flat mode, texts are not visible in polygon operations. In deep mode, texts appear as small 2x2 DBU rectangles. In flat mode, some operations such as clipping are not fully supported for texts. Also, texts will vanish in most polygon operations such as booleans etc.

Texts can later be selected on the layer returned by "input" with the Layer#texts method.

If you don't want to see texts, use polygons to create an input layer with polygon data only. If you only want to see texts, use labels to create an input layer with texts only.

labels also produces a true "text layer" which contains text objects. A variety of operations is available for these objects, such as boolean "and" and "not" with a polygon layer. True text layers should be preferred over mixed polygon/text layers if text object processing is required.

"input" without any arguments will create a new, empty original layer.

If you want to use user properties - for example with properties constraints in DRC checks - you need to enable properties on input:

```
input1_with_props = input(1, 0, enable_props)
```

You can also filter or map property keys, similar to the functions available on layers (DRCLayer#map_props, DRCLayer#select_props). For example to select property values with key 17 (numerical) only, use:

```
input1_with_props = input(1, 0, select_props(17))
```

Use the global version of "input" without a source object to address the default source.

"labels" - Gets the labels (texts) from an input layer

Usage:

- `source.labels`
- `source.labels(layer)`
- `source.labels(layer, datatype)`
- `source.labels(layer_into)`
- `source.labels(filter, ...)`

Creates a true text layer with the labels from the given layer of the source.

This method is identical to input, but takes only texts from the given input layer. Starting with version 0.27, the result is no longer a polygon layer that tries to provide text support but a layer type which is provided for carrying text objects explicitly.

"labels" without any arguments will create a new, empty original layer.

Use the global version of "labels" without a source object to address the default source.

"layers" - Gets the layers the source contains

Usage:

- `source.layers`

Delivers a list of LayerInfo objects representing the layers inside the source.

One application is to read all layers from a source. In the following example, the "and" operation is used to perform a clip with the given rectangle. Note that this solution is not efficient - it's provided as an example only:

```
output_cell("Clipped")

clip_box = polygon_layer
clip_box.insert(box(0.um, -4.um, 4.um, 0.um))
```

```
layers.each { |l| (input(l) & clip_box).output(l) }
```

"layout" - Returns the Layout object associated with this source

Usage:

- `layout`

"make_layer" - Creates an empty polygon layer based on the hierarchy of the layout

Usage:

- `make_layer`

This method delivers a new empty original layer. It is provided to keep old code working. Use "input" without arguments instead.

"overlapping" - Specifies input selected from a region in overlapping mode

Usage:

- `source.overlapping(...)`

Like clip, this method will create a new source delivering shapes from a specified rectangular region. In contrast to clip, all shapes overlapping the region with their bounding boxes are delivered as a whole and are not clipped. Hence shapes may extent beyond the limits of the specified rectangle.

touching is a similar method which delivers shapes touching the search region with their bounding box (without the requirement to overlap)

"path" - Gets the path of the corresponding layout file or nil if there is no path

Usage:

- `path`

"polygons" - Gets the polygon shapes (or shapes that can be converted polygons) from an input layer

Usage:

- `source.polygons`
- `source.polygons(layer)`
- `source.polygons(layer, datatype)`
- `source.polygons(layer_into)`
- `source.polygons(filter, ...)`

Creates a layer with the polygon shapes from the given layer of the source. With "polygon shapes" we mean all kind of shapes that can be converted to polygons. Those are boxes, paths and real polygons.

This method is identical to input with respect to the options supported.

"polygons" without any arguments will create a new, empty original layer.

Use the global version of "polygons" without a source object to address the default source.

"select" - Adds cell name expressions to the cell filters

Usage:

- `new_source = source.select(filter1, filter2, ...)`

This method will construct a new source object with the given cell filters applied. Note that there is a global version of "select" which does not create a new source, but acts on the default source.

Cell filters will enable or disable cells plus their subtree. Cells can be switched on and off, which makes the hierarchy traversal stop or begin delivering shapes at the given cell. The arguments of the select method form a sequence of enabling or disabling instructions using cell name pattern in the glob notation ("*" as the wildcard, like shell). Disabling instructions start with a "-", enabling instructions with a "+" or no specification.

The following options are available:

- + *name_filter* : Cells matching the name filter will be enabled
- *name_filter* : Same as "+name_filter"
- - *name_filter* : Cells matching the name filter will be disabled

To disable the TOP cell but enabled a hypothetical cell B below the top cell, use that code:

```
source_with_selection = source.select("-TOP", "+B")
l1 = source_with_selection.input(1, 0)
...
```

Please note that the sample above will deliver the children of "B" because there is nothing said about how to proceed with cells other than "TOP" or "B". Conceptually, the instantiation path of a cell will be matched against the different filters in the order they are given. A matching negative expression will disable the cell, a matching positive expression will enable the cell. Hence, every cell that has a "B" in the instantiation path is enabled.

The following code will just select "B" without its children, because in the first "-*" selection, all cells including the children of "B" are disabled:

```
source_with_selection = source.select("-*", "+B")
l1 = source_with_selection.input(1, 0)
...
```

The short form "-" will disable the top cell. This code is identical to the first example and will start with a disabled top cell regardless of its name:

```
source_with_selection = source.select("-", "+B")
l1 = source_with_selection.input(1, 0)
...
```

"touching" - Specifies input selected from a region in touching mode

Usage:

- `source.touching(box)`
- `source.touching(p1, p2)`

- `source.touching(l, b, r, t)`

Like clip, this method will create a new source delivering shapes from a specified rectangular region. In contrast to clip, all shapes touching the region with their bounding boxes are delivered as a whole and are not clipped. Hence shapes may extent beyond the limits of the specified rectangle.

overlapping is a similar method which delivers shapes overlapping the search region with their bounding box (and not just touching)

2.20.5. DRC Reference: Global Functions

"angle" - In universal DRC context: selects edges based on their orientation

Usage:

- `angle (in condition)`

"angle" represents the edge orientation filter on the primary shape edges in DRC expressions (see Layer#drc and DRC#angle for more details). In this context, the operation acts similar to Layer#with_angle.

"antenna_check" - Performs an antenna check

Usage:

- `antenna_check(gate, metal, ratio, [ diode_specs ... ])`

See Netter#antenna_check for a description of that function.

"area" - Computes the total area or in universal DRC context: selects the primary shape if the area is meeting the condition

Usage:

- `area (in condition)`
- `area(layer)`

This function can be used with a layer argument. In this case it is equivalent to "layer.area" (see Layer#area) and returns the total area of the polygons in the layer.

Without a layer argument, "area" represents an area filter for primary shapes in global expressions (see Layer#drc and DRC#area for more details).

"area_ratio" - Selects primary shapes based on the ratio of bounding box and polygon area

Usage:

- `area_ratio (in condition)`

See Layer#drc, area_ratio and DRC#area_ratio for more details.

"bbox_aspect_ratio" - Selects primary shapes based on the aspect ratio of their bounding boxes

Usage:

- `bbox_aspect_ratio (in condition)`

See Layer#drc, bbox_aspect_ratio and DRC#bbox_aspect_ratio for more details.

"bbox_height" - Selects primary shapes based on their bounding box height

Usage:

- `bbox_height (in condition)`

This method creates a universal DRC expression (see Layer#drc) to select primary shapes whose bounding box height satisfies the condition. Conditions may be written as arithmetic comparisons against numeric values. For example, "bbox_height < 2.0" will select all primary shapes whose bounding box height is less than 2 micrometers. See Layer#drc for more details about comparison specs. Plain "bbox_min" is equivalent to "primary.bbox_min" - i.e. it is used on the primary shape. Also see DRC#bbox_min.

"bbox_max" - Selects primary shapes based on their bounding box height or width, whichever is larger

Usage:

- `bbox_max (in condition)`

See Layer#drc, bbox_max and DRC#bbox_max for more details.

"bbox_min" - Selects primary shapes based on their bounding box height or width, whichever is smaller

Usage:

- `bbox_max (in condition)`

See Layer#drc, bbox_min and DRC#bbox_min for more details.

"bbox_width" - Selects primary shapes based on their bounding box width

Usage:

- `bbox_max (in condition)`

See Layer#drc, bbox_height and DRC#bbox_height for more details.

"bjt3" - Supplies the BJT3 transistor extractor class

Usage:

- `bjt3(name)`
- `bjt3(name, class)`

Use this class with extract_devices to specify extraction of a bipolar junction transistor

See DeviceExtractorBJT3Transistor for more details about this extractor.

"bjt4" - Supplies the BJT4 transistor extractor class

Usage:

- `bjt4(name)`
- `bjt4(name, class)`

Use this class with extract_devices to specify extraction of a bipolar junction transistor with a substrate terminal

See DeviceExtractorBJT4Transistor for more details about this extractor.

"box" - Creates a box object

Usage:

- `box(...)`

This function creates a box object. The arguments are the same than for the DBox constructors.

"capacitor" - Supplies the capacitor extractor class

Usage:

- `capacitor(name, area_cap)`
- `capacitor(name, area_cap, class)`

Use this class with extract_devices to specify extraction of a capacitor. The area_cap argument is the capacitance in Farad per square micrometer.

See DeviceExtractorCapacitor for more details about this extractor.

"capacitor_with_bulk" - Supplies the capacitor extractor class that includes a bulk terminal

Usage:

- `capacitor_with_bulk(name, area_cap)`
- `capacitor_with_bulk(name, area_cap, class)`

Use this class with extract_devices to specify extraction of a capacitor with a bulk terminal. The area_cap argument is the capacitance in Farad per square micrometer.

See DeviceExtractorCapacitorWithBulk for more details about this extractor.

"cell" - Selects a cell for input on the default source

Usage:

- `cell(args)`

See Source#cell for a description of that function. In addition to the functionality described there, the global function will also send the output to the specified cell.

The following code will select cell "MACRO" from the input layout:

```
cell("MACRO")
# shapes now will be taken from cell "MACRO"
l1 = input(1, 0)
```

"cheat" - Hierarchy cheats

Usage:

- `cheat(args) { block }`

Hierarchy cheats can be used in deep mode to shortcut hierarchy evaluation for certain cells and consider their local configuration only. Cheats are useful for example when dealing with memory arrays. Often such arrays are build from unit cells and those often overlap with their neighbors. Now, if the hierarchical engine encounters such a situation, it will first analyse all these interactions (which can be expensive) and then it may come to the conclusion that boundary instances need to be handled differently than inside instances. This in turn might lead to propagation of shapes and in an LVS context to device externalisation: because some devices might have different parameters for boundary cells than for inside cells, the device instances can no longer be kept inside the unit cell. Specifically for memory arrays, this is not desired as eventually this leads to flattening of the whole array.

The solution is to cheat: provided the unit cell is fully fledged and neighbors do not disturb the unit cell's configuration in critical ways, the unit cell can be treated as being isolated and results are put together in the usual way.

Cheats can be applied on layout operations - specifically booleans - and device extraction operations. Cheats are only effective in deep mode.

For booleans, a cheat means that the cheating cell's boolean results are computed locally and are combined afterwards. A cheat is introduced this way:

```
deep

l1 = input(1, 0)
l2 = input(2, 0)

# usual booleans
l1and2 = l1 & l2

# will compute "UNIT_CELL" isolated and everything else in normal hierarchical mode:
l1minus2 = cheat("UNIT_CELL") { l1 - l2 }
```

The cheat block can also be wrapped in do .. end statements and can return multiple layer objects:

```
deep

l1 = input(1, 0)
l2 = input(2, 0)

# computes both AND and NOT of l1 and l2 with cheating for "UNIT_CELL"
l1and2, l1minus2 = cheat("UNIT_CELL") do
[ l1 & l2, l1 - l2 ]
end
```

(Technically, the cheat code block is a Ruby Proc and cannot create variables outside its scope. Hence the results of this code block have to be passed through the "cheat" method).

To apply cheats for device extraction, use the following scheme:

```
deep

poly = input(1, 0)
active = input(2, 0)

sd = active - poly
gate = active & poly

# device extraction with cheating for "UNIT_CELL":
cheat("UNIT_CELL") do
extract_devices(mos3("NMOS"), { "SD" => sd, "G" => gate, "tS" => sd, "tD" => sd, "tG" => poly }
end
```

The argument to the cheat method is a list of cell name pattern (glob-style pattern). For example:

```
cheat("UNIT_CELL*") { ... }
cheat("UNIT_CELL1", "UNIT_CELL2") { ... }
cheat("UNIT_CELL{1,2}") { ... }
```

For LVS applications, it's usually sufficient to cheat in the device extraction step. Cheats have been introduced in version 0.26.1.

"clear_connections" - Clears all connections stored so far

Usage:

- `clear_connections`

See Netter#clear_connections for a description of that function.

"clip" - Specifies clipped input on the default source

Usage:

- `clip(args)`

See Source#clip for a description of that function.

The following code will select shapes within a 500x600 micron rectangle (lower left corner at 0,0) from the input layout. The shapes will be clipped to that rectangle:

```
clip(0.mm, 0.mm, 0.5.mm, 0.6.mm)
# shapes now will be taken from the given rectangle and clipped to it
l1 = input(1, 0)
```

To remove the clip condition, call "clip" without any arguments.

"connect" - Specifies a connection between two layers

Usage:

- `connect(a, b)`

See Netter#connect for a description of that function.

"connect_explicit" - Specifies explicit net connections

Usage:

- `connect_explicit(net_names)`
- `connect_explicit(cell_pattern, net_names)`

See Netter#connect_explicit for a description of that function. Net names is an array (use square brackets to list the net names).

"connect_global" - Specifies a connection to a global net

Usage:

- `connect_global(l, name)`

See Netter#connect_global for a description of that function.

"connect_implicit" - Specifies a label pattern for implicit net connections

Usage:

- `connect_implicit(label_pattern)`

- `connect_implicit(cell_pattern, label_pattern)`

See Netter#connect_implicit for a description of that function.

"corners" - Selects corners of polygons

Usage:

- `corners([ options ]) (in condition)`
- `corners(layer [, options ])`

This function can be used with a layer argument. In this case it is equivalent to "layer.corners" (see Layer#corners). Without a layer argument, "corners" represents the corner generator/filter in primary shapes for DRC expressions (see Layer#drc and corners for more details).

Like the layer-based version, the "corners" operator accepts the output type option: "as_dots" for dot-like edges, "as_boxes" for small (2x2 DBU) box markers and "as_edge_pairs" for edge pairs. The default output type is "as_boxes".

The "corners" operator can be put into a condition which means it's applied to corners meeting a particular angle constraint.

"covering" - Selects shapes entirely covering other shapes

Usage:

- `covering(other) (optionally in condition)`

This operator represents the selector of primary shapes which entirely cover shapes from the other layer. This version can be put into a condition indicating how many shapes of the other layer need to be covered. Use this operator within DRC expressions (also see Layer#drc). If can be used as method to an expression. See there for more details: covering.

"dbu" - Gets or sets the database unit to use

Usage:

- `dbu(dbu_value)`
- `dbu`

Without any argument, this method gets the database unit used inside the DRC engine.

With an argument, sets the database unit used internally in the DRC engine. Without using that method, the database unit is automatically taken as the database unit of the last input. A specific database unit can be set in order to optimize for two layouts (i.e. take the largest common denominator). When the database unit is set, it must be set at the beginning of the script and before any operation that uses it.

"deep" - Enters deep (hierarchical) mode

Usage:

- `deep`

In deep mode, the operations will be performed in a hierarchical fashion. Sometimes this reduces the time and memory required for an operation, but this will also add some overhead for the hierarchical analysis.

"deepness" is a property of layers. Layers created with "input" while in deep mode carry hierarchy. Operations involving such layers at the only or the first argument are carried out in hierarchical mode.

Hierarchical mode has some more implications, like "merged_semantics" being implied always. Sometimes cell variants will be created.

Deep mode can be cancelled with tiles or flat.

"deep_reject_odd_polygons" - Gets or sets a value indicating whether the reject odd polygons in deep mode

Usage:

- `deep_reject_odd_polygons(flag)`
- `deep_reject_odd_polygons`

In deep mode, non-orientable (e.g. "8"-shaped) polygons may not be resolved properly. By default the interpretation of such polygons is undefined - they may even vanish entirely. By setting this flag to true, the deep mode layout processor will reject such polygons with an error.

"device_scaling" - Specifies a dimension scale factor for the geometrical device properties

Usage:

- `device_scaling(factor)`

See Netter#device_scaling for a description of that function.

"diode" - Supplies the diode extractor class

Usage:

- `diode(name)`
- `diode(name, class)`

Use this class with extract_devices to specify extraction of a planar diode

See DeviceExtractorDiode for more details about this extractor.

"dmos3" - Supplies the DMOS3 transistor extractor class

Usage:

- `dmos3(name)`
- `dmos3(name, class)`

Use this class with extract_devices to specify extraction of a three-terminal DMOS transistor. A DMOS transistor is essentially the same than a MOS transistor, but source and drain are separated.

See DeviceExtractorMOS3Transistor for more details about this extractor (strict mode applies for 'dmos3').

"dmos4" - Supplies the MOS4 transistor extractor class

Usage:

- `dmos4(name)`
- `dmos4(name, class)`

Use this class with extract_devices to specify extraction of a four-terminal DMOS transistor. A DMOS transistor is essentially the same than a MOS transistor, but source and drain are separated.

See DeviceExtractorMOS4Transistor for more details about this extractor (strict mode applies for 'dmos4').

"edge" - Creates an edge object

Usage:

- `edge(...)`

This function creates an edge object. The arguments are the same than for the DEdge constructors.

"edge_layer" - Creates an empty edge layer

Usage:

- `edge_layer`

The intention of that method is to create an empty layer which can be filled with edge objects using Layer#insert.

"edge_pairs" - Gets the edges from an original layer

Usage:

- `edge_pairs(args)`

See Source#edge_pairs for a description of that function.

"edges" - Gets the edges from an original layer

Usage:

- `edges(args)`

See Source#edges for a description of that function.

"enc" - Synonym for "enclosing"

Usage:

- `enc(...)`

"enc" is the short form for enclosing.

"enclosed" - Performs an enclosing check (other enclosing layer)

Usage:

- `enclosed(other [, options ]) (in conditions)`
- `enclosed(layer, other [, options ])`

This check verifies if the polygons of the input layer are enclosed by shapes of the other input layer by a certain distance. It has manifold options. See Layer#width for the basic options such as metrics, projection and angle constraints etc. This check also features opposite and rectangle filtering. See Layer#separation for details about opposite and rectangle error filtering.

This function is essentially the reverse of enclosing. In case of "enclosed", the other layer must be bigger than the primary layer.

Classic mode

This function can be used in classic mode with a layer argument. In this case it is equivalent to "layer.enclosed" (see Layer#enclosed).

```
# classic "enclosed" check for < 0.2 um
in = layer(1, 0)
other = layer(2, 0)
errors = enclosed(in, other, 0.2.um)
```

Universal DRC

The version without a first layer is intended for use within DRC expressions together with the "universal DRC" method Layer#drc. In this case, this function needs to be put into a condition to specify the check constraints. The other options of Layer#enclosed (e.g. metrics, projection constraints, angle limits etc.) apply to this version too:

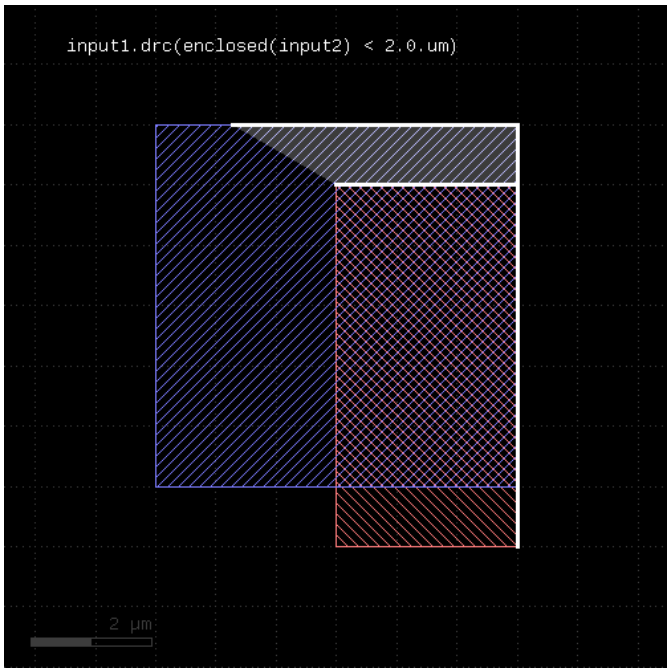
```
# universal DRC "enclosed" check for < 0.2 um
in = layer(1, 0)
other = layer(2, 0)
errors = in.drc(enclosed(other) < 0.2.um)
```

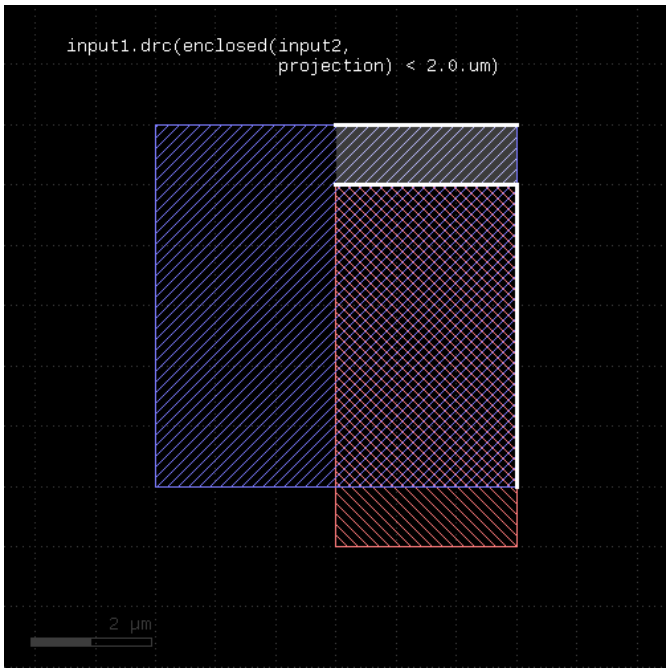
The conditions may involve an upper and lower limit. The following examples illustrate the use of this function with conditions:

```
out = in.drc(enclosed(other) < 0.2.um)
out = in.drc(enclosed(other) <= 0.2.um)
out = in.drc(enclosed(other) > 0.2.um)
out = in.drc(enclosed(other) >= 0.2.um)
out = in.drc(enclosed(other) == 0.2.um)
out = in.drc(enclosed(other) != 0.2.um)
out = in.drc(0.1.um <= enclosed(other) < 0.2.um)
```

The result of the enclosed check are edges or edge pairs forming the markers. These markers indicate the presence of the specified condition.

With a lower and upper limit, the results are edges marking the positions on the primary shape where the condition is met. With a lower limit alone, the results are edge pairs which are formed by two identical, but opposite edges attached to the primary shape. Without an upper limit only, the first edge of the marker is attached to the primary shape while the second edge is attached to the shape of the "other" layer.





When "larger than" constraints are used, this function will produce the edges from the first layer only. The result will still be edge pairs for consistency, but each edge pair holds one edge from the original polygon plus a reverse copy of that edge in the second member. Use "first_edges" to extract the actual edges from the first input (see separation for an example).

"enclosing" - Performs an enclosing check

Usage:

- `enclosing(other [, options ]) (in conditions)`
- `enclosing(layer, other [, options ])`

This check verifies if the polygons of the input layer are enclosing the shapes of the other input layer by a certain distance. It has manifold options. See Layer#width for the basic options such as metrics, projection and angle constraints etc. This check also features opposite and rectangle filtering. See Layer#separation for details about opposite and rectangle error filtering.

Classic mode

This function can be used in classic mode with a layer argument. In this case it is equivalent to "layer.enclosing" (see Layer#enclosing).

```
# classic "enclosing" check for < 0.2 um
in = layer(1, 0)
other = layer(2, 0)
errors = enclosing(in, other, 0.2.um)
```

Universal DRC

The version without a first layer is intended for use within DRC expressions together with the "universal DRC" method Layer#drc. In this case, this function needs to be put into a condition to specify the check constraints. The other options of Layer#enclosing (e.g. metrics, projection constraints, angle limits etc.) apply to this version too:

```
# universal DRC "enclosing" check for < 0.2 um
```

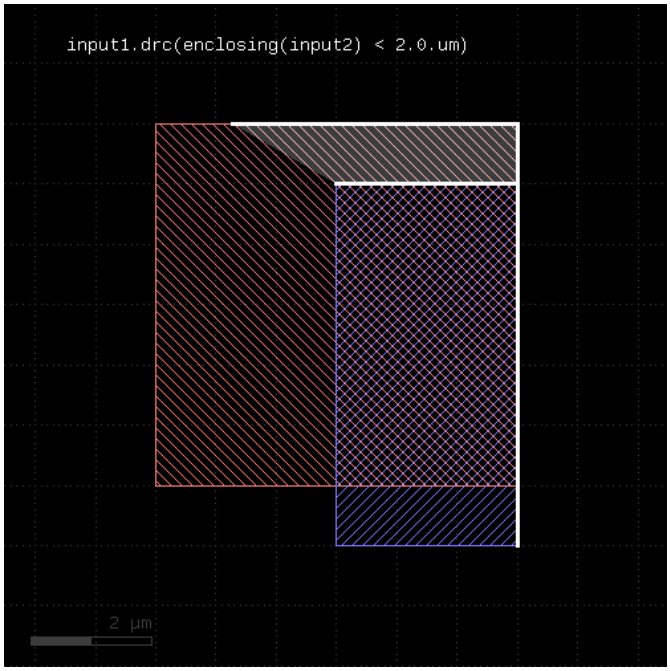
```
in = layer(1, 0)
other = layer(2, 0)
errors = in.drc(enclosing(other) < 0.2.um)
```

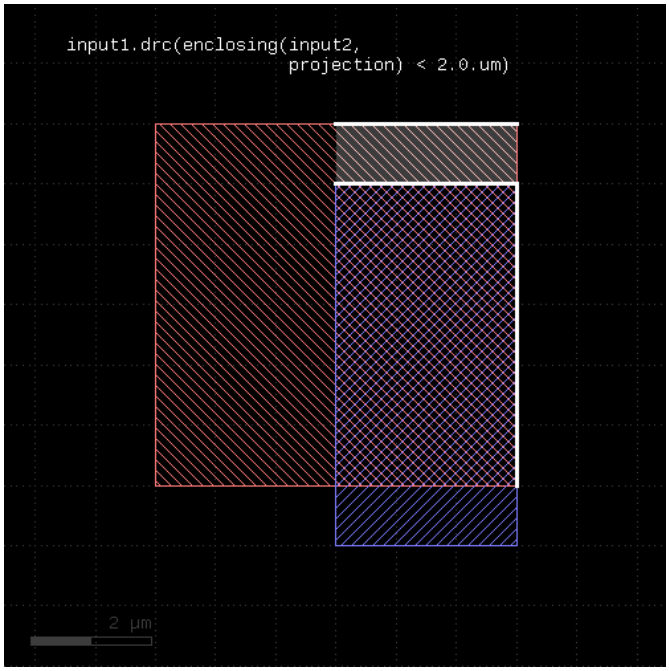
The conditions may involve an upper and lower limit. The following examples illustrate the use of this function with conditions:

```
out = in.drc(enclosing(other) < 0.2.um)
out = in.drc(enclosing(other) <= 0.2.um)
out = in.drc(enclosing(other) > 0.2.um)
out = in.drc(enclosing(other) >= 0.2.um)
out = in.drc(enclosing(other) == 0.2.um)
out = in.drc(enclosing(other) != 0.2.um)
out = in.drc(0.1.um <= enclosing(other) < 0.2.um)
```

The result of the enclosing check are edges or edge pairs forming the markers. These markers indicate the presence of the specified condition.

With a lower and upper limit, the results are edges marking the positions on the primary shape where the condition is met. With a lower limit alone, the results are edge pairs which are formed by two identical, but opposite edges attached to the primary shape. Without an upper limit only, the first edge of the marker is attached to the primary shape while the second edge is attached to the shape of the "other" layer.





When "larger than" constraints are used, this function will produce the edges from the first layer only. The result will still be edge pairs for consistency, but each edge pair holds one edge from the original polygon plus a reverse copy of that edge in the second member. Use "first_edges" to extract the actual edges from the first input (see separation for an example).

"error" - Prints an error

Usage:

- `error(message)`

Similar to log, but the message is printed formatted as an error

"extent" - Creates a new layer with the bounding box of the default source or cell bounding boxes

Usage:

- `extent`
- `extent(cell_filter)`

See Source#extent for a description of that function.

"extent_refs" - Returns partial references to the boundings boxes of the polygons

Usage:

- `extent_refs([ options ])`
- `extent_refs(layer, [ options ])`

This function can be used with a layer argument. In this case it is equivalent to "layer.extent_refs" (see Layer#extent_refs). Without a layer argument, "extent_refs" represents the partial extents extractor on primary shapes within DRC expressions (see Layer#drc and extent_refs for more details).

"extents" - Returns the bounding box of each input object

Usage:

- `extents([ enlargement ])`
- `extents(layer, [ enlargement ])`

This function can be used with a layer argument. In this case it is equivalent to "layer.extents" (see Layer#extents). Without a layer argument, "extents" represents the extents generator on primary shapes within DRC expressions (see Layer#drc and extents for more details).

"extract_devices" - Extracts devices for a given device extractor and device layer selection

Usage:

- `extract_devices(extractor, layer_hash)`
- `extract_devices(extractor_class, name, layer_hash)`

See Netter#extract_devices for a description of that function.

"flat" - Disables tiling mode

Usage:

- `flat`

Disables tiling mode. Tiling mode can be enabled again with tiles later.

"foreign" - Represents all other polygons from primary except the current one

Usage:

- `foreign`

The primary input of the universal DRC function is the layer the Layer#drc function is called on. This operation represents all "other" primary polygons while primary represents the current polygon.

This feature opens new options for processing layouts beyond the abilities of the classical DRC concept. For classic DRC, intra-layer interactions are always symmetric: a polygon cannot be considered separated from its neighbors on the same layer.

The following example computes every part of the input which is closer than 0.5 micrometers to other (disconnected) polygons on the same layer:

```
out = in.drc(primary & foreign.sized(0.5.um))
```

"global_transform" - Gets or sets a global transformation

Usage:

- `global_transform`
- `global_transform([ transformations ])`

Applies a global transformation to the default source layout. See Source#global_transform for a description of this feature.

"holes" - Selects all holes from the input polygons

Usage:

- `holes`
- `holes(layer)`

This function can be used with a layer argument. In this case it is equivalent to "layer.holes" (see Layer#hulls). Without a layer argument, "holes" represents a hole extractor for primary shapes in DRC expressions (see Layer#drc and DRC#hulls for more details).

"hulls" - Selects all hulls from the input polygons

Usage:

- `hulls`
- `hulls(layer)`

This function can be used with a layer argument. In this case it is equivalent to "layer.hulls" (see Layer#hulls). Without a layer argument, "hulls" represents a hull contour extractor for primary shapes in DRC expressions (see Layer#drc and hulls for more details).

"if_all" - Evaluates to the primary shape when all condition expression results are non-empty

Usage:

- `if_all(c1, ... cn)`

This function will evaluate the conditions c1 to cn and return the current primary shape if all conditions render a non-empty result. The following example selects all shapes which are rectangles and whose area is larger than 0.5 square micrometers:

```
out = in.drc(if_all(area > 0.5, rectangles))
```

The condition expressions may be of any type (edges, edge pairs and polygons).

"if_any" - Evaluates to the primary shape when any condition expression results is non-empty

Usage:

- `if_any(c1, ... cn)`

This function will evaluate the conditions c1 to cn and return the current primary shape if at least one condition renders a non-empty result. See if_all for an example how to use the if_... functions.

"if_none" - Evaluates to the primary shape when all of the condition expression results are empty

Usage:

- `if_none(c1, ... cn)`

This function will evaluate the conditions c1 to cn and return the current primary shape if all conditions renders an empty result. See if_all for an example how to use the if_... functions.

"ignore_extraction_errors" - Specifies whether to ignore extraction errors

Usage:

- `ignore_extraction_errors(value)`

See Netter#ignore_extraction_errors for a description of that function.

"info" - Outputs as message to the logger or progress window

Usage:

- `info(message)`
- `info(message, indent)`

Prints the message to the log window in verbose mode. In non-verbose more, nothing is printed but a statement is put into the progress window. log is a function that always prints a message.

"input" - Fetches the shapes from the specified input from the default source

Usage:

- `input(args)`

See Source#input for a description of that function. This method will fetch polygons and labels. See polygons and labels for more specific versions of this method.

"inside" - Selects shapes entirely inside other shapes

Usage:

- `inside(other)`

This operator represents the selector of primary shapes which are inside shapes from the other layer. Use this operator within DRC expressions (also see Layer#drc). If can be used as method to an expression. See there for more details: inside.

"interacting" - Selects shapes interacting with other shapes

Usage:

- `interacting(other) (optionally in condition)`

This operator represents the selector of primary shapes which interact with shapes from the other layer. This version can be put into a condition indicating how many shapes of the other layer need to be covered. Use this operator within DRC expressions (also see Layer#drc). If can be used as method to an expression. See there for more details: interacting.

"is_deep?" - Returns true, if in deep mode

Usage:

- `is_deep?`

"is_tiled?" - Returns true, if in tiled mode

Usage:

- `is_tiled?`

"iso" - Synonym for "isolated"

Usage:

- `iso(...)`

"iso" is the short form for isolated.

"isolated" - Performs an isolation (inter-polygon space) check

Usage:

- `isolated([ options ]) (in conditions)`
- `iso([ options ]) (in conditions)`
- `isolated(layer [, options ])`
- `iso(layer [, options ])`

Provides a intra-polygon space check for polygons. It is similar to space, but checks inter-polygon space only. "iso" is a synonym for "isolated". This check has manifold options. See Layer#width for the basic options such as metrics, projection and angle constraints etc. This check also features opposite and rectangle filtering. See Layer#separation for details about opposite and rectangle error filtering.

Classic mode

This function can be used in classic mode with a layer argument. In this case it is equivalent to "layer.isolated" (see Layer#isolated).

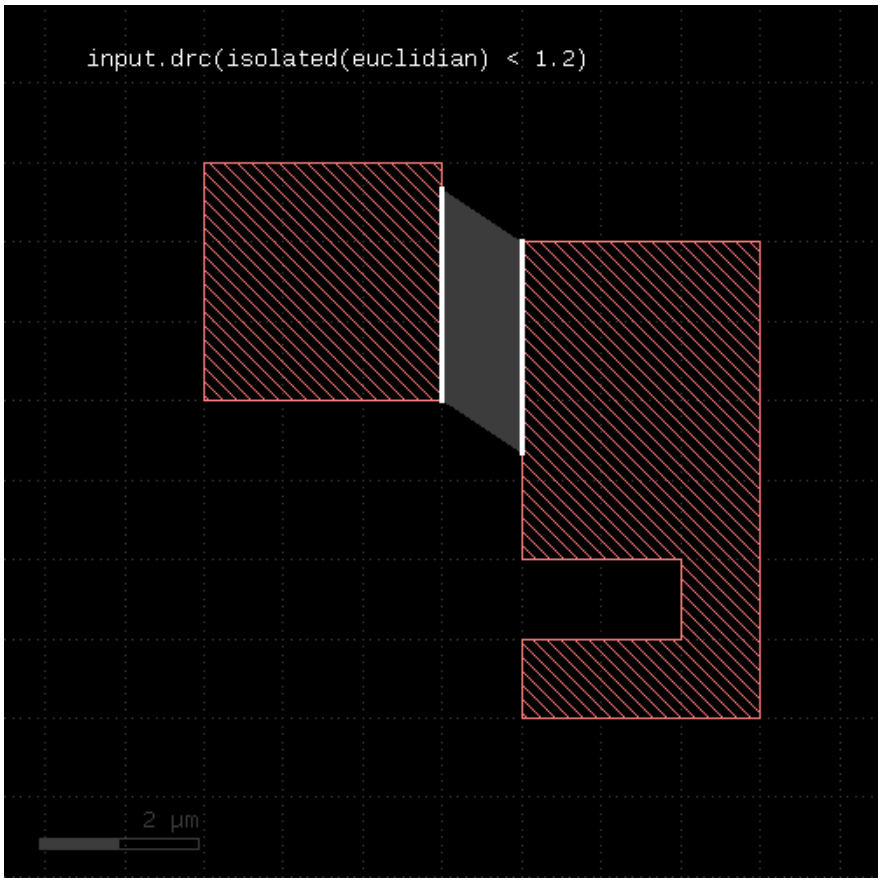
```
# classic "isolated" check for space < 1.2 um
in = layer(1, 0)
errors = isolated(in, 1.2.um)
```

Universal DRC

The version without a layer is intended for use within DRC expressions together with the "universal DRC" method Layer#drc. In this case, this function needs to be put into a condition to specify the check constraints. The other options of Layer#isolated (e.g. metrics, projection constraints, angle limits etc.) apply to this version too:

```
# universal DRC "isolated" check for space < 1.2.um
in = layer(1, 0)
errors = in.drc(isolated < 1.2.um)
```

See enclosing for more details about the various ways to specify conditions.



"l2n_data" - Gets the internal LayoutToNetlist object for the default Netter

Usage:

- `l2n_data`

See Netter#l2n_data for a description of that function.

"labels" - Gets the labels (text) from an original layer

Usage:

- `labels(args)`

See Source#labels for a description of that function.

"layers" - Gets the layers contained in the default source

Usage:

- `layers`

See Source#layers for a description of that function.

"layout" - Specifies an additional layout for the input source.

Usage:

- `layout`
- `layout(what)`

This function can be used to specify a new layout for input. It returns an Source object representing that layout. The "input" method of that object can be used to get input layers for that layout.

"what" specifies what input to use. "what" be either

- A string "@n" specifying input from a cellview in the current view
- A layout filename plus an optional cell name
- A Layout object
- A Cell object

Without any arguments the default layout is returned.

If a file name is given, a cell name can be specified as the second argument. If not, the top cell is taken which must be unique in that case.

Having specified a layout for input enables to use the input method for getting input:

```
# XOR between layers 1 or the default input and "second_layout.gds":
l2 = layout("second_layout.gds")
(input(1, 0) ^ l2.input(1, 0)).output(100, 0)
```

For further methods on the source object see Source.

"length" - Computes the total edge length of an edge layer or in universal DRC context: selects edges based on a length condition

Usage:

- `length (in condition)`
- `length(layer)`

This function can be used with a layer argument. In this case it is equivalent to "layer.length" (see Layer#length). Without a layer argument, "length" represents the edge length filter on the primary shape edges in DRC expressions (see Layer#drc and DRC#length for more details). In this context, the operation acts similar to Layer#with_length.

"log" - Outputs as message to the logger window

Usage:

- `log(message)`
- `log(message, indent)`

Prints the message to the log window. info is a function that prints a message only if verbose mode is enabled.

"log_file" - Specify the log file where to send to log to

Usage:

- `log_file(filename)`

After using that method, the log output is sent to the given file instead of the logger window or the terminal.

"make_layer" - Creates an empty polygon layer based on the hierarchical scheme selected

Usage:

- `make_layer`

The intention of this method is to provide an empty polygon layer based on the hierarchical scheme selected. This will create a new layer with the hierarchy of the current layout in deep mode and a flat layer in flat mode. This method is similar to polygon_layer, but the latter does not create a hierarchical layer. Hence the layer created by make_layer is suitable for use in device extraction for example, while the one delivered by polygon_layer is not.

On the other hand, a layer created by the make_layer method is not intended to be filled with Layer#insert.

"max_area_ratio" - Gets or sets the maximum bounding box to polygon area ratio for deep mode fragmentation

Usage:

- `max_area_ratio(ratio)`
- `max_area_ratio`

In deep mode, polygons with a bounding box to polygon area ratio bigger than the given number will be split into smaller chunks to optimize performance (which gets better if the polygon's bounding boxes do not cover a lot of empty space). The default threshold is 3.0 which means fairly compact polygons. Use this method with a numeric argument to set the value and without an argument to get the current maximum area ratio. Set the value to zero to disable splitting by area ratio.

See also max_vertex_count for the other option affecting polygon splitting.

"max_vertex_count" - Gets or sets the maximum vertex count for deep mode fragmentation

Usage:

- `max_vertex_count(count)`
- `max_vertex_count`

In deep mode, polygons with more than the given number of vertexes will be split into smaller chunks to optimize performance (which is better or less complex polygons). The default threshold is 16 vertexes. Use this method with a vertex count to set the value and without an argument to get the current maximum vertex count. Set the value to zero to disable splitting by vertex count.

See also max_area_ratio for the other option affecting polygon splitting.

"middle" - Returns the centers of polygon bounding boxes

Usage:

- `middle([ options ])`
- `middle(layer, [ options ])`

This function can be used with a layer argument. In this case it is equivalent to "layer.middle" (see Layer#middle). Without a layer argument, "middle" represents the bounding box center marker generator on primary shapes within DRC expressions (see Layer#drc and middle for more details).

"mos3" - Supplies the MOS3 transistor extractor class

Usage:

- `mos3(name)`
- `mos3(name, class)`

Use this class with extract_devices to specify extraction of a three-terminal MOS transistor.

See DeviceExtractorMOS3Transistor for more details about this extractor (non-strict mode applies for 'mos3').

"mos4" - Supplies the MOS4 transistor extractor class

Usage:

- `mos4(name)`
- `mos4(name, class)`

Use this class with extract_devices to specify extraction of a four-terminal MOS transistor.

See DeviceExtractorMOS4Transistor for more details about this extractor (non-strict mode applies for 'mos4').

"netlist" - Obtains the extracted netlist from the default Netter

The netlist is a Netlist object. If no netlist is extracted yet, this method will trigger the extraction process. See Netter#netlist for a description of this function.

"netter" - Creates a new netter object

Usage:

- `netter`

See Netter for more details

"new_report" - Creates a new report database object for use in "output"

Usage:

- `new_report(description [, filename [, cellname ] ])`

This method creates an independent report object. This object can be used in "output" to send a layer to a different report than the default report or target.

Arguments are the same than for report.

See Layer#output for details about this feature.

"new_target" - Creates a new layout target object for use in "output"

Usage:

- `new_target(what [, cellname])`

This method creates an independent target object. This object can be used in "output" to send a layer to a different layout file than the default report or target.

Arguments are the same than for target.

See Layer#output for details about this feature.

"no_borders" - Reset the tile borders

Usage:

- `no_borders`

Resets the tile borders - see tile_borders for a description of tile borders.

"notch" - Performs a notch (intra-polygon space) check

Usage:

- `notch([ options ]) (in conditions)`
- `notch(layer [, options ])`

Provides a intra-polygon space check for polygons. It is similar to space, but checks intra-polygon space only. It has manifold options. See Layer#width for the basic options such as metrics, projection and angle constraints etc.

Classic mode

This function can be used in classic mode with a layer argument. In this case it is equivalent to "layer.notch" (see Layer#notch).

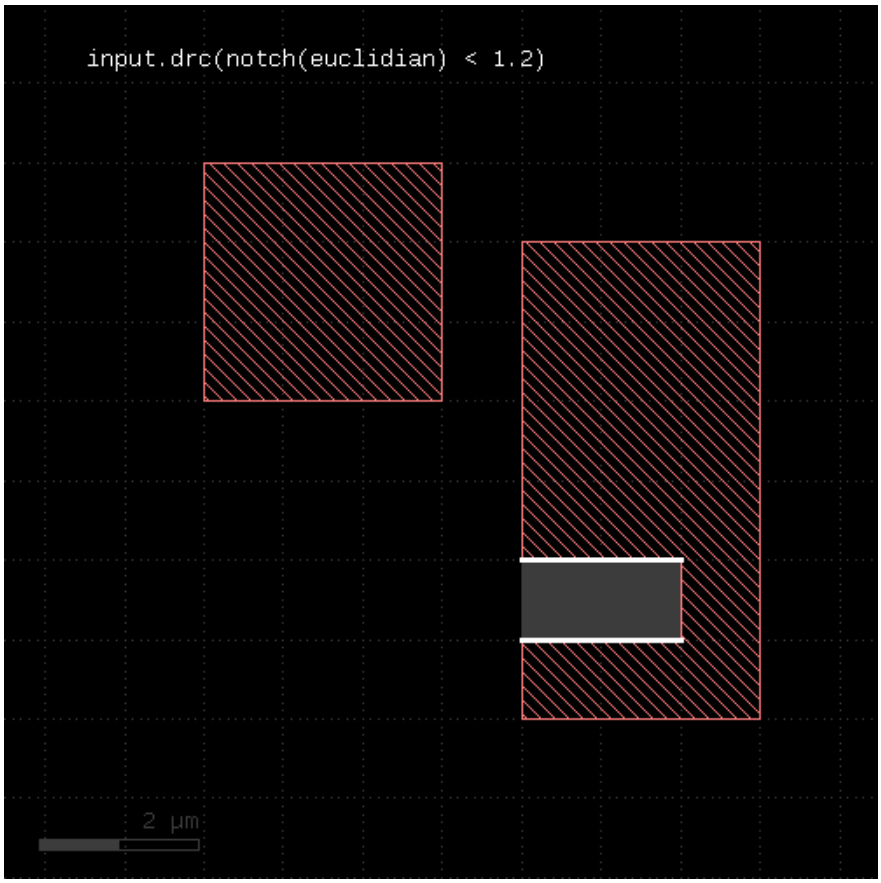
```
# classic "notch" check for space < 1.2 um
in = layer(1, 0)
errors = notch(in, 1.2.um)
```

Universal DRC

The version without a layer is intended for use within DRC expressions together with the "universal DRC" method Layer#drc. In this case, this function needs to be put into a condition to specify the check constraints. The other options of Layer#notch (e.g. metrics, projection constraints, angle limits etc.) apply to this version too:

```
# universal DRC "notch" check for space < 1.2.um
in = layer(1, 0)
errors = in.drc(notch < 1.2.um)
```

See enclosing for more details about the various ways to specify conditions.



"output" - Outputs a layer to the report database or output layout

Usage:

- `output(layer, args)`

This function is equivalent to "layer.output(args)". See Layer#output for details about this function.

"output_cell" - Specifies a target cell, but does not change the target layout

Usage:

- `output_cell(cellname)`

This method switches output to the specified cell, but does not change the target layout nor does it switch the output channel to layout if is report database.

"outside" - Selects shapes entirely outside other shapes

Usage:

- `outside(other)`

This operator represents the selector of primary shapes which are outside shapes from the other layer. Use this operator within DRC expressions (also see Layer#drc). If can be used as method to an expression. See there for more details: outside.

"overlap" - Performs an overlap check

Usage:

- `overlap(other [, options ]) (in conditions)`
- `overlap(layer, other [, options ])`

Provides an overlap check (primary layer vs. another layer). This check has manifold options. See Layer#width for the basic options such as metrics, projection and angle constraints etc. This check also features opposite and rectangle filtering. See Layer#separation for details about opposite and rectangle error filtering.

Classic mode

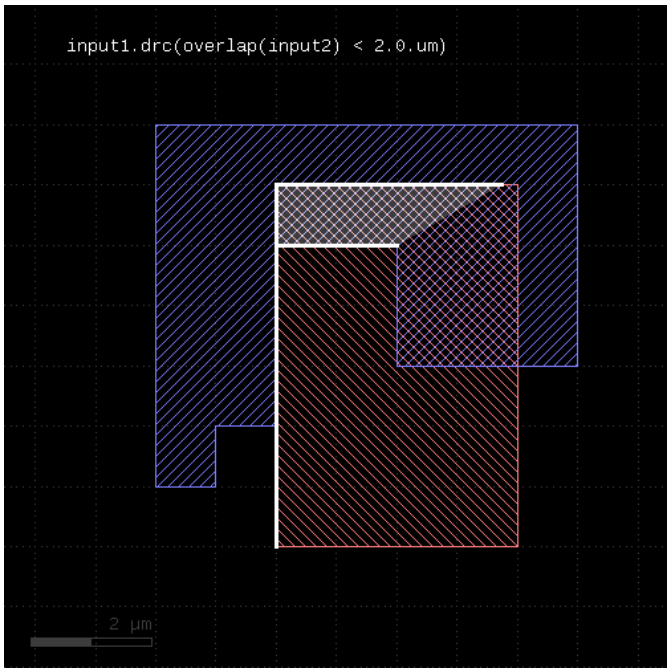
Like other checks, this function is available as a classic DRC function with a layer as the first argument and as an DRC expression operator for use with Layer#drc.

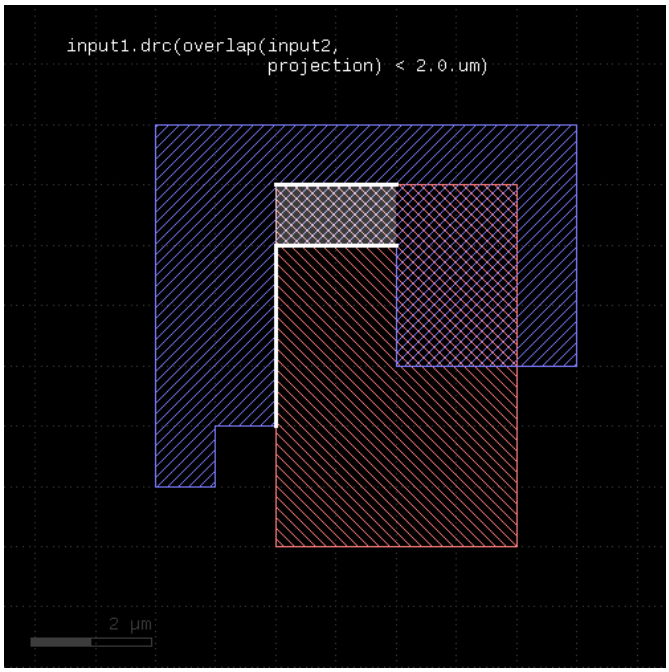
```
# classic "overlap" check for < 0.2 um
in = layer(1, 0)
other = layer(2, 0)
errors = overlap(in, other, 0.2.um)
```

Universal DRC

For use with the "unversal DRC" put the separation expression into the "drc" function call and use a condition to specify the constraint:

```
# universal DRC "overlap" check for < 0.2 um
in = layer(1, 0)
other = layer(2, 0)
errors = in.drc(overlap(other) < 0.2.um)
```





When "larger than" constraints are used, this function will produce the edges from the first layer only. The result will still be edge pairs for consistency, but each edge pair holds one edge from the original polygon plus a reverse copy of that edge in the second member. Use "first_edges" to extract the actual edges from the first input (see separation for an example).

"overlapping" - Selects shapes overlapping with other shapes

Usage:

- `overlapping(other) (optionally in condition)`

This operator represents the selector of primary shapes which overlap shapes from the other layer. This version can be put into a condition indicating how many shapes of the other layer need to be covered. Use this operator within DRC expressions (also see Layer#drc). If can be used as method to an expression. See there for more details: overlapping.

"p" - Creates a point object

Usage:

- `p(x, y)`

A point is not a valid object by itself, but it is useful for creating paths for polygons:

```
x = polygon_layer
x.insert(polygon([ p(0, 0), p(16.0, 0), p(8.0, 8.0) ]))
```

"path" - Creates a path object

Usage:

- `path(...)`

This function creates a path object. The arguments are the same than for the DPath constructors.

"perimeter" - Computes the total perimeter or in universal DRC context: selects the primary shape if the perimeter is meeting the condition

Usage:

- `perimeter (in condition)`
- `perimeter(layer)`

This function can be used with a layer argument. In this case it is equivalent to "layer.perimeter" (see Layer#perimeter) and returns the total perimeter of all polygons in the layer.

Without a layer argument, "perimeter" represents a perimeter filter for primary shapes in DRC expressions (see Layer#drc and DRC#perimeter for more details).

"polygon" - Creates a polygon object

Usage:

- `polygon(...)`

This function creates a polygon object. The arguments are the same than for the DPolygon constructors.

"polygon_layer" - Creates an empty polygon layer

Usage:

- `polygon_layer`

The intention of that method is to create an empty layer which can be filled with polygon-like objects using Layer#insert. A similar method which creates a hierarchical layer in deep mode is make_layer. This other layer is better suited for use with device extraction.

"polygons" - Fetches the polygons (or shapes that can be converted to polygons) from the specified input from the default source

Usage:

- `polygons(args)`

See Source#polygons for a description of that function.

"primary" - Represents the primary input of the universal DRC function

Usage:

- `primary`

The primary input of the universal DRC function is the layer the Layer#drc function is called on.

"profile" - Profiles the script and provides a runtime + memory statistics

Usage:

- `profile`
- `profile(n)`

Turns profiling on or off (default). In profiling mode, the system will collect statistics about rules executed, their execution time and memory information. The argument specifies how many operations to print at the end of the run. Without an argument, all operations are printed. Passing "false" for the argument will disable profiling. This is the default.

"props_copy" - Specifies "copy properties" on operations supporting user properties constraints

This properties constraint does not constrain the operation, but instructs it to attach the properties from the primary input to the output objects.

See also props_ne and props_eq.

"props_eq" - Specifies "same properties" for operations supporting user properties constraints

Some operations such as boolean AND support properties constraints. By giving a "props_eq" constraint, the operation is performed only on shapes with the same properties, where "properties" stands for the full set of key/value pairs.

Note that you have to enable properties explicitly or generate properties (e.g. with the DRCLayer#nets method).

Example:

```
connect(metal1, via1)
connect(via1, metal2)
... further connect statements

m1m2_overlap_connected = metal1.nets.and(metal2, props_eq)
```

"props_eq" can be combined with props_copy. In this case, properties are transferred to the output shapes and can be used in further processing:

```
m1m2_overlap_connected = metal1.nets.and(metal2, props_eq + props_copy)
```

See also props_ne.

"props_ne" - Specifies "different properties" for operations supporting user properties constraints

Some operations such as boolean AND support properties constraints. By giving a "props_ne" constraint, the operation is performed only on shapes with different properties, where "properties" stands for the full set of key/value pairs.

Note that you have to enable properties explicitly or generate properties (e.g. with the DRCLayer#nets method).

Example:

```
connect(metal1, via1)
connect(via1, metal2)
... further connect statements

m1m2_overlap_not_connected = metal1.nets.and(metal2, props_ne)
```

"props_ne" can be combined with props_copy. In this case, properties are transferred to the output shapes and can be used in further processing:

```
m1m2_overlap_connected = metal1.nets.and(metal2, props_ne + props_copy)
```

See also props_eq.

"rectangles" - Selects all polygons which are rectangles

Usage:

- `rectangles`
- `rectangles(layer)`

This function can be used with a layer argument. In this case it is equivalent to "layer.rectangles" (see Layer#rectangles). Without a layer argument, "rectangles" represents the rectangles filter for primary shapes in DRC expressions (see Layer#drc and rectangles for more details).

"rectilinear" - Selects all polygons which are rectilinear

Usage:

- `rectilinear`
- `rectilinear(layer)`

This function can be used with a layer argument. In this case it is equivalent to "layer.rectilinear" (see Layer#rectilinear). Without a layer argument, "rectilinear" represents the rectilinear polygons filter for primary shapes in DRC expressions (see Layer#drc and rectilinear for more details).

"region_overlap" - Specifies region selected input in "overlap mode"

Usage:

- `region_overlap(args)`

See Source#overlapping for a description of that function.

The following code will select shapes overlapping a 500x600 micron rectangle (lower left corner at 0,0) from the input layout. The shapes will not be clipped:

```
region_overlapping(0.mm, 0.mm, 0.5.mm, 0.6.mm)
# shapes will now be the ones overlapping the rectangular region
l1 = input(1, 0)
```

To remove this condition, call "region_overlapping" without any arguments.

"region_touch" - Specifies region selected input in "touch mode"

Usage:

- `region_touch(args)`

See Source#touching for a description of that function.

The following code will select shapes touching a 500x600 micron rectangle (lower left corner at 0,0) from the input layout. The shapes will not be clipped:

```
region_touch(0.mm, 0.mm, 0.5.mm, 0.6.mm)
# shapes will now be the ones touching the rectangular region
l1 = input(1, 0)
```

To remove this condition, call "region_touch" without any arguments.

"relative_height" - Selects primary shapes based on the ratio of height and width of their bounding boxes

Usage:

- `relative_height (in condition)`

See Layer#drc, relative_height and DRC#relative_height for more details.

"report" - Specifies a report database for output

Usage:

- `report(description [, filename [, cellname ] ])`

After specifying a report database for output, output method calls are redirected to the report database. The format of the output calls changes and a category name plus description can be specified rather than a layer/datatype number of layer name. See the description of the output method for details.

If a filename is given, the report database will be written to the specified file name. Otherwise it will be shown but not written.

If external input is specified with source, "report" must be called after "source".

The cellname specifies the top cell used for the report file. By default this is the cell name of the default source. If there is no source layout you'll need to give the cell name in the third parameter.

"report_netlist" - Specifies an extracted netlist report for output

Usage:

- `report_netlist([ filename [, long ] ])`

This method applies to runsets creating a netlist through extraction. Extraction happens when connections and/or device extractions are made. If this statement is used, the extracted netlist plus the net and device shapes are turned into a layout-to-netlist report (L2N database) and shown in the netlist browser window. If a file name is given, the report will also be written to the given file. If a file name is given and "long" is true, a verbose version of the L2N DB format will be used.

"resistor" - Supplies the resistor extractor class

Usage:

- `resistor(name, sheet_rho)`
- `resistor(name, sheet_rho, class)`

Use this class with extract_devices to specify extraction of a resistor.

The sheet_rho value is the sheet resistance in ohms/square. It is used to compute the resistance from the geometry.

See DeviceExtractorResistor for more details about this extractor.

"resistor_with_bulk" - Supplies the resistor extractor class that includes a bulk terminal

Usage:

- `resistor_with_bulk(name, sheet_rho)`
- `resistor_with_bulk(name, sheet_rho, class)`

Use this class with extract_devices to specify extraction of a resistor with a bulk terminal. The sheet_rho value is the sheet resistance in ohms/square.

See DeviceExtractorResistorWithBulk for more details about this extractor.

"rounded_corners" - Applies corner rounding

Usage:

- `rounded_corners(inner, outer, n)`
- `rounded_corners(layer, inner, outer, n)`

This function can be used with a layer argument. In this case it is equivalent to "layer.rounded_corners" (see Layer#rounded_corners). Without a layer argument, "rounded_corners" represents the corner rounding algorithm on primary shapes within DRC expressions (see Layer#drc and rounded_corners for more details).

"secondary" - Provides secondary input for the "drc" universal DRC function

Usage:

- `secondary(layer)`

To supply additional input for the universal DRC expressions (see Layer#drc), use "secondary" with a layer argument. This example provides a boolean AND between l1 and l2:

```
l1 = layer(1, 0)
l2 = layer(2, 0)
out = l1.drc(primary & secondary(l2))
```

"select" - Specifies cell filters on the default source

Usage:

- `select(args)`

See Source#select for a description of that function. Using the global version does not create a new source, but modifies the default source.

```
# Selects only B cell instances below the top cell
select("-", "+B*")
l1 = input(1, 0)
```

"sep" - Synonym for "separation"

Usage:

- `sep(...)`

"sep" is the short form for separation.

"separation" - Performs a separation check

Usage:

- `separation(other [, options ]) (in conditions)`

- `separation(layer, other [, options ])`

Provides a separation check (primary layer vs. another layer). Like enclosing this function provides a two-layer check, but checking the distance rather than the overlap. This check has manifold options. See Layer#width for the basic options such as metrics, projection and angle constraints etc. This check also features opposite and rectangle filtering. See Layer#separation for details about opposite and rectangle error filtering.

Classic mode

Like enclosing, this function is available as a classic DRC function with a layer as the first argument and as an DRC expression operator for use with Layer#drc.

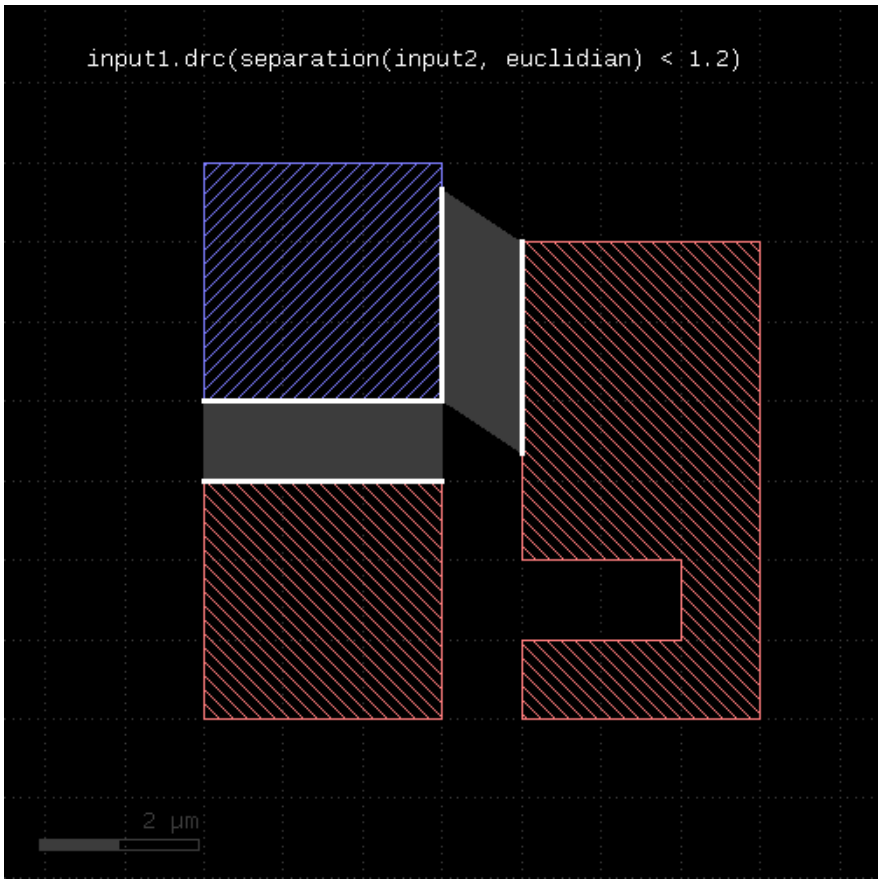
```
# classic "separation" check for distance < 0.2 um
in = layer(1, 0)
other = layer(2, 0)
errors = separation(in, other, 0.2.um)
```

Universal DRC

For use with the "universal DRC" put the separation expression into the "drc" function call and use a condition to specify the constraint:

```
# universal DRC "separation" check for distance < 0.2 um
in = layer(1, 0)
other = layer(2, 0)
errors = in.drc(separation(other) < 0.2.um)
```

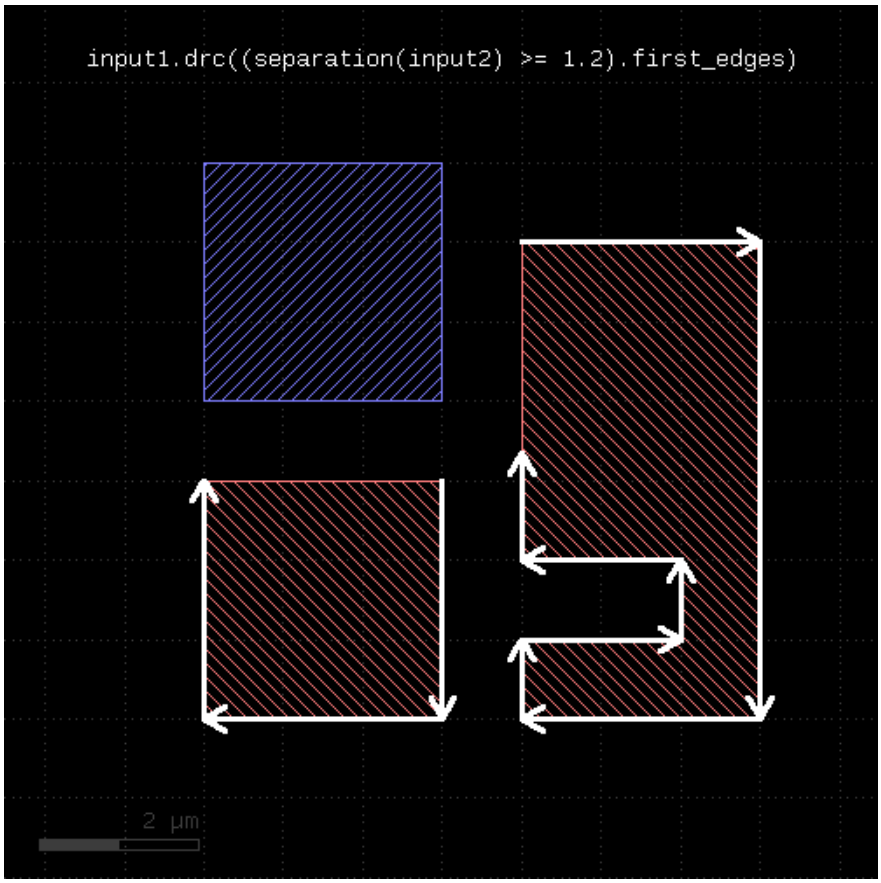
enclosing explains the constraints and how the work in generating error markers.



When "larger than" constraints are used, this function will produce the edges from the first layer only. The result will still be edge pairs for consistency, but each edge pair holds one edge from the original polygon plus a reverse copy of that edge in the second member. Use "first_edges" to extract the actual edges from the first input:

```
l1_edges_without_l2 = l1.drc((separation(l2) >= 1.0).first_edges)
```

The following image shows the effect of such a negative-output separation check:



"silent" - Resets verbose mode

Usage:

- `silent`

This function is equivalent to "verbose(false)" (see verbose)

"sized" - Returns the sized version of the input

Usage:

- `sized(d [, mode])`
- `sized(dx, dy [, mode]))`
- `sized(layer, d [, mode])`
- `sized(layer, dx, dy [, mode]))`

This function can be used with a layer argument. In this case it is equivalent to "layer.sized" (see Layer#sized). Without a layer argument, "sized" represents the polygon sizer on primary shapes within DRC expressions (see Layer#drc and sized for more details).

"smoothed" - Applies smoothing

Usage:

- `smoothed(d)`
- `smoothed(layer, d)`

This function can be used with a layer argument. In this case it is equivalent to "layer.smoothed" (see Layer#smoothed). Without a layer argument, "smoothed" represents the polygon smoother on primary shapes within DRC expressions (see Layer#drc and smoothed for more details).

"soft_connect" - Specifies a soft connection between two layers

Usage:

- `soft_connect(a, b)`

A "soft connection" is made between two layers and is a directional connection (like an ideal diode). Soft connections allow detecting if nets are connected via a high-ohmic substrate or diffusion layer (the "lower" layer). "b" is the "lower" and "a" the upper layer.

See Netter#connect for a more detailed description of that function.

"soft_connect_global" - Specifies a soft connection to a global net

Usage:

- `soft_connect_global(l, name)`

Like soft_connect, a soft connection is made between a layer and a global net (e.g. substrate). The global net is always the "lower" net of the soft connection.

See Netter#soft_connect_global for a more detailed description of that function.

"source" - Specifies a source layout

Usage:

- `source`
- `source(what)`

This function replaces the default source layout by the specified file. If this function is not used, the currently active layout is used as input.

layout is a similar method which specifies *an additional* input layout.

"what" specifies what input to use. "what" be either

- A string "@n" specifying input from a layout in the current panel
- A layout filename plus an optional cell name
- A Layout object plus an optional cell name
- A Cell object

Without any arguments the default layout is returned. If a filename is given, a cell name can be specified as the second argument. If none is specified, the top cell is taken which must be unique in that case.

```
# XOR between layers 1 of "first_layout.gds" and "second_layout.gds" and sends the results to
 "xor_layout.gds":
```

```
target("xor_layout.gds")
source("first_layout.gds")
l2 = layout("second_layout.gds")
(input(1, 0) ^ l2.input(1, 0)).output(100, 0)
```

For further methods on the source object see Source.

"space" - Performs a space check

Usage:

- `space([ options ]) (in conditions)`
- `space(layer [, options ])`

"space" looks for spacing violations between edges of the same polygon (intra-polygon checks) and between different polygons (inter-polygon checks). notch is similar function that provides only intra-polygon space checks. isolated is the version checking inter-polygon distance only. The check has manifold options. See Layer#width for the basic options such as metrics, projection and angle constraints etc.

Classic mode

This function can be used in classic mode with a layer argument. In this case it is equivalent to "layer.space" (see Layer#space). In this mode, "space" is applicable to edge layers too.

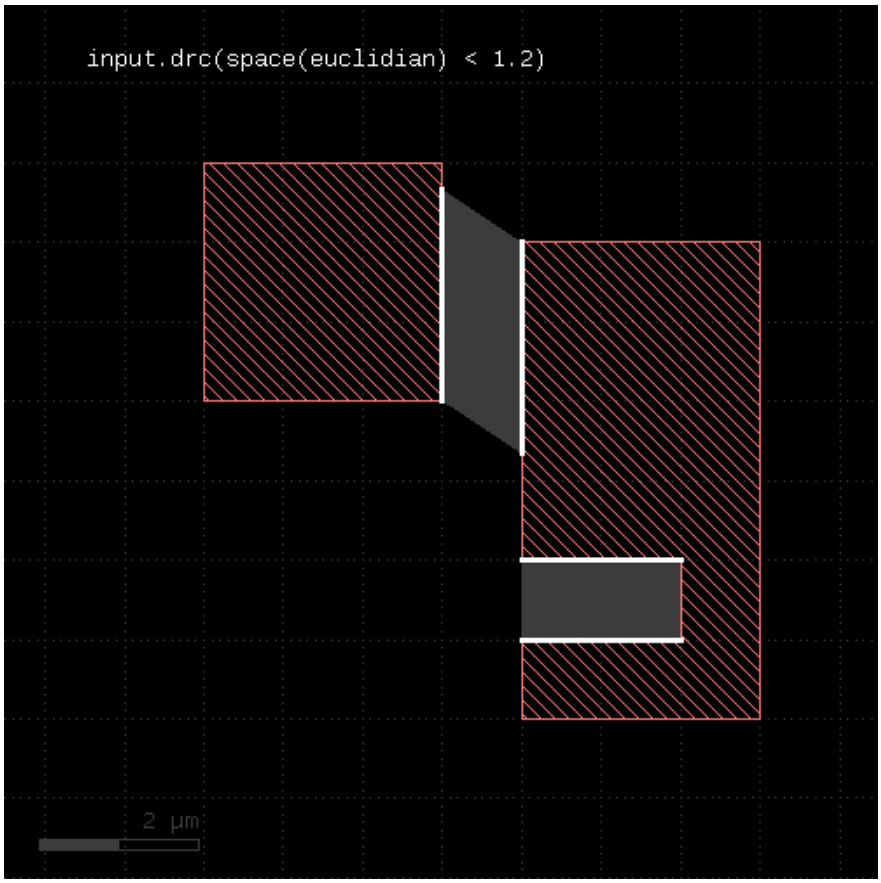
```
# classic "space" check for space < 0.2 um
in = layer(1, 0)
errors = space(in, 0.2.um)
```

Universal DRC

The version without a layer is intended for use within DRC expressions together with the "universal DRC" method Layer#drc. In this case, this function needs to be put into a condition to specify the check constraints. The other options of Layer#space (e.g. metrics, projection constraints, angle limits etc.) apply to this version too:

```
# universal DRC check for space < 0.2.um
in = layer(1, 0)
errors = in.drc(space < 0.2.um)
```

See enclosing for more details about the various ways to specify conditions.



"squares" - Selects all polygons which are squares

Usage:

- `squares`
- `squares(layer)`

This function can be used with a layer argument. In this case it is equivalent to "layer.squares" (see Layer#squares). Without a layer argument, "squares" represents the rectangles filter for primary shapes in DRC expressions (see Layer#drc and squares for more details).

"switch" - A conditional selector for the "drc" universal DRC function

Usage:

- `switch(...)`

This function provides a conditional selector for the "drc" function. It is used this way:

```
out = in.drc(switch(c1, r1, c2, r2, ..., cn, rn)
out = in.drc(switch(c1, r1, c2, r2, ..., cn, rn, rdef)
```

This function will evaluate c1 which is a universal DRC expression (see Layer#drc). If the result is not empty, "switch" will evaluate and return r1. Otherwise it will continue with c2 and the result of this expression is not empty it will return r2. Otherwise it will continue with c3/r3 etc.

If an odd number of arguments is given, the last expression is evaluated if none of the conditions c1..cn gives a non-empty result.

As a requirement, the result types of all r1..rn expressions and the rdef needs to be the same - i.e. all need to render polygons or edges or edge pairs.

"target" - Specify the target layout

Usage:

- `target(what [, cellname])`

This function can be used to specify a target layout for output. Subsequent calls of "output" will send their results to that target layout. Using "target" will disable output to a report database. If any target was specified before, that target will be closed and a new target will be set up.

"what" specifies what input to use. "what" be either

- A string "@n" (n is an integer) specifying output to a layout in the current panel
- A string "@+" specifying output to a new layout in the current panel
- A layout filename
- A Layout object
- A Cell object

Except if the argument is a Cell object, a cellname can be specified stating the cell name under which the results are saved. If no cellname is specified, either the current cell or "TOP" is used.

"target_netlist" - With this statement, an extracted netlist is finally written to a file

Usage:

- `target_netlist(filename [, format [, comment ] ])`

This method applies to runsets creating a netlist through extraction. Extraction happens when connections and/or device extractions are made. If this statement is used, the extracted netlist is written to the given file.

The format parameter specifies the writer to use. You can use nil to use the standard format or produce a SPICE writer with write_spice. See write_spice for more details.

"threads" - Specifies the number of CPU cores to use in tiling mode

Usage:

- `threads(n)`
- `threads`

If using threads, tiles are distributed on multiple CPU cores for parallelization. Still, all tiles must be processed before the operation proceeds with the next statement.

Without an argument, "threads" will return the current number of threads

"tile_borders" - Specifies a minimum tile border

Usage:

- `tile_borders(b)`
- `tile_borders(bx, by)`

The tile border specifies the distance to which shapes are collected into the tile. In order words, when processing a tile, shapes within the border distance participate in the operations.

For some operations such as booleans (Layer#and, Layer#or, ...), Layer#size and the DRC functions (Layer#width, Layer#space, ...) a tile border is automatically established. For other operations such as Layer#with_area or Layer#edges, the exact distance is unknown, because such operations may have a long range. In that cases, no border is used. The tile_borders function may be used to specify a minimum border which is used in that case. That allows taking into account at least shapes within the given range, although not necessarily all.

To reset the tile borders, use no_borders or "tile_borders(nil)".

"tiles" - Specifies tiling

Usage:

- `tiles(t)`
- `tiles(w, h)`

Specifies tiling mode. In tiling mode, the DRC operations are evaluated in tiles with width w and height h. With one argument, square tiles with width and height t are used.

Special care must be taken when using tiling mode, since some operations may not behave as expected at the borders of the tile. Tiles can be made overlapping by specifying a tile border dimension with tile_borders. Some operations like sizing, the DRC functions specify a tile border implicitly. Other operations without a defined range won't do so and the consequences of tiling mode can be difficult to predict.

In tiling mode, the memory requirements are usually smaller (depending on the choice of the tile size) and multi-CPU support is enabled (see threads). To disable tiling mode use flat or deep.

Tiling mode will disable deep mode (see deep).

"top_level" - Specifies that the circuit is a chip top level circuit

Usage:

- `top_level(flag)`

See Netter#top_level for a description of that function.

"verbose" - Sets or resets verbose mode

Usage:

- `verbose`
- `verbose(m)`

In verbose mode, more output is generated in the log file

"verbose?" - Returns true, if verbose mode is enabled

Usage:

- `verbose?`

In verbose mode, more output is generated in the log file

"warn" - Prints a warning

Usage:

- `warn(message)`

Similar to log, but the message is printed formatted as a warning

"width" - Performs a width check

Usage:

- `width([ options ]) (in conditions)`
- `width(layer [, options ])`

A width check is a check for the distance of edges of the same polygon.

Classic mode

This function can be used in classic mode with a layer argument. In this case it is equivalent to "layer.width" (see Layer#width).

```
# classic "width" check for width < 2 um
in = layer(1, 0)
errors = width(in, 0.2.um)
```

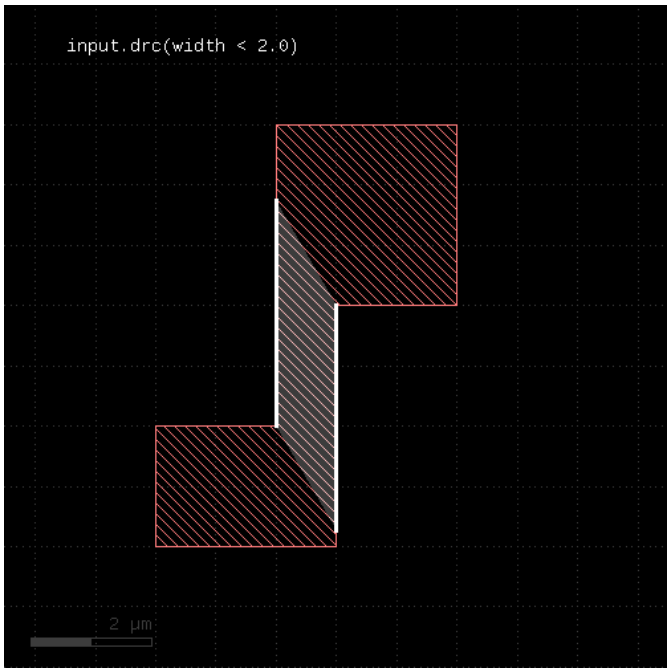
Universal DRC

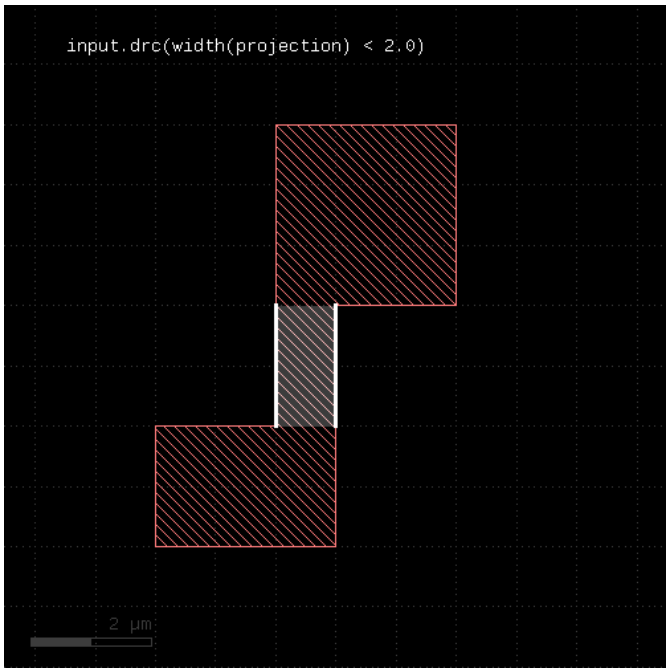
The version without a layer is intended for use within DRC expressions together with the "universal DRC" method Layer#drc. In this case, this function needs to be put into a condition to specify the check constraints. The other options of Layer#width (e.g. metrics, projection constraints, angle limits etc.) apply to this version too:

```
# universal DRC check for width < 2 um
in = layer(1, 0)
errors = in.drc(width < 0.2.um)
```

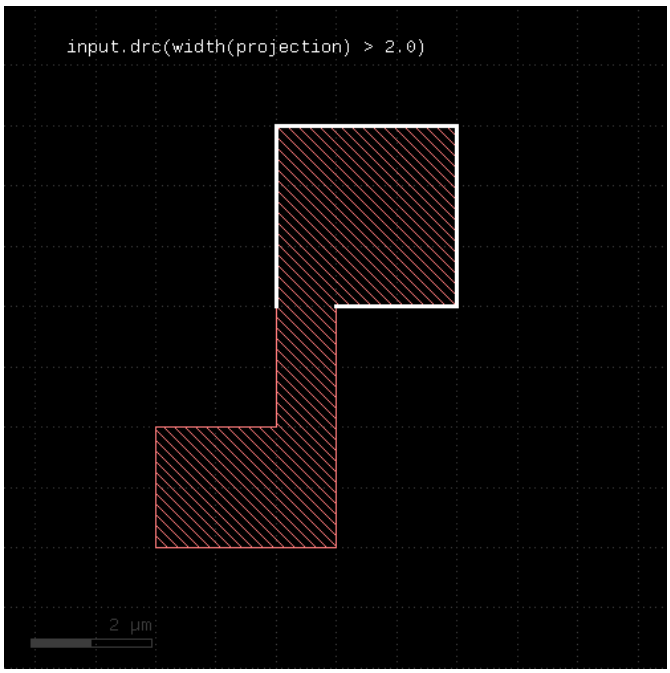
The conditions may involve an upper and lower limit. The following examples illustrate the use of this function with conditions:

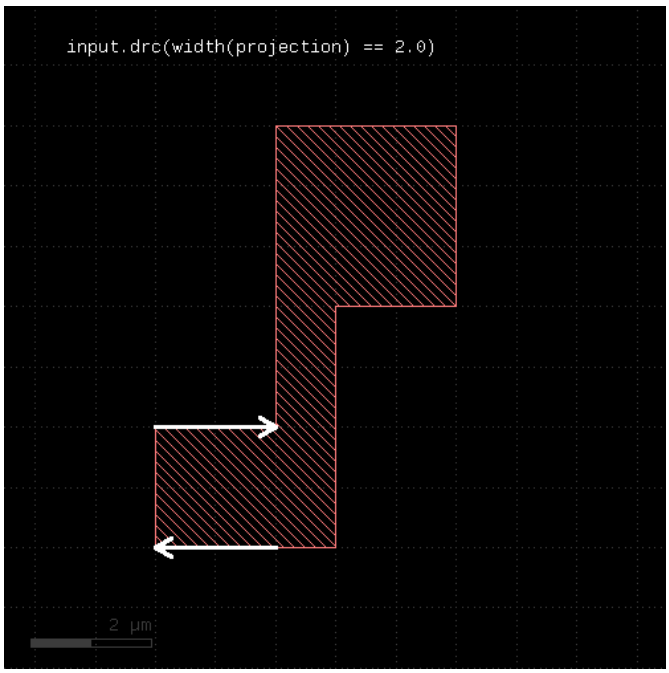
```
errors = in.drc(width < 0.2.um)
errors = in.drc(width <= 0.2.um)
errors = in.drc(width > 0.2.um)
errors = in.drc(width >= 0.2.um)
errors = in.drc(width == 0.2.um)
errors = in.drc(width != 0.2.um)
errors = in.drc(0.1.um <= width < 0.2.um)
```

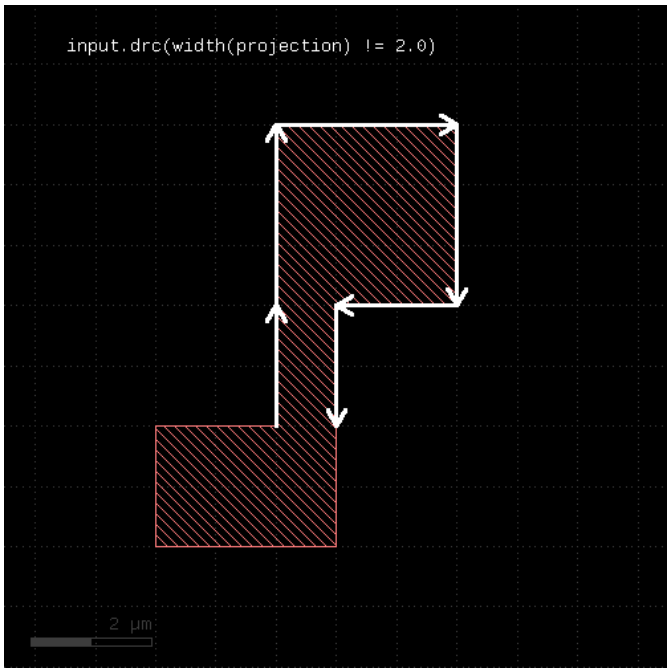


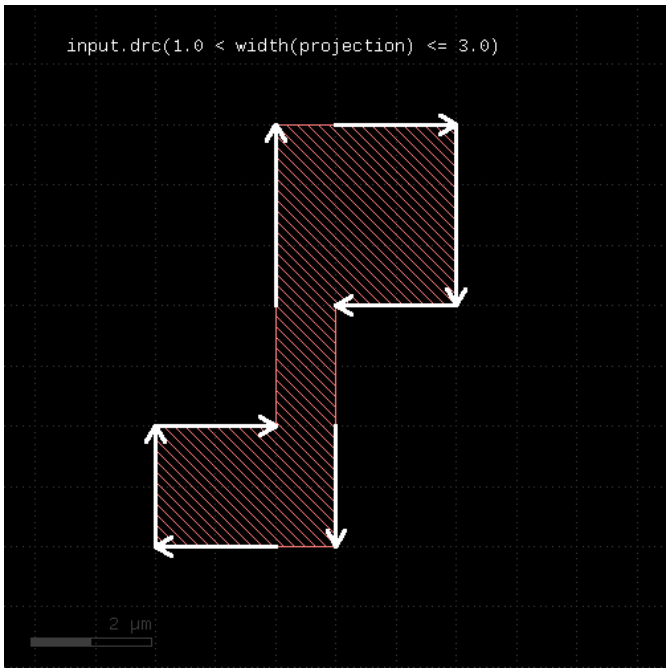


With a lower and upper limit or with the "equal" condition, the results are edges marking the positions on the primary shape where the condition is met. With a lower limit alone, the results are edge pairs which are formed by two identical, but opposite edges attached to the primary shape. Without an upper limit only, both edges are attached to different sides of the primary shape.









"with_holes" - Selects all input polygons according to their number of holes in DRC expressions

Usage:

- `with_holes (in condition)`

"with_holes" represents a polygon selector for DRC expressions selecting polygons of the primary by their number of holes (see Layer#drc and with_holes for more details).

"write_spice" - Defines SPICE output format (with options)

Usage:

- `write_spice([ use_net_names [, with_comments ] ])`
- `write_spice(writer_delegate [, use_net_names [, with_comments ] ])`

Use this option in target_netlist for the format parameter to specify SPICE format. "use_net_names" and "with_comments" are boolean parameters indicating whether to use named nets (numbers if false) and whether to add information comments such as instance coordinates or pin names.

"writer_delegate" allows using a NetlistSpiceWriterDelegate object to control the actual writing.

2.21. LVS Reference

2.21.1. LVS Reference: Netter object

The Netter object provides services related to network extraction from a layout plus comparison against a reference netlist. Similar to the DRC DRC::Netter (which lacks the compare ability), the relevant method of this object are available as global functions too where they act on a default incarnation. Usually it's not required to instantiate a Netter object explicitly.

The LVS Netter object inherits all methods of the DRC::Netter.

An individual netter object can be created, if the netter results need to be kept for multiple extractions. If you really need a Netter object, use the global netter function:

```
# create a new Netter object:
nx = netter

# build connectivity
nx.connect(poly, contact)
...

# read the reference netlist
nx.schematic("reference.cir")

# configure the netlist compare
nx.same_circuits("A", "B")
...

# runs the compare
if ! nx.compare
puts("no equivalence!")
end
```

"align" - Aligns the extracted netlist vs. the schematic

Usage:

- `align`

The align method will modify the netlists in case of missing corresponding circuits. It will flatten these circuits, thus improving the equivalence between the netlists. Top level circuits are not flattened.

This feature is in particular useful to remove structural cells like device PCells, reuse blocks etc.

This method will also remove schematic circuits for which there is no corresponding layout cell. In the extreme case of flat layout this will result in a flat vs. flat compare.

"netlist.flatten_circuit(...)" or "schematic.flatten_circuit(...)" are other (explicit) ways to flatten circuits.

Please note that flattening circuits has some side effects such as loss of details in the cross reference and net layout.

"blank_circuit" - Removes the content from the given circuits (blackboxing)

Usage:

- `blank_circuit(circuit_filter)`

This method will erase all content from the circuits matching the filter. The filter is a glob expression.

This has the following effects:

- The circuits are no longer compared (netlist vs. schematic)
- Named pins are required to match (use labels on the nets to name pins in the layout)

- Unnamed pins are treated as equivalent and can be swapped
- The selected circuits will not be purged on netlist simplification

Using this method can be useful to reduce the verification overhead for blocks which are already verifified by other ways or for which no schematic is available - e.g. hard macros.

Example:

```
# skips all MEMORY* circuits from compare
blank_circuit("MEMORY*")
```

"compare" - Compares the extracted netlist vs. the schematic

Usage:

- `compare`

Before using this method, a schematic netlist has to be loaded with schematic. The compare can be configured in more details using same_nets, same_circuits, same_device_classes and equivalent_pins.

The compare method will also modify the netlists in case of missing corresponding circuits: the unpaired circuit will be flattened then.

This method will return true, if the netlists are equivalent and false otherwise.

"consider_net_names" - Indicates whether the netlist comparer shall use net names

Usage:

- `consider_net_names(f)`

If this value is set to true (the default), the netlist comparer will employ net names to resolve ambiguities. If set to false, ambiguities will be resolved based on the topology alone. Topology resolution is more expensive.

"disable_parameter" - Indicates whether to disable a specific parameter for a given device

Usage:

- `disable_parameter(device_class_name, parameter_name)`

Disabling a parameter is the inverse of enable_parameter. Disabling a parameter will reset the "primary" flag of the parameter. This has several effects - e.g. the parameter will not be used in device compare during netlist matching by default.

This is not a strong concept but rather a hint for the system. Disabling a parameter for netlist compare without side effects is possible with the ignore_parameter function. In the same way, tolerance will enable a parameter for netlist compare regardless of the "primary" status of the parameter.

"enable_parameter" - Indicates whether to enable a specific parameter for a given device

Usage:

- `enable_parameter(device_class_name, parameter_name)`

The parameter is made "primary" which enables further applications - e.g. it is netlisted for some elements which normally would not print that parameter, and the parameter is compared in the default device compare scheme during netlist matching.

Enabling a parameter is rather a hint for the system and the effects can be controlled by other means, so this is not a strong concept. For example, once a tolerance is specified for a parameter, the "primary" flag of the parameter is not considered anymore. The inverse the this function is disable_parameter.

"equivalent_pins" - Marks pins as equivalent

Usage:

- `equivalent_pins(circuit, pin ...)`

This method will mark the given pins as equivalent. This gives the compare algorithm more degrees of freedom when establishing net correspondence. Typically this method is used to declare inputs from gates are equivalent where are are logically, but not physically (e.g. in a CMOS NAND gate):

```
netter.equivalent_pins("NAND2", 0, 1)
```

The circuit argument is either a circuit name (a string) or a Circuit object from the schematic netlist.

Names are case sensitive for layout-derived netlists and case-insensitive for SPICE schematic netlists.

The pin arguments are zero-based pin numbers, where 0 is the first number, 1 the second etc. If the netlist provides named pins, names can be used instead of numbers. Again, use upper case pin names for SPICE netlists.

Use this method andwhere in the script before the compare call.

"ignore_parameter" - Skip a specific parameter for a given device class name during device compare

Usage:

- `ignore_parameter(device_class_name, parameter_name)`

Use this function is ignore a parameter for a particular device class during the netlist compare. Some parameters - for example "L" and "W" parameters of the resistor device - are "secondary" parameters which are not ignored by default. Using "ignore_parameter" on such devices does not have an effect.

"ignore_parameter" and "tolerance" only have an effect with the default device comparer. Using a custom device comparer will override the definitions by "ignore_parameter" or "tolerance".

"join_symmetric_nets" - Joins symmetric nets of selected circuits on the extracted netlist

Usage:

- `join_symmetric_nets(circuit_filter)`

Nets are symmetrical if swapping them would not modify the circuit. Hence they will carry the same potential and can be connected (joined). This will simplify the circuit and can be applied before device combination (e.g. through "netlist.simplify") to render a schematic-equivalent netlist in some cases where symmetric nodes are split (i.e. "split gate" configuration).

This method operates on the extracted netlist (layout). The circuit filter specifies the circuits to which to apply this operation. The filter is a glob-style pattern. Using "*" for all circuits is possible, but it's discouraged currenty until the reliability of the symmetry detection algorithm is established. Currently it is recommended to apply it only to those circuits for which this feature is required.

For the symmetry detection, the specified constraints (e.g. tolerances, device filters etc.) apply.

"lvs_data" - Gets the internal LayoutVsSchematic object

Usage:

- `lvs_data`

The LayoutVsSchematic object provides access to the internal details of the netter object.

"max_branch_complexity" - Configures the maximum branch complexity for ambiguous net matching

Usage:

- `max_branch_complexity(n)`

The netlist compare algorithm is basically a backtracing algorithm. With ambiguous nets, the algorithm picks possible net pairs and tries whether they will make a good match. Following the deduction path for this nets may lead to further branches if more ambiguous nets are encountered. To avoid combinational explosion, the maximum branch complexity is limited to the value configured with this function. The default value is 500 which means not more than 500 combinations are tried for a single seed pair. For networks with inherent ambiguity such as decoders, the complexity can be increased at the expense of potentially larger runtimes. The runtime penality is roughly proportional to the branch complexity.

By default, the branch complexity is unlimited, but it may be reduced in order to limit the compare runtimes at the cost of a less elaborate compare attempt. The preferred solution however is to use labels for net name hints which also reduces the depth.

"max_depth" - Configures the maximum search depth for net match deduction

Usage:

- `max_depth(n)`

The netlist compare algorithm works recursively: once a net equivalence is established, additional matches are derived from this equivalence. Such equivalences in turn are used to derive new equivalences and so on. The maximum depth parameter configures the number of recursions the algorithm performs before picking the next net. With higher values for the depth, the algorithm pursues this "deduction path" in greater depth while with smaller values, the algorithm prefers picking nets in a random fashion as the seeds for this deduction path. The default value is 8.

By default, the depth is unlimited, but it may be reduced in order to limit the compare runtimes at the cost of a less elaborate compare attempt. The preferred solution however is to use labels for net name hints which also reduces the branch complexity.

"max_res" - Ignores resistors with a resistance above a certain value

Usage:

- `max_res(threshold)`

After using this method, the netlist compare will ignore resistor devices with a resistance value above the given threshold (in Farad).

"min_caps" - Ignores capacitors with a capacitance below a certain value

Usage:

- `min_caps(threshold)`

After using this method, the netlist compare will ignore capacitance devices with a capacitance values below the given threshold (in Farad).

"no_lvs_hints" - Disables LVS hints

Usage:

- `no_lvs_hints`

LVS hints may be expensive to compute. Use this function to disable generation of LVS hints

"same_circuits" - Establishes an equivalence between the circuits

Usage:

- `same_circuits(circuit_a, circuit_b)`

This method will force an equivalence between the two circuits. By default, circuits are identified by name. If names are different, this method allows establishing an explicit correspondence.

circuit_a is for the layout netlist, circuit_b for the schematic netlist. Names are case sensitive for layout-derived netlists and case-insensitive for SPICE schematic netlists.

One of the circuits may be nil. In this case, the corresponding other circuit is mapped to "nothing", i.e. ignored.

Use this method andwhere in the script before the compare call.

"same_device_classes" - Establishes an equivalence between the device classes

Usage:

- `same_device_classes(class_a, class_b)`

This method will force an equivalence between the two device classes. Device classes are also known as "models". By default, device classes are identified by name. If names are different, this method allows establishing an explicit correspondence.

Before this method can be used, a schematic netlist needs to be loaded with schematic.

class_a is for the layout netlist, class_b for the schematic netlist. Names are case sensitive for layout-derived netlists and case-insensitive for SPICE schematic netlists.

One of the device classes may be "nil". In this case, the corresponding other device class is mapped to "nothing", i.e. ignored.

A device class on one side can be mapped to multiple other device classes on the other side by using this function multiple times, e.g.

```
same_device_classes("POLYRES", "RES")
same_device_classes("WELLRES", "RES")
```

will match both "POLYRES" and "WELLRES" on the layout side to "RES" on the schematic side.

Once a device class is mentioned with "same_device_classes", matching by name is disabled for this class. So after using 'same_device_classes("A", "B")' "A" is no longer equivalent to "A" on the other side. If you want "A" to stay equivalent to "A" too, you need to use 'same_device_classes("A", "A")' in addition.

Use this method andwhere in the script before the compare call.

"same_nets" - Establishes an equivalence between the nets

Usage:

- `same_nets(circuit_pattern, net_pattern)`
- `same_nets(circuit_pattern, net_a, net_b)`
- `same_nets(circuit_a, net_a, circuit_b, net_b)`

This method will force an equivalence between the net_a and net_b from circuit_a and circuit_b (circuit in the three-argument form is for both circuit_a and circuit_b).

In the four-argument form, the circuits can be either given by name or as Circuit objects. In the three-argument form, the circuits have to be given by name pattern. Nets can be either given by name or as Net objects. In the two-argument form, the circuits and nets have to be given as name pattern.

"name pattern" are glob-style pattern - e.g. the following will identify the all nets starting with "A" from the extracted netlist with the same net from the schematic netlist for all circuits starting with "INV":

```
same_nets("INV*", "A*")
```

After using this function, the compare algorithm will consider these nets equivalent. Use this method to provide hints for the comparer in cases which are difficult to resolve otherwise.

circuit_a and net_a are for the layout netlist, circuit_b and net_b for the schematic netlist. Names are case sensitive for layout-derived netlists and case-insensitive for SPICE schematic netlists.

Use this method andwhere in the script before the compare call.

"same_nets!" - Establishes an equivalence between the nets with matching requirement

Usage:

- `same_nets!(circuit_pattern, net_pattern)`
- `same_nets!(circuit_pattern, net_a, net_b)`
- `same_nets!(circuit_a, net_a, circuit_b, net_b)`

This method is equivalent to same_nets, but requires identity of the given nets. If the specified nets do not match, an error is reported.

"schematic" - Gets, sets or reads the reference netlist

Usage:

- `schematic(filename)`
- `schematic(filename, reader)`
- `schematic(netlist)`
- `schematic`

If no argument is given, the current schematic netlist is returned. nil is returned if no schematic netlist is set yet.

If a filename is given (first two forms), the netlist is read from the given file. If no reader is provided, Spice format will be assumed. The reader object is a NetlistReader object and allows detailed customization of the reader process.

Alternatively, a Netlist object can be given which is obtained from any other source.

"split_gates" - Implements the "split gates" feature

Usage:

- `split_gates(device_name)`
- `split_gates(device_name, circuit_filter)`

Multi-fingered, multi-gate MOS transistors can be built without connecting the source/drain internal nets between the fingers. This will prevent "combine_devices" from combining the single gate transistors of the different fingers into single ones.

"split_gates" now marks the devices of the given class so that they will receive a special treatment which joins the internl source/drain nodes.

By default, this method is applied to all circuits. You can specify a circuit pattern to apply it to certain circuits only.

"device_name" must be a valid device name and denote a MOS3, MOS4, DMOS3 or DMOS4 device.

"tolerance" - Specifies compare tolerances for certain device parameters

Usage:

- `tolerance(device_class_name, parameter_name, absolute_tolerance [, relative_tolerance])`
- `tolerance(device_class_name, parameter_name [, :absolute => absolute_tolerance] [, :relative => relative_tolerance])`

Specifies a compare tolerance for a specific parameter on a given device class. The device class is the name of a device class in the extracted netlist. Tolerances can be given in absolute units or relative or both. The relative tolerance is given as a factor, so 0.1 is a 10% tolerance. Absolute and relative tolerances add, so specifying both allows for a larger deviation.

Some device parameters - like the resistor's "L" and "W" parameters - are not compared by default. These are "secondary" device parameters. Using a tolerance on such parameters will make these parameters being compared even if they are secondary ones.

A function is skip a parameter during the device compare is "ignore_parameter".

"tolerance" and "ignore_parameter" only have an effect with the default device comparer. Using a custom device comparer will override the definitions by "ignore_parameter" or "tolerance".

2.21.2. LVS Reference: Global Functions

Some functions are available on global level and can be used without any object. Most of them are convenience functions that basically act on some default object or provide function-like alternatives for the methods.

LVS is built upon DRC. So all functions available in DRC are also available in LVS. In LVS, DRC functions are used to derive functional layers from original layers or specification of the layout source.

For more details about the DRC functions see DRC::global.

"align" - Aligns the extracted netlist vs. the schematic by flattening circuits where required

Usage:

- `align`

See Netter#align for a description of that function.

"blank_circuit" - Removes the content from the given circuits (blackboxing)

Usage:

- `blank_circuit(circuit_filter)`

See Netter#blank_circuit for a description of that function.

"compare" - Compares the extracted netlist vs. the schematic netlist

Usage:

- `compare`

See Netter#compare for a description of that function.

"consider_net_names" - Indicates whether the netlist comparer shall use net names

Usage:

- `consider_net_names(f)`

See Netter#consider_net_names for a description of that function.

"disable_parameter" - Specifies whether to disable a parameter from a given device class for netlisting and default compare

Usage:

- `disable_parameter(device_class_name, parameter_name)`

See Netter#disable_parameter for a description of that function.

"enable_parameter" - Specifies whether to enable a parameter from a given device class for netlisting and default compare

Usage:

- `enable_parameter(device_class_name, parameter_name)`

See Netter#enable_parameter for a description of that function.

"equivalent_pins" - Marks pins as equivalent

Usage:

- `equivalent_pins(circuit, pins ...)`

See Netter#equivalent_pins for a description of that function.

"ignore_parameter" - Specifies whether to ignore a parameter from a given device class for the compare

Usage:

- `ignore_parameter(device_class_name, parameter_name)`

See Netter#ignore_parameter for a description of that function.

"join_symmetric_nets" - Joins symmetric nets of selected circuits on the extracted netlist

Usage:

- `join_symmetric_nets(circuit_filter)`

See Netter#join_symmetric_nets for a description of that function.

"lvs_data" - Gets the LayoutVsSchematic object after compare was used

Usage:

- `lvs_data`

See Netter#lvs_data for a description of that function.

"max_branch_complexity" - Configures the maximum branch complexity for ambiguous net matching

Usage:

- `max_branch_complexity(n)`

See Netter#max_branch_complexity for a description of that function.

"max_depth" - Configures the maximum search depth for net match deduction

Usage:

- `max_depth(n)`

See Netter#max_depth for a description of that function.

"max_res" - Ignores resistors with a resistance above a certain value

Usage:

- `max_res(threshold)`

See Netter#max_res for a description of that function.

"min_caps" - Ignores capacitors with a capacitance below a certain value

Usage:

- `min_caps(threshold)`

See Netter#min_caps for a description of that function.

"netter" - Creates a new netter object

Usage:

- `netter`

See Netter for more details

"no_lvs_hints" - Disables LVS hints

Usage:

- `no_lvs_hints`

See Netter#no_lvs_hints for a description of that feature.

"report_lvs" - Specifies an LVS report for output

Usage:

- `report_lvs([ filename [, long ] ])`

After the comparison step, the LVS database will be shown in the netlist database browser in a cross-reference view. If a filename is given, the LVS database is also written to this file. If a file name is given and "long" is true, a verbose version of the LVS DB format will be used.

If this method is called together with report_netlist and two files each, two files can be generated - one for the extracted netlist (L2N database) and one for the LVS database. However, report_netlist will only write the extracted netlist while report_lvs will write the LVS database which also includes the extracted netlist.

report_lvs is only effective if a comparison step is included.

"same_circuits" - Establishes an equivalence between the circuits

Usage:

- `same_circuits(circuit_a, circuit_b)`

See Netter#same_circuits for a description of that function.

"same_device_classes" - Establishes an equivalence between the device_classes

Usage:

- `same_device_classes(class_a, class_b)`

See Netter#same_device_classes for a description of that function.

"same_nets" - Establishes an equivalence between the nets

Usage:

- `same_nets(circuit_pattern, net_pattern)`
- `same_nets(circuit_pattern, net_a, net_b)`
- `same_nets(circuit_a, net_a, circuit_b, net_b)`

See Netter#same_nets for a description of that function.

"same_nets!" - Establishes an equivalence between the nets (must match)

Usage:

- `same_nets!(circuit_pattern, net_pattern)`
- `same_nets!(circuit_pattern, net_a, net_b)`
- `same_nets!(circuit_a, net_a, circuit_b, net_b)`

See Netter#same_nets! for a description of that function.

"schematic" - Reads the reference netlist

Usage:

- `schematic(filename)`
- `schematic(filename, reader)`
- `schematic(netlist)`

See Netter#schematic for a description of that function.

"split_gates" - Implements the "split gates" feature for the given device and circuits

Usage:

- `split_gates(device_name)`
- `split_gates(device_name, circuit_filter)`

See Netter#split_gates for a description of that function.

"tolerance" - Specifies compare tolerances for certain device parameters

Usage:

- `tolerance(device_class_name, parameter_name, absolute_tolerance [, relative_tolerance])`
- `tolerance(device_class_name, parameter_name [, :absolute => absolute_tolerance] [, :relative => relative_tolerance])`

See Netter#tolerance for a description of that function.

3. Programming scripts

This category is about programming KLayout using the integrated Ruby or Python scripting language. The following topics are available:

3.1. Introduction

This chapter is about programming extensions for KLayout using the integrated Ruby API (RBA) or Python API (pya).

To use RBA scripts, KLayout must be compiled with the Ruby interpreter. Check under "Help/About" whether support is available. If there is, the "Build options" will include a "Ruby" or "Python" interpreter or both. RBA scripts require a Ruby interpreter. To use pya scripts, Python support must be included.

KLayout comes with the Qt library included into the Ruby or Python API. This means, KLayout scripts can access the full Qt API if Qt binding is available. Check whether "Qt bindings for scripts" is included in the build options on the "Help/About" page.

Basically there are scripts and macros:

- **Scripts** are simple text files which are prepared externally and KLayout acts as an interpreter for these scripts. A special case of scripts is included code, while is loaded into other scripts or macros using "require" on Ruby or "import" on Python. Scripts have been the only way to code Ruby functionality in version 0.21 and earlier.
- **Macros** are special XML files which contain Ruby code plus some additional information required to link them into the system, i.e. automatically execute them on startup or provide menu entries for them. They can load normal ".rb" or ".py" files to implement libraries of classes in the usual way. Macros are managed and developed conveniently in the integrated macro development environment along with the supporting files. This method is the preferred way of creating application extensions and is described in this chapter.

Before you start, please make yourself familiar with the macro development integrated environment (About Macro Development). This documentation also assumes that you familiar with the Ruby programming language. There are numerous books and tutorials about Ruby. The most famous one is the "pickaxe book" (Programming Ruby - The Pragmatic Programmers Guide) by Dave Thomas. If you are familiar with Ruby there is a technical article about the way Ruby and KLayout's core are integrated (The Ruby Language Binding). There are special articles about the integrated Qt binding (The Qt Binding) and PCell programming (Coding PCells In Ruby). If you want to use Python, please read the python implementation article (Using Python) for details about how to translate Ruby samples into Python and specific details of the Python integration.

An introduction into the basic concepts of the KLayout API are given in the article about the application API (The Application API) and about the database API (The Database API).

A First Sample

The first sample is already a complete macro which counts all selected paths, boxes, polygons or text objects. It demonstrates how to set up a macro, how to deal with the selection and how to access the layout database.

Here is the code:

```
module MyMacro

  include RBA

  app = Application.instance
  mw = app.main_window

  lv = mw.current_view
  if lv == nil
    raise "Shape Statistics: No view selected"
  end

  paths = 0
  polygons = 0
  boxes = 0
  texts = 0

  lv.each_object_selected do |sel|

    shape = sel.shape

    if shape.is_path?
      paths += 1
    elsif shape.is_box?
```

```
      boxes += 1
    elsif shape.is_polygon?
      polygons += 1
    elsif shape.is_text?
      texts += 1
    end

  end

  s = "Paths: #{paths}\n"
  s += "Polygons: #{polygons}\n"
  s += "Boxes: #{boxes}\n"
  s += "Texts: #{texts}\n"

  MessageBox::info("Shape Statistics", s, MessageBox::Ok)

end
```

To run the macro, create a new macro in the macro development IDE: choose "Macros/Macro Development". Create a new macro using the "+" button. Rename the macro to a suitable name. Copy the code above into the text. Load a layout, select some objects and in the macro development IDE press F5. A message box will appear the tells us how may boxes, polygons etc. we have selected.

If we look at the code, the first observation is that we put the whole script into our own namespace (we can use any name which is not used otherwise). The advantage of that approach is that we can import the "RBA" namespace which makes life somewhat easier. The RBA namespace contains all KLayout classes and constants. If we would import the RBA namespace into the main namespace we would do that for all other scripts in KLayout since the main namespace is a common resource for all scripts.

The first thing we do inside the macro is to access the layout view:

```
app = Application.instance
mw = app.main_window

lv = mw.current_view
if lv == nil
  raise "Shape Statistics: No view selected"
end
```

The Application class (Application) is a representative for the KLayout application. Since there is only one application, it is a singleton. We can obtain the singleton instance with the class method ("static" in the language of C++) "instance". It delivers a reference to the only Application object which is the main entrance to all internals of KLayout.

The next object which is important is the MainWindow object (MainWindow). Currently there is only one MainWindow object which can be obtained with the "main_window" method of the Application object. The MainWindow object represents the application's window and manages the top level visual objects of the application. The main visual components of the main window are the menus, the tool panels (cell tree, layer list, tool box, navigator ...) and the layout views.

The layout view is the representation of a layout tab (LayoutView). That is basically the window to the layouts loaded into that tab. All related information such as the display settings, the zoom area, the layer properties and the information about the cell shown, the hierarchy levels and further settings go here.

A main window can display multiple tabs. Hence there are multiple LayoutView objects available. The currently selected tab can be addressed with the "current_view" method. This method delivers the LayoutView object associated with that tab. If no layout is loaded, that method returns nil (the Ruby for "nothing")

Actually the preparation step can be simplified without needing the Application and MainWindow object. For demonstration purposes it was included however. Here is the short version:

```
lv = LayoutView.current || raise "Shape Statistics: No view selected"
```

The actual layouts loaded are entities separated from the views. Technically, there is a many-to-many relationship between layout views and layout objects. A layout view may display multiple layouts and one layout may be displayed in multiple layout views. In addition, a layout view can address different cells from a layout. A layout view has a current cell and a path that leads to that cell. The path consists of a specific and unspecific part. The unspecific part of the path tells where the cell we show as the current cell is located in the cell tree. The unspecific part is a tribute to the fact that a cell can appear in different branches of the cell tree (i.e. as child of cell A and cell B). The

specific part of the path addresses a specific instance of within some cell (the "context cell") above in the hierarchy. A specific path is created when we descend down in the hierarchy along a certain instantiation path.

Layout, current cell, context cell, specific and unspecific path are combined into the CellView object (CellView). A layout view can have multiple cell views corresponding to the different layouts that can be loaded into a panel. The cell views do not necessarily have to point to different layouts.

For our sample we don't need the CellView objects, because we get all information directly from the view. But the concept of that object is important to understand the API documentation. Here we ask the layout view for all selected objects and collect the object counts:

```
lv.each_object_selected do |sel|

  shape = sel.shape

  if shape.is_path?
    paths += 1
  elsif shape.is_box?
    boxes += 1
  elsif shape.is_polygon?
    polygons += 1
  elsif shape.is_text?
    texts += 1
  end

end
```

"each_object_selected" is a method of the LayoutView object. More precisely it's an iterator which calls the given block for each selected object. Since the layout view can show multiple layouts, the selected objects may originate from different layouts. In addition, the object may be selected in a child cell of the current cell. Hence, the selection is described by a cell view index (indicating which layout it resided in), an instantiation path (a sequence of instances leading to the cell containing the selected object from the current cell) and the actual object selected. That information is combined into an ObjectInstPath object (ObjectInstPath).

In our case we are not interested in the cell view that shape lives in. Neither are we in the instantiation path. Hence all we need is the shape and we can obtain it with the "shape" method. This method delivers a Shape object (Shape), which is some kind of pointer (a "proxy") to the actual shape. The actual shape is either a polygon, a box, a text or a path. The Shape object has multiple identities and we can ask it what shape type is represents. For that, the Shape object offers methods like "is_box?" etc. If we know the type we can ask it for the actual object and fetch a Polygon (Polygon), a Box (Box), a Text (Text) or a Path object (Path). For our sample however we don't need access to the actual object.

Finally we put together a message and display it in a message box:

```
s = "Paths: #{paths}\n"
s += "Polygons: #{polygons}\n"
s += "Boxes: #{boxes}\n"
s += "Texts: #{texts}\n"

MessageBox::info("Shape Statistics", s, MessageBox::Ok)
```

MessageBox (MessageBox) is a class that provides modal message dialogs through several class methods. "info" shows an information box and with the given title and message. The third parameter indicates which buttons will be shown. In that case, one "Ok" button is sufficient because we don't want to take specific actions when the message box is closed. MessageBox is not the Qt class, which is also available (QMessageBox), but less portable in case a user does not have Qt binding enabled.

This is just a simple example, but it already illustrates some basic concepts. For a in-depth introduction into the API, read The Application API and The Database API.

3.2. Using Python

KLayout does not come with one integrated interpreter. Instead Python and Ruby can **both** be used together. So it is possible to write one script in Ruby and another one in Python. Just pick your favorite language. Scripts written in different languages share the same KLayout data structures. Naturally they cannot directly share variables or language-specific data. But you can, for example, implement PCells in Python and Ruby and use those different PCells in the same layout at the same time. Depending on the type of PCell, KLayout will either execute Python or Ruby code.

Python macros are loaded into KLayout using either ".py" files or ".lym" files with the interpreter set to "Python". To create Python macros, a new tab is available in the Macro Development IDE. When creating macros in the "Python" tab, they will use the Python interpreter. Macros created in the "Ruby" tab will use the Ruby interpreter. Files loaded by "import" need to be in plain text format and use the ".py" suffix. The macro folder is called "pymacros" for a clean separation between the two macro worlds. Technically, both Ruby and Python macros are .lym files with a different interpreter specified in these files.

The Python macro folder is in the "sys.path" search path so it is possible to install modules there. To install libraries globally use "*inst_path*/lib/python/Lib" and "*inst_path*/lib/python/DLLs" on Windows. *inst_path* is the installation path (where klayout.exe is located). On Linux, the installation will share the Python interpreter with the system and modules installed there will be available for KLayout too.

"$PYTHONHOME" is not supported to prevent interference with other Python consumers. Instead, KLayout will read the Python path from "$KLAYOUT_PYTHONPATH" (for Python >= 3.x).

Writing Macros in Python

A good way is to start with the samples provided when creating new macros on the Python tab. The samples are available at the end of the template list. There is a sample for a PCell implementation, a sample for a Qt dialog, a sample for using Qt's .ui files in Python macros and one sample turning KLayout into a HTTP server using a Python macro.

Apart from a few specialities and the different language of course, Python macros do not look much different from Ruby macros. Ruby's "RBA" namespace is "pya" for Python (lowercase to conform with PEP-8). The class and methods names are the same with very few exceptions and the documentation can be used for Python too. Where necessary, a special remark is made regarding the Python implementation.

Here is a basic Python Macro. It creates a layout with a single cell and single layer and puts one rectangle on that layer:

```
# Python version:

import pya

layout = pya.Layout()
top = layout.create_cell("TOP")
l1 = layout.layer(1, 0)
top.shapes(l1).insert(pya.Box(0, 0, 1000, 2000))

layout.write("t.gds")
```

Here is the Ruby variant to demonstrate the similarity:

```
# Ruby version:

layout = RBA::Layout::new()
top = layout.create_cell("TOP")
l1 = layout.layer(1, 0)
top.shapes(l1).insert(RBA::Box::new(0, 0, 1000, 2000))

layout.write("t.gds")
```

Of course, not everything can be translated that easily between Ruby and Python. The details are given below. Usually however, it's straightforward to translate Ruby into Python.

There is no clear advantage of one language over the other. The Python community is somewhat stronger, but performance-wise, Ruby is better. In KLayout, the debugger support for Python is slighly better, since the guts of the interpreter are better documented for Python.

Apart from that, Python and Ruby coexist remarkably well and it is amazing, how easy it it to extend the interfaces from Ruby to Python: not counting the different in the memory management model (mark and sweep garbage collector in Ruby, reference counting in Python), the concepts are very similar.

Please read the Python specific notes below before you start. Some things need to be considered when going from Ruby to Python.

Python PCells

Please have a look at the PCell sample available in the templates. Pick the PCell sample after you have created a new Python macro.

PCell implementation in Python is very similar to Ruby.

Python macros are ".lym" files that are placed into the "pymacro" subfolder in the KLayout path. Python libraries can be put into the "python" subfolder. This subfolder is included into the "sys.path" variable, so macros can load libraries simply by using "import".

Python Implementation Notes

- **KLayout module:** KLayout's module is "pya" (lowercase conforming to PEP 8).
- **Reserved names:** Some methods with reserved names are not available (i.e. "exec", "in"). Some of these methods have been renamed and their original name is still available in Ruby, but use is deprecated. Where this was not possible, they are available with an appended underscore. For example: "QDialog.exec" is available as "QDialog.exec_". That is the same scheme PyQt uses.
- **Assignment methods (attribute setters):** Assignment methods (i.e. "Box#left=" are available as attributes. If there is a read accessor method too, the attribute can be read and written. For example:

  ```
  box = pya.Box()
  box.left = 10
  box.right = box.right + 100
  ```

  If the translation is ambiguous (i.e. because there is more than one getter or setter, the setter will be translated to a method "set_x(value)" where "x" is the attribute name.
- **Predicate getters:** Question-mark names for predicates are translated to non-question-marker names:

  ```
  # Ruby:
    edges.is_empty?

  # Python:
    edges.is_empty()
  ```

- **Constants:** Constants (upper-case static variable) are made available as static attributes.
- **Arrays:** Arrays will be represented as lists, but on assignment, they accept tuples as well.
- **Boolean values:** Boolean values are True and False.
- **No protected methods:** Protected methods are not supported - methods are public always.
- **"nil" value:** The Python equivalent to Ruby's "nil" is "None".
- **Iterators:** Iterator binding:

  ```
  edges = pya.Edges()
  ...
  for edge in edges.each():
    ...
  ```

  If there is an iterator named "each", it will become the default iterator:

```
for edge in edges:
  ...
```

- **Keyword arguments:**
  Most methods support keyword arguments, for example:

  ```
  # a 45 degree rotation
  t = pya.CplxTrans(rot = 45)
  ```

  Exceptions are some built-in methods like "assign". Keyword arguments can be used when the non-optional arguments are specified either as positional or other keyword arguments.

- **Standard protocols:**
  "x.to_s()" is available as "str(x)" too.

  "x.size()" is available as "len(x)" too.

  If there is a "[]" operator and a "size" method, the object implements the sequence protocol too.

- **Operators:**
  Operators are made available through Python operators. For example

- "+" will be available as "+" ("__add__")
- "&" will be available as "and" ("__and__")
- "|" will be available as "or" ("__or__")
- "==" will be available as "==" ("__eq__")

- **Deep copies:** Deep copies of pya objects can be made with dup()

  ```
  box = pya.Box(10, 20, 110, 220)
  copy_box = box.dup()
  ```

- **Events (signals):** Events can be bound to lambdas or functions:

  ```
  action.on_triggered( lambda: action.text += "X" )
  ```

  or to function:

  ```
  def f():
    print "triggered"

  action.on_triggered(f)
  ```

  Events have to match precisely - exactly the number of arguments have to be declared.

- **sys.settrace:** Using "sys.settrace" will disable the debugger support permanently.

- **Instance attributes can't reimplement virtual methods:** This is a limitation driven by the need to avoid cyclic references. Instance-bound methods require a reference to the instance and that will create a cycle with the reimplementation callable object which is held by the class itself.

- **Tips when developing own modules:**
- The "python" subfolders of the KLayout path are added to sys.path, so modules can be put as plain .py files and imported with "import module".
- Or: modules can be put into folders inside "python" using an "__init__.py" file to indicate the folder is a module.
- Use "reload(module)" on the console to refresh the module cache if changes have been applied.

3.3. The Application API

This section covers the basic application API. The application API consists of the main application class and several classes that represent the user interface. This sections presents a selection of classes that make up the application API. These classes provide the main entry points into the application API. Further classes are documented in RBA Class Index.

All classes discussed herein are contained in the RBA namespace. In you code you either have to use qualified names (i.e. RBA::Application) or include the RBA module in you macro's namespace.

The Application class

The Application class is documented in detail in Application. It represents the application and because there is just one application, there also is just one instance of the application object. That instance can be obtained through the "instance" class method:

```
Application::instance
```

The application object is the main entry point into the API. It offers several methods and attributes. In particular:

- Application#application_data_path: returns the user-local storage path. This is where KLayout saves user-specific files, for example the configuration file.
- Application#execute: runs the application. Normally, this method is called implicitly when the application is started. It is possible to use KLayout as a Ruby interpreter by supplying a Ruby script on the command line with the "-r" option. Such scripts must run the application explicitly if they want to.
- Application#exit: exits the application. This method unconditionally terminates the application in a clean way.
- Application#get_config and Application#set_config: read and write the configuration database. The configuration database is a storage of name/value pairs which is stored in the configuration file. These methods can be used to manipulate that storage. Use the Application#get_config_names method to retrieve the names of the configuration parameters stored inside the configuration database. Use the Application#commit_config method to activate settings that have been made with "set_config".
- Application#inst_path: returns the installation path. That is where the executable is located.
- Application#is_editable?: returns true, if KLayout runs in editable mode.
- Application#klayout_path: returns the KLAYOUT_PATH value. This is the search path where KLayout looks for library files or macros. This method delivers the application data path and can be used to look up files required by the macro.
- Application#main_window: delivers the MainWindow object which represents the application's main window. See below for a description of that class.
- Application#process_events: process pending events. If that method is called periodically during long operations, the application will be able to process events and thus handle clicks on a "Stop" button for example. Please note that calling this method is not safe in every context, because not every execution context is reentrant.
- Application#read_config and Application#write_config: reads and writes the configuration database from a file.
- Application#version: delivers KLayout's version string. This string can be used to switch the implementation of a script depending on KLayout's version.

The MainWindow class

The MainWindow class is documented in detail in MainWindow. It represents the main application window. The main window instance can be obtained with:

```
Application::instance.main_window
```

The main window object is the entry point to all user-interface related objects. It offers a couple of methods. In particular:

- MainWindow#cancel: cancels any pending operation (i.e. dragging of an object in move mode) and resets the mode to the default mode (Select). Use this method to establish a known user interface state.
- MainWindow#close_all and MainWindow#close_current_view: close all or the current tab.
- MainWindow#cm_*: these are methods which are bound to the menu items in the menu bar. They can be used to trigger a menu function from a script.
- MainWindow#create_layout: create a new layout and load it into a layout view. This method has a parameter that controls whether the layout is shown in a new tab, replaces the layout in the current tab or adds to the current tab.
- MainWindow#create_layout: creates a new, empty layout and loads it.
- MainWindow#create_view: creates a new, empty tab.
- MainWindow#current_view: returns a LayoutView object (see below) which represents the current tab.
- MainWindow#current_view_index: returns the index of the current tab. Some methods like "select_view" operate with view indexes. The view index is the number of the tab (0 is the leftmost one). The "view" method allows obtaining the LayoutView object from a view index. The same way MainWindow#current_view_index= selects the view with the index given in this call.
- MainWindow#grid_micron: gets the global grid in micrometer units.
- MainWindow#initial_technology and MainWindow#initial_technology=: gets or sets the name of the technology to use to new layouts or for layouts loaded without an explicit technology specification.
- MainWindow#load_layout: loads a layout into a tab. There are various variants of this method, offering various levels of configuration. All these variants have a parameter that controls whether the layout is shown in a new tab, replaces the layout in the current tab or adds to the current tab.
- MainWindow#menu: provides access to the menu object of class AbstractMenu (see AbstractMenu). This object provides access to the main menu, the toolbar and various context menus. With this object it is possible to manipulate the menu.
- MainWindow#message: show a message in the status bar.
- MainWindow#save_session and MainWindow#restore_session: save or restore a session. Sessions contain a window settings and information about the layouts loaded. Sessions allows storing and restoring of the state of the main window.
- MainWindow#select_view: switches to the given tab. This equivalent to using MainWindow#current_view_index=.
- MainWindow#view: gets the LayoutView object for a given tab index.
- MainWindow#views: gets the number of tabs.

The MainWindow supplies three events. See Events And Callbacks for details about events. These are the events:

- **on_current_view_changed**: This event is triggered when the current tab changes. The signal is available with an integer parameter: this is the index of the previous tab. The new tab is already the current tab when this event is triggered.
- **on_view_created**: This event is triggered when a new view is created. The signal is available with an integer parameter: this is the index of the new tab.
- **on_view_closed**: This event is triggered when a new view is closed. The signal is available with an integer parameter: this is the index of the tab that was closed.

In addition, the MainWindow class features many parameterless methods starting with "cm_...". These methods are identical with the methods called when the respective menu functions are triggered. They are of use when menu events need to be emulated in code, for example to implement special key bindings.

The LayoutView class

The LayoutView class is documented in detail in LayoutView. It represents one layout tab in the main window. A single layout view can show multiple layouts. The CellView objects represent one layout loaded into a view. They specific the layout loaded plus the cell selected for drawing. Each LayoutView has a list of CellView objects corresponding to the layouts shown in the same panel.

A LayoutView object can be obtained from the main window either by reading the current view or by getting the view object for a tab by the tab index:

```
# Current view:
Application::instance.main_window.current_view
# or short:
LayoutView::current

# By index:
Application::instance.main_window.view(index)

# Note: the index of the current view is
Application::instance.main_window.current_view_index
# and the number of views is
Application::instance.main_window.views
```

The index is 0 for the first tab. Note that the value returned by LayoutView#current or MainWindow#current_view can be "nil" if no layout is shown.

A layout view is the container for a variety of "visual" objects. These resources are mainly display objects like annotations, markers and images. In addition, the report database system is anchored in the LayoutView object. The following resources are managed in the layout view:

- **Annotations (rulers)**: an arbitrary number of annotations can be registered in the view. The annotations are objects of the Annotation class (Annotation). Annotations are independent of layouts and are defined in micron units.
- **Images**: images are also objects independent of layouts. Any number of images can be placed below the drawn layout.
- **Markers**: markers are temporary overlay objects which can be used a highlights or to add some elaborate annotation to a layout view. Markers can be layout database objects, hence it is possible to draw polygons or other objects over the layout. Markers can be configured to a large degree, so different colors can be used for example. Markers are objects of class Marker (Marker).
- **Local configuration**: be default, the layout view pulls its configuration from the global configuration database. It is possible however to override certain configuration parameters for a particular view. This allows for example to set the background color for a particular view without affecting the other views.
- **Layer properties**: the layer properties tree is also managed by the layout view. Since there can be multiple layer properties trees in different tabs in the layer properties panel, there are method to access either the current or a specific one of the layer properties trees.
- **Custom stipples and line pattern**: custom stipplesu and line styles can be set in the layout view and used in the layer properties. Custom stipples are bitmaps that define the fill pattern used for the inside area of a polygon. Line styles are bit pattern that make lines being resolved into dots.
- **Selection**: the layout view also manages the selection. This is a set of objects and their instantiation path in the layout database. It represents the set of selected objects. Each selected object is described by a instantiation path and the object itself. That information is combined in the ObjectInstPath object (ObjectInstPath).
- **Transient selection**: this is the object that is highlighted briefly when the mouse hovers over it.
- **Cell views**: the list of layouts and cells shown in the layout view as overlays. Cell views are created when layouts are loaded and deleted when layouts are closed. One of the cell views is the "active" one. That is the one which is selected in the drop-down box in the cell tree and for which the cell tree is shown.
- **Cell visibility**: the information about what cell is visible and what cell is not. Each cell can be made invisible. In that case, only the cell frame is drawn and the cell is shown stroked out in the cell tree.

- **Hierarchy levels**: this attribute controls which hierarchy levels are shown by default.
- **Viewport**: the geometrical dimensions of the area which is drawn in micron space.
- **Report databases**: a layout view can have multiple report databases attached to it. Report databases can be shown in the marker browser and are collections of general information or geometrical information related to a certain position or area.
- **Transactions**: transactions are grouped layout operations which form an atomic operation which can be undone. Transactions can be created within the layout view. Transactions must be opened and closed before they are available as operations on the undo stack.
- **Plugins**: plugins are a way to implement new functionality inside the layout view related to mouse actions. By using plugins it is possible to track the mouse and implement actions related to mouse activity.
- **Title**: finally, a layout view has a title which is shown in the tab.

Being the central class, the layout view naturally offers many methods and attributes. Here's a brief explanation of some of these methods:

- LayoutView#active_cellview and LayoutView#active_cellview_index: gets the active CellView object or index of this object. The active cell view is the one that is selected in the drop-down box above the cell tree. CellView#active gets the active cellview of the current layout view.
- LayoutView#add_missing_layers will add the layers to the layer tree for which there is no layer properties entry yet. This method can be used after a layout has been created and populated to show all layers of the layout.
- LayoutView#add_stipple, LayoutView#clear_stipples and LayoutView#remove_stipple: manage custom stipples.
- LayoutView#add_line_style, LayoutView#clear_line_styles and LayoutView#remove_line_style: manage custom line styles.
- LayoutView#ascend and LayoutView#descend: moves the context cell up or down in the hierarchy.
- LayoutView#begin_layers and LayoutView#end_layers: gets an start or end iterator object that allows traversing of the layer properties tree in a recursive or non-recursive fashion. See below for a description of how to deal with the layer properties.
- LayoutView#each_layer is a convenient alternative way of iterating over the layers without directly using the layer tree iterator.
- LayoutView#box: gets the display area in micron units (the viewport).
- LayoutView#cancel: returns the view into idle state (nothing selected, no editing in progress, "Select" mode is active).
- LayoutView#cellview: gets the CellView object for a given index.
- LayoutView#cellviews: gets the number of cell views registered.
- LayoutView#clear_annotations, LayoutView#insert_annotation, LayoutView#erase_annotation and LayoutView#replace_annotation: manage annotations (rulers).
- LayoutView#clear_images, LayoutView#insert_image, LayoutView#erase_image and LayoutView#replace_image: manage images.
- LayoutView#clear_config, LayoutView#get_config, LayoutView#set_config and LayoutView#commit_config: allow manipulation of the configuration for that layout view only. For example it is possible to set a different background color for that specific layout view.
- LayoutView#clear_layers, LayoutView#delete_layer, LayoutView#delete_layer_list, LayoutView#insert_layer, LayoutView#insert_layer_list, LayoutView#replace_layer_node and LayoutView#remove_unused_layers: manage the layer properties. See below for a detailed explanation.
- LayoutView#clear_transactions: clears all transactions (clears the undo stack).
- LayoutView#transaction and LayoutView#commit: starts or ends a transaction. All operations between the start and end of a transaction can be undone in one step.
- LayoutView#clear_object_selection: clears the selection of geometrical objects (shapes or cell instances).

- LayoutView#create_layout and LayoutView#load_layout: creates a new layout or loads a layout. In both cases, you can either replace the current layouts or add the new one to the layouts present.
- LayoutView#current_layer: returns an iterator pointing to the current layer (the one that has the focus frame in the layer tree.
- LayoutView#current_layer_list: returns the index of the current layer list (if multiple tabs are present in the layer control panel, the current layer list is the tab that is selected).
- LayoutView#each_annotation and LayoutView#each_annotation_selected: delivers all or the selected annotations.
- LayoutView#each_image and LayoutView#each_image_selected: delivers all or the selected images.
- LayoutView#each_object_selected and LayoutView#each_object_selected_transient: delivers ObjectInstPath objects (ObjectInstPath) that point to one selected object each.
- LayoutView#erase_cellview: close a cell view, i.e. remove that specific layout from the list of loaded layouts.
- LayoutView#enable_edits: Enables or disables editing. This method will enable or disable all editing features. This is intended for temporarily disallowing edits. This is not the same than edit and viewer mode.
- LayoutView#get_image, LayoutView#get_image_with_options and LayoutView#get_screenshot: dumps the screen content into a QImage with or without a specific resolution.
- LayoutView#init_layer_properties: provides an initialization of a "LayerProperties" object for a new layer according to the current settings of the view.
- LayoutView#is_cell_hidden?, LayoutView#hide_cell, LayoutView#show_cell and LayoutView#show_all_cells: manages cell visibility.
- LayoutView#load_layer_props and LayoutView#save_layer_props: loads or saves layer properties files.
- LayoutView#max_hier, LayoutView#max_hier_levels= and LayoutView#min_hier_levels=: manages hierarchy levels shown.
- LayoutView#object_selection, LayoutView#object_selection=, LayoutView#select_object and LayoutView#clear_object_selection: return or manipulate the selection of geometrical objects (shapes, instances). The key descriptor object for that purpose is ObjectInstPath, which refers to a geometrical object throug an instantiation path.
- LayoutView#pan_center (and other pan... methods), LayoutView#zoom_box (and other zoom... methods): changes the viewport.
- LayoutView#reload_layout: reloads a given layout.
- LayoutView#create_rdb, LayoutView#remove_rdb, LayoutView#rdb and LayoutView#num_rdbs: Create, delete and get report databases stored inside the LayoutView object.
- LayoutView#rename_cellview: changes the name of a cellview.
- LayoutView#title, LayoutView#title= and LayoutView#reset_title: sets or resets the layout view's title.
- LayoutView#save_as: Saves a layout to a file (with options).
- LayoutView#show_image: shows or hides an image.
- LayoutView#viewport_width, LayoutView#viewport_height and LayoutView#viewport_trans: gets the viewport parameters.

Implementing Undo/Redo

Undo/Redo functionality is implemented by using "transactions". Transactions are groups of operations which implement one user operation. Transactions are built internally and automatically once a transaction is initiated. Most operations performed in the framework of the LayoutView and Layout objects are tracked within these transactions. When a transacting is finished, it needs to be committed. After that, a new operation will be available for "Undo" or "Redo".

Transactions can be initiated with LayoutView#transaction and committed with LayoutView#commit. To ensure, every initiation of a transaction is matched by a "commit", it is recommended to employ "ensure":

```
begin

  view.transaction("Some operation")

  ... do your thing here ...

ensure
  view.commit
end
```

Manipulating the selection

The selection of geometrical objects can be manipulated by providing the necessary ObjectInstPath objects. Each such object provides a "pointer" to a shape or instance through the hierarchy. Specifically it lists all the cells and their instantiation transformations down to the shape selected. By accumulating these selections, a shape can be addressed in a flat view, even if the shape is instantiated many levels down in the hierarchy.

Generating such instantiation path objects is somewhat tedious, but usually the requirement is not to generate such paths, but to take an existing selecting, manipulate it somehow and then to set the selection to the new one. This is fairly easy by taking a copy of the selection, manipulation of the shapes and setting the manipulated selection as the new one.

The following is a sample which replaces all shapes by their hull polygons. Note that is provides undo/redo support through a "transaction":

```
view = mw.current_view

begin

  view.transaction("Convert selected shapes to polygons")

  sel = view.object_selection

  sel.each do |s|
    if !s.is_cell_inst? && !s.shape.is_text?
      ly = view.cellview(s.cv_index).layout
      # convert to polygon
      s.shape.polygon = s.shape.polygon
    end
  end

Events

The LayoutView object supplies several events. See Events And Callbacks for details about events. These are the events:

- **on_active_cellview_changed**: This event is triggered when the active cellview changes. The active cellview is the one indicated by the drop-down-box atop of the cell list if multiple layouts are loaded into one view.
- **on_annotation_changed**: This event is triggered if an annotation is changed. The ID of the annotation is sent along with the event.
- **on_annotation_selection_changed**: This event is triggered if the selection of annotations is changed.
- **on_annotations_changed**: This event is triggered if an annotation is added or deleted.
- **on_cell_visibility_changed**: This event is triggered when the visibility of a cell changes. The visibility of a cell is changed by using "Hide Cell" or "Show Cell" from the cell tree's context menu.
- **on_cellviews_changed**: This event is triggered when a new cellview is added or a cellview is removed.

- **on_cellview_changed**: This event is triggered when a cellview changed (i.e. the current cell has been changed. The index of the changed cell view is sent along with the event.
- **on_close**: This event is triggered when a cell view is closed.
- **on_file_open**: This event is triggered when a file is loaded.
- **on_hide**: This event is triggered when a cell view is going to become invisible (i.e the tab changed).
- **on_current_layer_list_changed**: This event is triggered when the current layer list was changed (i.e. the tab in the layer list has been changed).
- **on_image_changed**: This event is triggered when an image was edited. The ID of the image is sent along with the event.
- **on_image_selection_changed**: This event is triggered when an image was selected or unselected.
- **on_images_changed**: This event is triggered when an image was added or deleted.
- **on_layer_list_changed**: This event is triggered if a layer was changed, added or deleted.
- **on_layer_list_deleted**: This event is triggered if a layer list was deleted (i.e. a tab was removed).
- **on_layer_list_inserted**: This event is triggered if a layer list was inserted (i.e. a tab was added).
- **on_rdb_list_changed**: This event is triggered when a report database is opened or removed.
- **on_selection_changed**: This event is triggered when the selection has changed.
- **on_show**: This event is triggered when a cell view is going to become visible (i.e the tab changed).
- **on_transient_selection_changed**: This event is triggered when the transient selection has changed.
- **on_viewport_changed**: This event is triggered when the viewport has changed, for example the view is zoomed in or panned.

Working with layer properties

The API provides methods by which the layer properties list of the layout view can be traversed and manipulated in many ways. In particular:

- Add or remove entries to or from the layer properties list: LayoutView#insert_layer and LayoutView#delete_layer
- Clear all entries: LayoutView#clear_layers
- Manage custom stipple pattern: LayoutView#add_stipple, LayoutView#clear_stipples and LayoutView#remove_stipple
- Add, rename or remove tabs, get or change the current tab: LayoutView#insert_layer_list, LayoutView#rename_layer_list, LayoutView#delete_layer_list, LayoutView#current_layer_list and LayoutView#set_current_layer_list
- Remove unused layers from the layer list or add entries for missing layers: LayoutView#remove_unused_layers, LayoutView#add_missing_layers
- Load or save layer properties from or to a ".lyp" file: LayoutView#load_layer_props and LayoutView#save_layer_props
- Obtain the selected entries from the layer properties tree: LayoutView#selected_layers and LayoutView#current_layer
- Initialize layer properties with the default settings: LayoutView#init_layer_properties
- Expand layer properties which contain wildcard entries ("stylesheet" layer properties files): LayoutView#expand_layer_properties
- Manipulate layer properties by setting the properties of the LayerPropertiesNodeRef object returned by LayoutView#each_layer or LayerPropertiesIterator#current.

Many of these functions use LayerPropertiesIterator objects to identify entries in the layer tree. Such an object is basically a pointer into the tree. The term "iterator" refers means that such a pointer can be moved to neighboring entries in the layer tree. By default, the LayerPropertiesIterator performs a preorder, depth-first traversal of the layer properties tree (the virtual root object is omitted). This is how to work with LayerPropertiesIterator objects:

```
layout_view = Application::instance.main_window.current_view
# Get the iterator for the first entry:
lp = layout_view.begin_layers
# advance to the next entry (preorder, depth-first traversal):
lp.next
# advance to the next sibling
lp.next_sibling(1)
# advance to the previous sibling
lp.next_sibling(-1)
# move down in the hierarchy to the first child
lp.down_first_child
# move down in the hierarchy to the last child
lp.down_last_child
# move up to the parent node
lp.up
# get the value of the current node
props = lp.current
```

The LayerPropertiesIterator has a couple of attributes:

- LayerPropertiesIterator#current: returns the LayerPropertiesNodeRef object (LayerPropertiesNodeRef) which is a representative for the layer the iterator points to. This object can be manipulated which has an immediate effect on the layer list of the view.
- LayerPropertiesIterator#at_end?: returns true, if the iterator is at the end of the layer properties tree (if "next" is used to traverse) or at the end of the current child node list if other methods of traversal are used. It "at_end?" is true, the iterator does not point to a valid entry.
- LayerPropertiesIterator#is_null?: returns true, if this iterator is a null iterator (i.e. default-constructed).
- LayerPropertiesIterator#at_top?: returns true, if this iterator is pointing to a top-level entry.
- LayerPropertiesIterator#child_index: returns the index of the current entry in the current child list.

Iterators can be compared against each other. If two iterators point to the same object, the equality operator "==" returns true.

The actual entry that the iterators "current" property is a LayerPropertiesNodeRef object (a reference to a LayerPropertiesNode object). If behaves the same way than a LayerPropertiesNode object (LayerPropertiesNode), but modifications of the latter will change the way the layer is displayed in the view.

The LayerPropertiesNode object contributes only a few methods, namely:

- LayerPropertiesNode#id: an integer ID that uniquely identifies the entry in the tree.
- LayerPropertiesNode#flat: computes and delivers an effective set of properties as a LayerProperties object.
- LayerPropertiesNode#bbox: computes the bounding box of the drawn layer represented by this entry.
- LayerPropertiesNode#has_children?: returns true, if this node is not a leaf node.
- LayerPropertiesNode#add_child: adds a child node to the node. It returns a reference to the new node created inside the node's hierarchy. Is is possible to add new children to the node returned.
- LayerPropertiesNode#clear_children: removes all children from the node.

The actual properties of the layer are accessible through methods of the LayerProperties object. Since the parent node may override or contribute properties, a LayerProperties object has a twofold identity: the way it appears finally ("real") and the way it is configured ("local"). The property accessors have a "real" parameter and deliver the real value if this parameter is set to true and the local value otherwise. There are also convenience methods which always deliver the "real" value.

```
lp = layout_view.begin_layers

# manipulate the layer
lp.current.width = 2
lp.current.fill_color = 0x80ff40

# which is equivalent to this somewhat more efficient way:
props = lp.current.dup
props.width = 2
props.fill_color = 0x80ff40
lp.current.assign(props)
```

It is possible to directly manipulate the hierarchy this way:

```
lp = layout_view.begin_layers
# create a copy that we can manipulate
# add two child nodes
cp = RBA::LayerProperties::new
cp.source = "100/0"
lp.current.add_child(cp)
cp = RBA::LayerProperties::new
cp.source = "101/0"
lp.current.add_child(cp)
```

New entries can be created by using LayoutView's insert_layer method and a LayerPropertiesIterator to specify the location where the node shall be created. Here is an example how to create a child entry using that technique. Please note how "down_first_child" is used to navigate into the node's child space which works even if there are no children yet:

```
lp = layout_view.begin_layers
# let the iterator point to the first child, even if it does not exist
lp.down_first_child
# (lp.current may not be valid, but still lp is a valid insert position)
# prepare a new entry for insert:
props = RBA::LayerProperties.new
props.source = "100/0"
# insert the child node:
layout_view.insert_layer(lp, props)
# now, lp points to a valid object: lp.current.source == "100/0"
```

LayerProperties objects

The LayerProperties object represents one entry in the layer properties tree and has several basic properties. For each of these properties, a getter for the real and local value exists as well as a setter that installs a local value. For example, for the width property, the following methods are defined:

- **width(real)**: the getter for the real ("width(true)") or local ("width(false)") value.
- **width**: the real value.
- **width=**: the setter for the local value.

Width is a "weak" property. That means that for computing the effective width, child nodes can override the settings inherited from the parent nodes. A width of 0 is considered "not set" and does not override parent defined widths. Other properties like visibility are "strong", i.e. the parent can override the properties set for its children. Another form of combination is "additive" where the effective property value is the "sum" (or in general combination) of all local properties from parent to child.

Some properties like "fill_color" do not have a neutral value but instead they can be cleared (in that case with "clear_fill_color"). The LayerProperties object can be asked whether a fill color is set using the "has_fill_color?" method.

This is a brief list of properties:

- LayerProperties#animation (strong): specifies animation (blinking, scrolling)
- LayerProperties#dither_pattern (strong): specifies the fill pattern
- LayerProperties#line_style (strong): specifies the line style
- LayerProperties#fill_brightness (additive): specifies the fill color's brightness
- LayerProperties#fill_color (strong): specifies the fill color
- LayerProperties#frame_brightness (additive): specifies the frame color's brightness
- LayerProperties#frame_color (strong): specifies the frame color
- LayerProperties#lower_hier_level (weak): the lower hierarchy level shown. This property has various flavors related to the definition of "lower level".
- LayerProperties#upper_hier_level (weak): the upper hierarchy level shown. This property has various flavors related to the definition of "upper level".
- LayerProperties#marked? (strong): specifies whether the layout is rendered with small crosses at each vertex
- LayerProperties#xfill? (strong): Specifies whether a cross is drawn in rectangles
- LayerProperties#transparent? (strong): specifies whether the layer is semi-transparent (color bitmap combination)
- LayerProperties#visible? (strong): specifies whether the layer is visible
- LayerProperties#valid? (strong): specifies whether the layer is valid
- LayerProperties#width (weak): specifies the line width
- LayerProperties#source (weak, additive): specifies the origin of the data. This property can be set or obtained either a string using KLayout's source notation or be accessed through a couple of specialized properties delivering a part of the source specification each (LayerProperties#source_layer, LayerProperties#source_datatype, LayerProperties#source_name, LayerProperties#source_layer_index, LayerProperties#source_cellview and LayerProperties#trans)

In addition, a couple of getters for computed and derived values are present (i.e. "eff_frame_color"). There are no setters for these properties. The effective frame color for example delivers the frame color which results from combining the frame color and the frame brightness.

The CellView class

The CellView (CellView) identifies the cell drawn and the context the cell is drawn in. A CellView can be created as a object but usually it is obtained from a LayoutView object. In the following example, the active cell view is used:

```
RBA::Application::instance.main_window.current_view.active_cellview
```

Alternatively, a cell view can be addressed by index:

```
lv = RBA::Application::instance.main_window.current_view
num_cellviews = lv.cellviews # number of cell views
lv.cellview(0) # first one
```

A cellview carries the following information:

- CellView#cell: a reference to the cell shown (a Cell object: Cell).
- CellView#layout: a reference to the layout object (a Layout object: Layout) which contains the cell shown.

- CellView#name: the unique name of the layout.
- CellView#filename: the name (actually the path) of the file loaded if the layout was loaded from a file.
- CellView#path: the unspecific path (see below)
- CellView#context_path: the specific path (see below)
- CellView#ctx_cell: the context cell (see below). Alternatively the cell index of the context cell is available by CellView#ctx_cell_index.
- CellView#technology: the technology (name) used with this layout
- CellView#is_cell_hidden?: returns a value indicating whether a given cell is hidden

A cellview can be manipulated to change the cell shown in the layout view. For this purpose, assignment methods exist which will reconfigure the cellview:

- CellView#cell=: a reference to the cell shown (a Cell object: Cell).
- CellView#cell_index=: a reference to the cell shown (by cell index).
- CellView#name=: the unique name of the layout.
- CellView#path=: sets the unspecific path (see below)
- CellView#context_path=: sets the specific path (see below)
- CellView#technology=: applies the given technology to this layout
- CellView#show_cell, CellView#show_all_cells, CellView#hide_cell: shows or hides cells
- CellView#close: closes this cell view (removes it from the layout view)

Unspecific and specific path and context cell

In addition to the cell itself, the cell view specifies how the cell is embedded in the hierarchy. Embedding can happen in two ways: an unspecific and a specific way. Both ways contribute to a path which leads from a top cell to the cell drawn.

The first part is always the unspecific path. This path specifies, where the cell drawn is located in the cell tree. That has no effect on the drawing, but is determines what entry in the cell tree is selected. Giving a path for that information is required, because a cell can be child of different cells which itself can be children of other cells. The unspecific path lists the top cell and further cells which are all direct or indirect parents of the cell addressed.

The unspecific path ends at the "context cell" which usually is identical to the cell addressed by the cell view. KLayout allows addressing of a specific instance of a direct or indirect child cell as the actual cell. In that case, the specific path comes into play. Bascially that means, that a cell is drawn within a context of embedding layout. The specific path leads from the context cell to the cell view's target cell and consists of specific instances (hence the name "specific path"). The "descend" and "ascend" feature bascially adds or removes instances from that path.

The unspecific path can be obtained with the CellView#path method, the specific path with the CellView#context_path method. The unspecific path is just an array of cell indexes specifying the top cell and further cells down to the context cell and includes the context cell. The specific path is an array of InstElement objects (InstElement). Each InstElement object describes a specific instantiation (a cell instance plus information when a specific array instance is addressed). When there is no context, the specific path is an empty array. Using the setters CellView#path= and CellView#context_path= these paths can be changed to select a new cell into the layout view.

The Image class

Images can be placed onto the drawing canvas and display colored or monochrome images below the layout. Images are represented by Image objects (Image). Basically an image is a two-dimensional array of pixel values with a specification how these pixels are to be displayed on the canvas. An image can be created an placed on the canvas like this:

```
lv = RBA::Application::instance.main_window.current_view
image = RBA::Image::new("image.png")
```

```
lv.insert_image(image)
```

An image can be configured by using different properties and attributes:

- The images' data can be loaded from a file by using a constructor with a file name. In addition, the image can use data from an array of floating-point values using either a constructor or the Image#set_data method. An image can be colored, in which case three channels are present or it can be monochrome. In the latter case, a single channel is present only. Together with the data, the dimensions of the image have to be specified (width and height in pixel units).
- The image's data can be manipulated per pixel using the Image#get_pixel or Image#set_pixel method.
- The data range for the data stored in the image can be set using the Image#min_value= and Image#max_value= attributes. The data range determines which value is considered "maximum intensity" (max_value) and "zero intensity" (min_value).
- For monochrome images, a data mapping can be specified. A data mapping converts a monochrome value (a scalar) to a color. Data mapping is specified through a ImageDataMapping object (ImageDataMapping) using the Image#data_mapping method.
- The geometrical properties of an image are encapsulated in a Matrix3d object (Matrix3d). Such a matrix describes the transformation from pixel coordinates to the micron unit space of the canvas. A 3x3 matrix is a generic way to specify a transformation, including translation, rotation, mirror, shear or perspective distortion. The matrix is obtained and set using the Image#matrix attribute. Convenience methods like Image#trans, Image#pixel_width and Image#pixel_height allow accessing sub-aspects of the generic transformation (affine transformation, scaling).

An image can be transformed using one of the Image#transformed methods. It can be hidden or shown using the Image#visible= method. The bounding box of the image can be obtained with the Image#box method.

The Annotation class

Annotations (Annotation) are basically rulers and other "overlay objects" but can be used for other purposes as well, for example to simply add a text object. Annotations, like images, are objects stored in the LayoutView and can be selected, deleted, transformed etc.

Programmatically, annotations are created this way:

```
lv = RBA::Application::instance.main_window.current_view
ant = RBA::Annotation::new
ant.p1 = RBA::DPoint.new(0.0, 0.0)
ant.p2 = RBA::DPoint.new(100.0, 0.0)
lv.insert_annotation(ant)
```

The annotation carries several attributes. Those are the same attributes that can be configured in the annotation properties dialog. The most important properties are the two positions (start and end position) accessible through the Annotation#p1 and Annotation#p2 properties, the style (Annotation#style property) and the outline (Annotation#outline property).

If properties are changed using the attribute setters, their appearance will change as well. The following example demonstrates how rulers are manipulated. In this example, the style of all rulers is set to "arrow on both sides". Note, how in this example transactions are used to implement undo/redo:

```
view = RBA::LayoutView::current

begin

  view.transaction("Restyle annotations")

  view.each_annotation do |a|
    a.style = RBA::Annotation::StyleArrowBoth
  end

ensure
  view.commit
end
```

The Marker class

A marker is a temporary highlight object. A marker is represented by the Marker class (Marker). Markers appear when they are created and disappear when they are destroyed. Since destruction by the garbage collector happens at undefined times, the destroy method can be used to destroy the marker explicitly. Markers accept some plain shapes (i.e. a Box) which will be displayed as the marker. Markers can be configures in manifold ways, i.e. the colors, the fill pattern, line width etc. See the class documentation for details about the configuration properties.

This is how to create and destroy a marker:

```
lv = RBA::Application::instance.main_window.current_view
marker = RBA::Marker.new(lv)
marker.set(RBA::DBox::new(0.0, 0.0, 100.0, 200.0))
# to hide the marker:
marker.destroy
```

Markers are temporary objects intended for highlighting a certain area or shape. Markers are not persisted in sessions nor can they be edited.

The Plugin and PluginFactory classes

Plugins (Plugin) are objects which provide modular extensions of KLayout. Plugins are the only way to handle mouse events in the canvas. The basic operation of a plugin is the following:

- For each plugin type, a PluginFactory (PluginFactory) object must be provided. KLayout uses this object to configure itself and to create a particular plugin instance for each LayoutView. The PluginFactory must provide certain configuration information and can handle some events in a global manner, for example menu entries that do not refer to a certain plugin instance. The PluginFactory must register itself in the KLayout framework. After doing so, KLayout will provide a new button in the tool bar. If this button is selected, the plugin will be activated.
- When a LayoutView is created, it will use the PluginFactory to create a specific Plugin instance for the view. When the tool bar button is pressed which relates to this plugin, the plugin will be activated and mouse or other events will be redirected to this plugin.

The PluginFactory itself acts as a singleton per plugin class and provides not only the ability to create Plugin objects but also a couple of configuration options and a global handler for configuration and menu events. The configuration includes:

- Menu items: by configuring menu items in the PluginFactory, KLayout can create these items when the plugin is initialized. Each menu entry is connected with the plugin through a symbol: this is a string that tells the plugin's Plugin#menu_activated method which menu item was selected. By configuring a menu rather than creating it explicitly, KLayout has a somewhat better control over what menu items belong to which plugin. Menu items are configured by calling PluginFactory#add_menu_entry in the PluginFactory's constructor.
- Configuration options: Instead of directly taking values from the configuration database, it is more convenient to register configuration keys in the PluginFactory's constructor using the PluginFactory#add_option method. After an option is configured, the individual Plugin objects and the PluginFactory receives "configure" calls when a configuration option changes or for the initial configuration.

A PluginFactory must be instantiated and register itself. Menu items and configuration options should be set before the object is registered. Upon registration, a unique name must be specified for the plugin class. Also, the tool button title and optionally an icon can be specified.

The main objective of the PluginFactory class however is to create the actual plugin object. For this, the create_plugin method needs to be reimplemented. The implementation is supposed to create an object of the specific class.

The actual implementation of the plugin is a class derived from Plugin (Plugin). The plugin comes into life, when it is activated. That is, when the tool button is pressed that is associated with the plugin. When the plugin is activated, the Plugin#activated method is called. The method can be reimplemented in order to prepare the plugin for taking actions on mouse events. When the plugin is not longer active, i.e. because another mode has been selected, the Plugin#deactivated method is called.

Every plugin has the ability to receive and intercept mouse events. Various mouse events are available: mouse moved, mouse button clicked (button pressed and released), mouse button double clicked, mouse button pressed, mouse button released, entry or leave of the window and agitation of the mouse wheel. Each event follows a certain protocol depending whether the plugin is active or not. In addition, plugins can request exclusive control over the mouse by "grabbing" the mouse. Each event is associated with a certain callback. The callback has a parameter - "prio" - which determines the role of the event. The protocol is described here:

- First, all plugins that grabbed the mouse with grab_mouse will receive an event callback with 'prio' set to true in the reverse order the plugins grabbed the mouse. If any one of the mouse event handlers returns true, the protocol terminates.
- If that is not the case or no plugin has grabbed the mouse, the active plugin receives the mouse event with 'prio' set to true.
- If no receiver accepted the mouse event by returning true, it is sent again to all plugins with 'prio' set to false. Again, the loop terminates if one of the receivers returns true. The second pass gives inactive plugins a chance to monitor the mouse and implement specific actions - i.e. displaying the current position.

In an mouse event handler, the plugin can take any action, i.e. transform objects or create/remove markers. This allows implementing of interactive functionality upon KLayout's canvas object. Using "set_cursor", the plugin can set the mouse cursor to a specific shape for example. A plugin should consider implementing "drag_cancel" in order to terminate any pending dragging operations. Plugin#drag_cancel is called by KLayout to regain control over the mouse in certain circumstances and is supposed to put the plugin into a "watching" instead of "dragging" state.

3.4. The Database API

The basic object of the database is the Layout object. A Layout object represents a layout file or a layout generated. Basically, a layout is a collection of cells and geometrical shapes. The shapes are organised in layers and the cells can be instantiated in other cells creating a hierarchy of cells. Hence, the basic objects of the database are Layout, Cell, Shapes and the geometrical primitives like Box, Path, Polygon, Text and Edge.

The Layout class

The Layout object is the basic container for a layout. Multiple layouts can live within KLayout. Some are stored inside the application and are created when a layout is loaded for example. However, layout objects can also be created as standalone objects for manipulation by Ruby scripts. Such a layout can be an isolated entity without connection to a view.

A basic sample

This is a sample how to create a layout in a layout view with one cell ("TOP"), one layer (layer 10, datatype 0) and one shape (a 1x2 micron box). This sample also shows how to set up the layout view properly:

```
# create a new view (mode 1) with an empty layout
main_window = RBA::Application::instance.main_window
layout = main_window.create_layout(1).layout
layout_view = main_window.current_view

# set the database unit (shown as an example, the default is 0.001)
layout.dbu = 0.001

# create a cell
cell = layout.create_cell("TOP")

# create a layer
layer_index = layout.insert_layer(RBA::LayerInfo::new(10, 0))

# add a shape
cell.shapes(layer_index).insert(RBA::Box::new(0, 0, 1000, 2000))

# select the top cell in the view, set up the view's layer list and
# fit the viewport to the extensions of our layout
layout_view.select_cell(cell.cell_index, 0)
layout_view.add_missing_layers
layout_view.zoom_fit
```

It is also possible to create a standalone layout. Here is an example how to create the layout without a connection to a view and save that layout to a file:

```
# create the layout
layout = RBA::Layout::new

# set the database unit (shown as an example, the default is 0.001)
layout.dbu = 0.001

# create a cell
cell = layout.create_cell("TOP")

# create a layer
layer_index = layout.insert_layer(RBA::LayerInfo::new(10, 0))

# add a shape
cell.shapes(layer_index).insert(RBA::Box::new(0, 0, 1000, 2000))

# save the layout
layout.write("my_layout.gds")
```

Overview over the Layout object

The basic building blocks of layouts are layers and cells. Layers are not individual objects. Instead, a layer is rather an index and the various methods allow addressing shapes inside layers by using that index. However, the layout object stores the layer properties, i.e. the layer and datatype number.

Cells are represented by Cell objects which are described later. Cells are often referred to by a cell index which is basically an ID which allows identification of a cell without having to keep a reference. The Layout object allows converting of a cell index to a cell reference with the Layout#cell method. Cells can be instantiated inside other cells. Instances are described by CellInstArray objects.

Another important property of the layout object is the database unit. In the layout, all geometrical coordinates are stored as integer values for efficiency. The database unit specifies the length of one unit in micrometers. The database unit can be accessed with the Layout#dbu attribute. Changing the database unit effectively scales a layout. Often the database unit is a fixed value and compatibility between different layouts in a flow often demands use of a specific database unit. Hence, changing the value of the database unit is possible but requires some careful consideration.

The Layout object keeps shapes (texts, polygons, boxes, paths etc.) on "layers". A layer is a collection of shapes. A layout features a set of layers and each cell provides space for each layer. The shapes are stored inside the cells while the layers are managed by the layout. For doing so, the Layout object keeps layers as a table of LayerInfo objects. The LayerInfo object carries information about the description of a layer, for example layer and datatype number and/or the layer name. A layer is basically just an index in that table. Layers can be created using the Layout#insert_layer method. Each layer is present in every cell and inside a cell, a shape storage for each layer is provided.

Inside the layout object, shapes are kept with integer coordinates. The physical units can be obtained by multiplying the integer coordinates with the database unit. The integer type objects are Box, Polygon etc. Most objects also support floating-point coordinate objects (DBox, DPolygon etc.). These objects are then given in micrometer units - i.e. already multiplied by the database unit. If using these objects, keep in mind that internally they are still integer-type objects. This means, rounding to the database will happen and if you change the database unit, the objects will effectively scale.

A Layout object provides some basic layout manipulation and query methods. For example, it provides a method to retrieve shapes touching or overlapping a certain rectangular region of a cell. It also provides a clip method which extracts a rectangular region from a layout (Layout#clip, Layout#clip_into, Layout#multi_clip, Layout#multi_clip_into). It provides methods to delete cells and cell trees and (Layout#delete_cell, Layout#delete_cell_rec, Layout#delete_cells, Layout#prune_cell, Layout#prune_subcells). There are also methods to manipulate layers (Layout#clear_layer, Layout#copy_layer, Layout#move_layer, Layout#delete_layer).

Some convenience functions are provide to read and write a layout from or to a file. The Layout#read method reads a layout from a file. It basically merges the contents of the file with the layout so it's possible to combine multiple files by using read more than once. The method comes in two flavors: a simple one and one that allows specification of reader options with a LoadLayoutOptions object. There is also a Layout#write method which writes the layout to a file. The simple form writes the layout to a file and the file type is determined by the file extension. A full-featured version exists which allows to specify the format and many more options with a SaveLayoutOptions object.

Layouts can also import cells from Libraries (Library). Such imported cells are basically cells linked to another cell inside the library. Library cells are imported using the Layout#add_lib_cell method. This method creates a "proxy" cell which is a copy of the library cell but is linked to the library. As long as the library is present in the system, this link is maintained and stored in the layout files. If the link is lost because the library is removed, the proxy cell becomes a normal cell. Such proxy cells basically behave like normal cells but should not be manipulated.

Layout objects are also responsible for handling properties. Properties are basically arbitrary sets of data (key/value pairs) attached to shapes, cells or instances. For efficiency, the property data is not attached to every shape, cell or instance. Instead, the layout object manages different property sets and associate each distinct set with an integer ID. The shape, cell or cell instance only stores that ID. To create, query or change property sets, the layout object provides the Layout#properties and Layout#properties_id methods. Since that is inconvenient, shapes, cells and instances provide access to the properties by providing methods to set, get and delete properties from the set (for example Shape#property, Shape#delete_property and Shape#set_property). Internally, these methods create a new ID if necessary and assign that ID to the shape, cell or instance.

A layout can provide and import PCells. PCells are cells that provide its geometry through program code (for example written in Ruby) and provide parameters which can be adjusted to change the appearance of the cell. For each PCell a "declaration" must be provided which basically contains the code for the PCell and some information about the parameters provided by the PCell. PCells are stored in the layout and are referred to by a PCell ID (an integer). PCells are added to a layout using Layout#register_pcell and retrieved by ID or name using Layout#pcell_declaration. PCells are instantiated with a specific parameter set using the Layout#add_pcell_variant. This method creates a cell representing the layout generated by the PCell code for a particular set of parameters. The layout internally caches the PCell layouts so the PCell code is executed only if a new parameter set is requested. Usually PCells are provided through libraries. In that case, the library provides the PCell variant through Layout#add_pcell_variant which is imported into the target layout through Layout#add_lib_cell. There is a overload of Layout#add_pcell_variant which combines both steps.

The following code demonstrates how to create a PCell (in that case a "TEXT" cell from the "Basic" library):

```
ly = RBA::Layout.new
top = ly.add_cell("TOP")

# Find the lib
lib = RBA::Library.library_by_name("Basic")
lib || raise("Unknown lib 'Basic'")

# Find the pcell
pcell_decl = lib.layout.pcell_declaration("TEXT")
pcell_decl || raise("Unknown PCell 'TEXT'")

# Set the parameters (text string, layer to 10/0, magnification to 2.5)
param = { "text" => "KLAYOUT RULES", "layer" => RBA::LayerInfo::new(10, 0), "mag" => 2.5 }

# Build a param array using the param hash as a source.
# Fill all remaining parameter with default values.
pv = pcell_decl.get_parameters.collect do |p|
  param[p.name] || p.default
end

# Create a PCell variant cell
pcell_var = ly.add_pcell_variant(lib, pcell_decl.id, pv)

# Instantiate that cell
t = RBA::Trans::new(RBA::Trans::r90, 0, 0)
pcell_inst = ly.cell(top).insert(RBA::CellInstArray::new(pcell_var, t))
```

Editable mode

A layout can exist in two flavors: editable and non-editable. In editable mode, some optimisations are disabled. For example, OASIS shape arrays are expanded into single shapes. This enables manipulation of the database. For example, the shape replacement, property manipulation and other operations are only possible in editable mode. On the other hand, the memory footprint of a layout may be larger in editable mode. Independent of the mode, layouts can be created and cells, instances and shapes can be added, but not manipulated.

A layout object living in the application is created in editable or non-editable mode depending on the application setting. Layout objects explicitly created by RBA code can either be in editable or non-editable mode:

```
editable_layout = RBA::Layout.new
non_editable_layout = RBA::Layout.new(false)
```

The Layout#is_editable? method returns true, if a layout is in editable mode. Once the layout is created, the editable mode cannot be changed.

Meta information

A layout object can keep arbitrary meta data in the form of key/value pairs. This meta data is extracted during the reading of a layout and will reflect special properties of the layout file. For example, the GDS2 library name is available as meta information with key "libname".

The layout object offers methods to retrieve that information: Layout#each_meta_info will iterate over the meta data (returning a LayoutMetaInfo object). Layout#meta_info_value will get the value for a given name. Layout#add_meta_info will add a new meta information object and Layout#remove_meta_info will delete one.

Meta information is a different concept than properties.

Cell related methods

Cells can be created using the Layout#create_cell method. This method expects a cell name. If a cell with that name already exists, a new name is generated by appending a suffix. The method returns the Cell object of the new cell. Layout#rename_cell or Cell#name= can be used to change the name of a cell. The Cell object for a given name can be obtained with Layout#cell which returns the Cell object or nil if no cell with that name exists.

The cell name can be obtained from the cell index with the Layout#cell_name method or Cell#name). Layout#has_cell? can be used to determine whether a cell with the given name exists. Layout#is_valid_cell_index? can be used to determine whether a given index is a valid

cell index. Layout#cells returns the number of cells in the layout. To work with cells, the Cell object is required. It can be obtained from the cell index using the Layout#cell method.

The top cell of a layout can be obtained using Layout#top_cell. If multiple top cells exist, this method will raise an exception. In that case, Layout#top_cells can be used to obtain all top cells.

All cells in the layout can be iterated using the Layout#each_cell iterator. All top cells (cells which are not instantiated itself) can be iterated with the Layout#each_top_cell iterator. The cells can be iterated bottom-up (all child cells come before their parents) or top-down (all parents come before their children) using the Layout#each_cell_bottom_up or Layout#each_cell_top_down.

Layout#delete_cell deletes a cell. This method will keep the child cells, which may become top cells because their parent cell is deleted. Layout#delete_cells deletes multiple cells and is more efficient than deleting cell by cell. Layout#delete_cell_rec will delete a cell and all child cells (direct and indirect), irregardless whether they are used otherwise or not. Layout#prune_cell does the same but is somewhat more sensitive in that respect and does not delete child cells if they are instantiated by parents not in the cell tree below the cell being deleted. Layout#prune_subcells as prune_cell deletes the child cells or a cell but in contrast to prune_cell does not delete the cell itself.

Layer related methods

Layout#insert_layer creates a new layer in the layout. The layer will be available to all cells. This method receives a LayerInfo object which holds the information about the layer's name, layer and datatype. It returns a layer index which can be used to address shapes in the cells. Layout#insert_layer_at can be used to create a layer with a specific layer index, provided that index is not used yet.

Layout#is_valid_layer? can be used to determine whether a layer index is a valid index. Layout#layer_indices returns a list of indexes of all layers present. Layout#layers returns the number of layers present.

Layout#find_layerReturns the layer index for a given layer in various flavors. Layout#layer finds or creates a layer if it does not exist yet. Again, the layer can be given in various flavors - for example by layer and datatype, by name or with a LayerInfo object.

Layout#set_info can be used to change the LayerInfo object for a layer. Layout#get_info returns the LayerInfo object for a layer. To modify the information, obtain the information with get_info, modify it, and set the new information with set_info:

```
lv = RBA::Application::instance.main_window.current_view
ly = lv.current_cellview.layout
info = ly.get_info(0)
info.layer = 100
ly.set_info(0, info)
lv.add_missing_layers
lv.remove_unused_layers
```

The previous sample changes the layer number for layer index 0 to 100. "add_missing_layers" and "remove_unused_layers" will create new layer entries in the layer list and remove the entry for the previous layer.

For special purposes, special (temporary) layers can be created in the layout. Those layers basically behave like normal layers but don't appear in the layer list and are not saved to a file. Special layers can be created using Layout#insert_special_layer and Layout#insert_special_layer_at. Layout#is_special_layer? returns true if a given index is a special layer.

In addition, a layout contains a special layer which is used to implement the "guiding shape" feature of PCells. It is a special layer that serves as a container for shapes which parametrize PCells. The index of that layer can be obtained with Layout#guiding_shape_layer.

A list of the indexes for all layers inside the layout can be obtained with Layout#layer_indexes. A corresponding list of LayerInfo objects can be obtained with Layout#layer_infos.

Recursive full or region queries

A layout provides methods to retrieve shapes recursively. That means, that the shapes are delivered from all cells instantiated below a given top cell. Cells instantiated multiple times are also visited multiple times. While the shapes are delivered, information is provided what cell instances the specific shape instance is found in.

Recursive shape retrieval is done through a iterator, the RecursiveShapeIterator. This object delivers one shape each time. A RecursiveShapeIterator is created for example using the Layout#begin_shapes method. This method requires the cell index of the starting (initial) cell and a layer index. This code demonstrates how to use the RecursiveShapeIterator:

```
layout = RBA::Application::instance.main_window.current_view.active_cellview.layout
# start iterating shapes from cell "TOP", layer index 0
si = layout.begin_shapes(layout.cell_by_name("TOP"), 0)
while !si.at_end?
  puts si.shape.to_s + " with transformation " + si.trans.to_s
  si.next
```

```
end
```

The RecursiveShapeIterator's shape method delivers a shape reference (see description of the Shape class or Shape) which basically points to a shape inside a cell. Since the cell may be a child cell of the initial cell the RecursiveShapeIterator was created with, in general a transformation is present that tells how the cell's content shows up in the initial cell. The generic form of that transformation is a CplxTrans object which is delivered by the RecursiveShapeIterator's "trans" method. This transformation renders floating-point coordinates which is precise but not a suitable representation for transforming shapes into a form compatible with the database. For that purpose, a ICplxTrans object is provided as well through the "itrans" method. This transformation renders integer coordinates which may imply rounding effects in some cases. The RecursiveShapeIterator delivers the cell from which the current shape is taken through the "cell_index" method.

A RecursiveShapeIterator can be configured to retrieve only certain type of shapes (i.e. boxes, texts etc.). To do so, set the shape_flags attribute of the shape iterator before using it:

```
layout = RBA::Application::instance.main_window.current_view.active_cellview.layout
# start iterating shapes from cell "TOP", layer index 0
si = layout.begin_shapes(layout.cell_by_name("TOP"), 0)
si.shape_flags = RBA::Shapes::SBoxes
while !si.at_end?
  puts si.shape.to_s + " with transformation " + si.trans.to_s
  si.next
end
```

Also the maximum depth at which the RecursiveShapeIterator will traverse the hierarchy can be set using the "max_depth" attribute. Setting this attribute to 0 will report only shapes from the initial cell. The depth must be set before the first shape is retrieved.

The RecursiveShapeIterator can also deliver shapes from a region. The region is a rectangle specified in coordinates of the initial cell. To create a RecursiveShapeIterator that only delivers shapes inside that region use the Layout#begin_shapes_touching or Layout#begin_shapes_overlapping methods of the Layout object. These methods expect a Box object that specifies that rectangle. All shapes delivered will either touch or overlap that box when projected into the initial cell.

Shape manipulations should be avoided inside loops that iterate over shapes using a RecursiveShapeIterator. The reason is that shape manipulations may invalidate the internal state of the RecursiveShapeIterator. Instead, collect all shape references that need to be manipulated in an array and do the manipulations later.

Properties

As stated earlier, shapes can carry an arbitrary number of user properties in form of key/value pairs. For efficiency, these properties are not stored directly but in form of a property ID which identifies a unique set of properties. Retrieving a property hence requires an indirection over the property ID:

```
layout = RBA::Application::instance.main_window.current_view.active_cellview.layout
# first shape of cell "TOP", layer index 0
layer_index = 0
iter = layout.begin_shapes(layout.cell("TOP").cell_index, layer_index)
shape = iter.shape
# create a hash from the properties of that shape
props = Hash[*layout.properties(shape.prop_id).flatten]
# print the value of the property with key 1
puts props[1]
```

Since that scheme is somewhat tedious to use, a nice shortcut exists by using the "properties" method on the shape reference. This method implicitly modifies the property set and assigns a new property ID:

```
layout = RBA::Application::instance.main_window.current_view.active_cellview.layout
# first shape of cell "TOP", layer index 0
layer_index = 0
iter = layout.begin_shapes(layout.cell("TOP").cell_index, layer_index)
shape = iter.shape
# print the value of the property with key 1
puts shape.properties(1)
```

Changing a property requires to obtain a new property ID for the changed set:

```
layout = RBA::Application::instance.main_window.current_view.active_cellview.layout
# first shape of cell "TOP", layer index 0
layer_index = 0
iter = layout.begin_shapes(layout.cell("TOP").cell_index, layer_index)
shape = iter.shape
cell = layout.cell(iter.cell_index)
# create a hash from the properties of that shape
props = Hash[*layout.properties(shape.prop_id).flatten]
# change or add a property with key 1
props[1] = "NewValue"
# store the new properties
shape.prop_id = layout.properties_id(props.to_a)
```

For that problem also a shortcut exists. Use the "set_properties" method on the shape reference. This method implicitly modifies the property set and assigns a new property ID:

```
layout = RBA::Application::instance.main_window.current_view.active_cellview.layout
# first shape of cell "TOP", layer index 0
layer_index = 0
iter = layout.begin_shapes(layout.cell("TOP").cell_index, layer_index)
shape = iter.shape
# change or add a property with key 1 and value "NewValue"
shape.set_property(1, "NewValue")
```

A property ID of 0 in general indicates that no properties are attached. Please note that replacing a property ID and modifying the properties also invalidates any iterators and should not be done in a loop over shapes.

Cell instances and cells also carry a properties ID which can be used to assign user properties to cell instances. The cell instance properties ID is used like the shape properties ID. The shortcut methods "property", "set_property" and "delete_property" also are provided for cells and cell instances (Cell and Instance).

Note: The GDS format does not have string names for properties. As a result GDS only supports numeric property keys. OASIS, on the other hand, can handle string and numeric property "names". When saving layouts in GDS format, KLayout tries to convert the properties' names into numbers if possible (i.e. if it sees that the string is a number). If it can't, then the property is not saved. When the layout is read by KLayout upon opening, it gets converted to integer.

The LayerInfo class

The LayerInfo object encapsulates the layer's naming properties. In GDS, a layer is described by a layer number and datatype number. In OASIS, a text name can be added to that description. In other formats like DXF, a layer has just a text name.

The LayerInfo object thus has a twofold identity: a numeric identity (layer and datatype number) and a text layer name. Both properties can be specified. In that case, the numeric identity has precendence over the text name.

When a layout is loaded, LayerInfo objects are used to represent a layer's naming properties in the Layout object. The LayerInfo object associated with a layer can be retrieved using the Layout's "get_info" method. It can be set using the "set_info" method. In general, the LayerInfo property is detached from the layer index, so it can be assigned and manipulated freely.

The default constructor of LayerInfo will create a nameless object. Nameless layers are not saved to any file and can be used for internal purposes such as temporary or intermediate layers.

The LayerInfo#layer attribute allows read and write access to the layer number. LayerInfo#datatype is the attribute for the datatype number. LayerInfo#name gives access to the text name. LayerInfo#is_named? returns true, if the LayerInfo object represents a named layer (no layer or datatype number are specified). LayerInfo#is_equivalent? compares two LayerInfo objects and returns true, if both denote the same layer. This is not exact equivalence but follows the logical precendence: two layers are equivalent if layer or datatype number match (in that case the text name is ignored) or, if no layer and datatype number are specified, the name matches exactly.

LayerInfo objects supply a hash value (LayerInfo#hash) and can therefore be used as keys in Ruby hashes.

The Cell class

After the Layout object, the Cell object is the most fundamental object in KLayout's database API. It represents a cell, which itself is a collection of shapes per layer and instances of other cells. The methods provided by the Cell class deal with either the shape or the

instance aspect. A cell is also responsible for handling parts of the PCell scheme, either for the cell itself (if it is an incarnation of a PCell) or instances of PCells.

A cell has a name which can be retrieved using the Cell#name method and which can be set using the Cell#name= method. Setting the name is equivalent to using the Layout's "rename_cell" method. Cell#basic_name delivers the PCell or library cell name for cells imported from a library or PCell variants. "name" will deliver an internal unique name in that case. Cell#display_title is a string that encodes library name and PCell parameters as well and can be used as a descriptive title for the cell in user interfaces.

If the cell is a library cell (a "proxy"), it will have a database name (something like "TEXT$1") and a qualified name which states the library and the cell name separated with a dot (i.e. "Basic.TEXT"). The qualified name is not neccessarily unique. The qualified name of the cell can be obtained with Cell#qname.

A cell that represents a cell imported from a library or a PCell variant (or both) is called a proxy cell. For such cells, Cell#is_proxy? returns true. Such cells should not be manipulated since they may be refreshed when required and the original state is restored. Cell#is_library_cell? and Cell#is_pcell_variant? deliver a more detailed information about the nature of the proxy cell.

The layout that the cell lives in can be retrieved with the Cell#layout method. If the cell is created standalone (without layout), this method returns nil. In that case, a cell is not named either.

A cell can be a "ghost cell". A ghost cell is an empty cell which is not written to a layout write and created when a layout file is read with an unsatisfied reference. Unsatisfied references are present in some GDS files which represent partial layouts. By simple merging of two GDS files, such references can be made true instances, when another file contributes the cell for that reference. KLayout supports such unsatisfied references by providing the "ghost cells" which serve as a instance target but are not written. Ghost cells are simply cells where the Cell#is_ghost_cell? attribute is true. An empty cell can be made a ghost cell by setting the Cell#ghost_cell= property.

A cell has a bounding box which includes child cells as well. KLayout keeps a per-layer bounding box, so it's very simple to tell whether a cell is empty in a certain layer (including the hierarchy below). In that case the per-layer bounding box is an empty box. The overall bounding box can be derived with the Cell#bbox method. The per-layer bounding box can be derived with the Cell#bbox_per_layer method.

Cells can be marked as "ghost cells" using the Cell#ghost_cell=. Ghost cells are not saved into GDS files (but their references are). Also, ghost cells act as "placeholders" for cells - for example if a cell is pasted into a layout, it will replace any ghost cell with the same name. If a normal cell with the same name exists, a copy will be created instead. A cell can be asked whether it is a ghost cell using Cell#is_ghost_cell?.

Starting with version 0.23, cells can have properties as well, but writing cell properties to layout files is subject to some restrictions. Properties are only written to GDS if a special option is enabled because a potentially incompatible extension of GDS is used to store the properties. OASIS files support cell properties without restrictions.

Cells and shapes

A cell carries a set of geometrical shapes, organised in layers. A layer is specified by a layer index. The layer index is managed by the Layout object. It is basically an integer that identifies the layer in the layout. The shapes are stored in containers of the Shapes class. Given a layer index, the shapes object can be obtained from the cell through the Cell#shapes method:

```
shapes = cell.shapes(layer_index)
shapes.each do |shape|
  puts shape.to_s
end
```

The same can be achieved by directly iterating over the shapes in the cell:

```
cell.each_shape(layer_index) do |shape|
  puts shape.to_s
end
```

That iterator also allows specification of a filter so it delivers only a certain subset, i.e. only text objects. See Cell and Shapes for more details.

There are iterators that deliver shapes within a rectangular region, either overlapping or touching that region (Cell#each_overlapping_shape, Cell#each_touching_shape). They basically work like the "each_shape" iterator. Please note that these iterators are not recursive, i.e. they don't deliver shapes from child cells. Recursive iteration can be performed using Layout's "begin_shapes" method and the RecursiveShapeIterator object.

All shapes in a cell can be cleared using Cell#clear_shapes. A single layer can be cleared using the Cell#clear method with the layer index to clear. Both methods are not recursive, i.e. they only clear the shapes on the given cell, not on the child cells.

Layers can be copied using the Cell#copy method. The shapes of a layer can be moved to another layer using the Cell#move method. In both cases, the target layer is not overwritten, but the shapes from the source layer are added to the target layer. Cell#swap will swap the shapes of two layers. In all these cases, the operation is local on the cell, i.e. child cells are not affected.

Shapes within a cell are represented as Shape objects. A shape object is a generic object which represents either a polygon, a box, a path, a text or an edge object. Shapes provide some generic methods such as Shape#bbox to retrieve the bounding box or Shape#transform. Shapes act as "pointers" to geometrical objects inside the database. Manipulating a shape will also manipulate the database object.

To work with specific kind of shapes, the working classes such as Polygon are provided. Shapes can be converted into these working objects. The working objects are not related to the layout object and not having a connection to the layout makes them lightweight objects. A usual way of manipulating a shape is to translate it to a working object, modify that and assign the working object back to the shape.

Interfaces to floating-point working classes such as DPolygon are provided too. By convention such objects represent shapes in micrometer units. If such an object is requested from the shapes container it is converted from an integer-type object in database units to a floating-point type object in micrometer units by multiplying with the database unit. When sending such an object to the Shapes container the same happens in reverse. Internally, the integer type is used.

Cells and hierarchy

The direct children of a cell can be iterated with Cell#each_child_cell. That iterator delivers the cell index of each child cell of the cell. Similar, there is a Cell#each_parent_cell iterator. It delivers the cell indexes of all cells calling that cells. For a top cell that iterator delivers nothing. Cell#is_leaf? returns true, if the cell does not have child cells. Cell#is_top? returns true, if the cell is top cell.

Cells and their children form a directed acyclic cell graph. That means, no cell may instantiate a cell which itself calls the cell whether directly or indirectly. There is a set of cells called by a given cell, either directly or indirectly through children of the cell. That set is the "called" cell set. That cell set can be obtained with the Cell#called_cells method in form of an array of cell indexes.

Similar, there is a set of cells calling a cell, either directly or indirectly. That set of cells can be obtained with the Cell#caller_cells method. For a top cell that set is empty.

The number of hierarchy levels can be obtained with Cell#hierarchy_levels. This method delivers the length of the longest path to a leaf cell. A leaf cell has a hierarchy level count of 0.

A cell can be flattened using Cell#flatten. Child cells can be removed using Cell#prune_subcells. The cell can be removed with Cell#delete or Cell#prune_cell. The latter will also remove any child cells which are not used otherwise.

Copying information between cells

Instances can be copied from one cell to another using Cell#copy_instances. Shapes can be copied using Cell#copy_shapes. The latter method supports layer conversions by employing a LayerMapping object to specify input and output layers. In addition, shapes can be copied to another layout which automatically performs database unit conversion if necessary.

A full cell tree can be copied using Cell#copy_tree. This method will create a new hierarchy below the target cell matching the source cell's hierarchy and copy all shapes from source to target using that new hierarchy. Source and target cell may reside in different layouts and database unit conversion is done automatically.

The content of a cell can be copied to another cell hierarchically using Cell#copy_tree_shapes, provided a cell mapping exists. A cell mapping specifies, how child cells of the source cell are identified in the target, which can be a different layout. For the cell mapping a CellMapping object is employed. In addition, a LayerMapping object can be used to specify layer mapping to the target. If no cell mapping is provided, shapes are flattened into the next possible parent, which provides a way to creating flat copies of cells. "copy_tree" is a convenience method and is a special case of "copy_tree_shapes".

For all methods, "move" flavors are available (Cell#move_instances, Cell#move_shapes, Cell#move_tree and Cell#move_tree_shapes), which not only copy the information but also remove the respective objects in the source cell. That somewhat reduces the memory required for such operations.

Cells and instances

A cell also plays a role as container for the instances. An instance describes a cell that is placed into another cell. Technically an instance is a combination of a cell reference and a transformation. Raw instances are represented by CellInstArray objects. Instances inside a cell are referred to by Instance objects. An Instance object is basically a pointer into a CellInstArray stored inside a cell and associates properties with raw instances for example.

Instances can be created by using the various Cell#insert methods of Cell. Instances can have properties, so a property ID can be provided (see Layout class for a discussion about property ID's). Instances can be deleted using the Cell#erase method. All instances of a cell can be deleted using the Cell#clear_insts method.

An instance can be replaced by another CellInstArray object using the Cell#replace method. The properties ID can be changed using the Cell#replace_prop_id method. It is easier however to use the Instance object's "cell_inst=" or "prop_id=" method.

Instances can be iterated with Cell#each_inst. Cell#each_overlapping_inst and Cell#each_touching_inst delivers all instances overlapping or touching a given rectangular region. That means, the instance's overall bounding box overlaps or touches the search rectangle.

Cell#each_parent_inst delivers all parent instances. Parent instances are basically reverse instances represented by the ParentInstArray object. A parent instance identifies are parent cell and the instance of the given cell in that parent cell. This iterator allows deriving all instances of the given cell in other cells.

Instances can be transformed with a given transformation (either a orthogonal or a general complex transformation) using the Cell#transform method. This method invalidates the Instance pointer given as the argument and returns a new Instance pointer to the new cell instance.

A floating-point integer class exists too (DCellInstArray). By convention this object represent an instance in micrometer units. If such an object is requested from the cell it is converted from an integer-type object in database units to a floating-point type object in micrometer units by multiplying with the database unit. When sending such an object to the cell the same happens in reverse. Internally, the integer type is used.

Cells, libraries and PCells

If a cell is a cell imported from a library, Cell#is_library_cell? will return true and it is possible to derive the Library object from which this cell is imported using the Cell#library method. Cell#library_cell_index will return the cell index of the cell in the library's local layout.

If a cell is a PCell variant, either directly from the layout or from a library, Cell#is_pcell_variant? returns true. This method can also be called on an Instance object in which case it delivers true if the instance is an instance of a PCell. Cell#pcell_id returns the PCell declaration ID if the cell is a PCell variant. Cell#pcell_declaration will return the PCell declaration object. There is also a overload of "pcell_declaration" that determines the PCell declaration object for an Instance if it is a PCell instance. Cell#pcell_parameters delivers the PCell parameters for a cell (if it is a PCell variant) or an instance (if it is a PCell instance). The PCell parameters are an array of variable-type values and the interpretation is dependent on the PCell implementation. The PCellDeclaration object which can be obtained through "pcell_declaration" gives the necessary information about the interpretation of the parameters.

Finally, Cell#refresh allows refreshing the layout of a proxy cell, i.e. transfer the current state of a library cell into this cell or recompute the PCell layout. Usually this method needs not to be called. When PCell parameters change for example, the layout is automatically recomputed.

Cells and PCell instances

A cell can be a PCell variant as we've seen above. In addition, a cell can hold PCell instances. The parameters of PCell instances can be modified from the cell using Cell#change_pcell_parameter for individual parameters given by name or Cell#change_pcell_parameters for all parameters. For changing all parameters it is required to know the parameter's order and meaning. The order can be obtained from the PCell declaration class which itself can be retrieved from a PCell instance with Cell#pcell_declaration (with the instance as the first argument).

The PCell parameters of a PCell instance can be obtained with Cell#pcell_parameters (with the instance as the first argument). To get a specific parameter, use the PCell declaration object which lists the parameters on the order they are delivered by the "pcell_parameters" method.

The CellInstArray class

Despite its name, a CellInstArray object holds a cell reference which is not only an array, but also a single instances. The object represents a raw instance, in contrast to the Instance object which is basically a pointer to an instance inside the database. CellInstArray objects as raw instances can be created, copied, modified and stored in the usual containers, but once they are stored inside the Cell object, they can be addressed by the Instance object.

The CellInstArray object represents either single instances or array instances. Array instances correspond to GDS AREF records and are regular, two-dimensional (not necessarily orthogonal) arrays of instances. A single instance consist of a cell index, denoting the cell that is instantiated and a single transformation, which can be either a simple, orthogonal affine transformation without a magnification (a Trans object, see Trans) or a general affine transformation (a CplxTrans object, see CplxTrans). A cell instance array in addition specifies two dimensions (na, nb) and shift vectors (a, b). For each individual instance of the array, an additional displacement is added to the transformation which is computed by the following formula:

```
d=i*a+j*b   (i=0..na-1, j=0..nb-1)
```

A CellInstArray object that represents an array will return true on CellInstArray#is_regular_array?. In that case, the CellInstArray#a and CellInstArray#b attributes are the basic vectors of the array and CellInstArray#na and CellInstArray#nb are the dimensions of the array. CellInstArray#size is the number of instances in the array.

A CellInstArray with a simple transformation will return false on CellInstArray#is_complex? and the CellInstArray#trans attributes gives the basic transformation of the instance. If the transformation is complex, i.e. has a rotation angle which is not a multiple of 90 degree or a magnification, CellInstArray#is_complex? will return true and CellInstArray#cplx_trans should be used instead of CellInstArray#trans. In any case, CellInstArray#cplx_trans gives the correct transformation.

The CellInstArray#cell_index attribute gets or sets the cell index. The CellInstArray#bbox and CellInstArray#bbox_per_layer methods deliver the total bounding box of the instance including all instances for an array. CellInstArray#bbox_per_layer gives the bounding box for a single layer. Since the instance only knows the cell index, these methods require a Layout object in order to derive the actual cell's bounding box.

A CellInstArray object can be inverted using the CellInstArray#invert method. This method returns an array which represents the ways the parent cell is seen from the child cell. A CellInstArray object can also be transformed by a given transformation. The CellInstArray#transform method will (like CellInstArray#invert) transform the object in-place, i.e. modify the object. CellInstArray#transformed will do the same, but leave the object it is called on and return a modified copy (out-of-place). Various variants of the CellInstArray#transform and CellInstArray#transformed methods exist taking different forms of transformations (simple, complex).

The floating-point variant (DCellInstArray) behaves the same way, except that by convention the unit of coordinates is micrometers.

The Instance class

As stated earlier, the Instance object represents a cell instance in the database. Technically it acts as a proxy to some CellInstArray inside the database. In addition, it provides access to properties attached to the instance. Instance objects play an important role in the Cell class to identify a certain instance, for example to delete it.

The Instance class provides a couple of methods that give read access to the underlying CellInstArray object (Instance#a, Instance#b, Instance#na, Instance#nb, Instance#size, Instance#trans, Instance#cplx_trans, Instance#cell_index, Instance#cell, Instance#is_complex? or Instance#is_regular_array?). The whole CellInstArray object can be read with the Instance#cell_inst method. It is possible to copy (dup) and modify that object and replace the current CellInstArray with the new one using Instance#cell_inst=. Please note, that this operation may invalidate iterators and should not be done inside a loop using "Cell::each_inst" for example.

The cell the Instance object lives in can be obtained with Instance#cell. Instance#cell_index basically renders the same information, but in form of a cell index. The cell can be assigned (Instance#cell=) which changes is to refer to a different cell.

The layout the instance lives in can be obtained with Instance#layout. The cell the instance lives in is returned by Instance#parent_cell. The parent cell can be assigned (Instance#parent_cell=), which effectively moves the instance to a different cell.

User properties can be accessed through the Instance#prop_id attribute or, more convenient, through the Instance#property, Instance#delete_property or Instance#set_property methods. Please note that changing the property ID or the property values may invalidate iterators as well.

An instance has an equality operator. That operator returns true, if the Instances indentify the same object.

The Shapes class

The Shapes object is the basic container for geometrical shapes. It stores geometrical primitives (Boxes, Polygons, Paths, Texts and Edges) either directly or in compressed form to achieve a low memory usage. For example, OASIS shape arrays are stored as compact arrays when KLayout is used in viewer mode. The Shapes container provides a simplified view through the Shape object which is basically a pointer to an individual instance of a geometrical primitive. The Shapes container provides access to the primitives through Shape objects.

In editable mode (i.e. if a Shapes container lives in an editable Layout object), the shapes can be modified or deleted after they have been inserted. In the opposite mode (viewer mode), shapes can be added, but not modified nor deleted.

A Shapes container is usually obtained from a cell with a given layer index and is filled with geometrical primitives using one of the Shapes#insert methods. Please note that the shapes are specified in integer coordinates when you use the integer type objects and micrometer units when using the floating-point type objects (whose classes start with "D"):

```
# cell = a Cell object
# layer_index = the index of a the layer
shapes = cell.shapes(layer_index)
shapes.insert(RBA::Box::new(0, 0, 1000, 2000))
```

With floating-point objects:

```
# cell = a Cell object
# layer_index = the index of a the layer
shapes = cell.shapes(layer_index)
```

```
shapes.insert(RBA::DBox::new(0.0, 0.0, 1.0, 2.0))
```

A Shapes object can also be created without a cell:

```
shapes = RBA::Shapes::new
shapes.insert(RBA::Box::new(0, 0, 1000, 2000))
```

Standalone Shapes objects can be useful when the methods of the Shapes object are required (for example, region queries through "each_overlapping"). There are are variety of "insert" methods available, some of which copy shapes from other Shapes containers using a Shape object as the reference for the source object. Some of these variants allow one to specify a transformation which is applied before the shape is inserted. There are also variants for all geometrical primitives with or without a properties ID.

If a Shapes container is empty, Shapes#is_empty? will return true. The content of another Shapes container can be assigned to a Shapes object with the Shapes#assign method. The number of geometrical primitives inside the Shapes container can be obtained with the Shapes#size method. All shapes in the Shapes container can be deleted with the Shapes#clear method.

The content of the Shapes container can be iterated with the Shapes#each iterator. If will deliver Shape objects pointing to the current geometrical primitive. The Shapes#each_overlapping and Shapes#each_touching methods deliver only those primitives whose bounding box overlaps or touches the given rectangle. All iterators allow one to specify flags which confine the kind of shape delivered. The flags are a combination of the "S..." constants. For example:

```
# delivers all primitives:
shapes.each(RBA::Shapes::SAll) { |s| ... }
# delivers all primitives which have user properties attached:
shapes.each(RBA::Shapes::SAllWithProperties) { |s| ... }
# delivers only texts:
shapes.each(RBA::Shapes::STexts) { |s| ... }
# delivers only polygons and boxes:
shapes.each(RBA::Shapes::SBoxes | RBA::Shapes::SPolygons) { |s| ... }
```

A geometrical primitive inside the container can be erased using the Shapes#erase method. It is safe to erase shapes inside an iterator loop for editable containers.

Shapes can be replaced by other primitives using one of the methods. Please note that using "replace" inside an iterator loop may lead to unexpected behavior of the iterator, so modifying a shape inside an iterator loop should be avoided. Here is an example:

```
# DON'T:
# (replace polygons by their bounding boxes)
shapes.each do |shape|
  if shape.is_polygon?
    shapes.replace(shape, shape.bbox)
  end
end

# DO
# (replace polygons by their bounding boxes)
shapes_to_modify = []
shapes.each do |shape|
  if shape.is_polygon?
    shapes_to_modify.push(shape)
  end
end
shapes_to_modify.each do |shape|
  shapes.replace(shape, shape.bbox)
end
```

The latter solution requires some more memory but is in general safer. It is safe however to replace an object by the same kind of object inside a loop.

Shapes can be transformed by using one of the Shapes#transform methods provided by the Shapes object. Variants for simple and complex transformations exist. Please note that using a arbitrary-angle transformation on a box (i.e. a CplxTrans object with a rotation angle of 45 degree) will not render a rotated box since a box is by definition parallel to the axes. Instead this operation will render the bounding box of the rotated box. Transforming shapes is safe inside an iterator loop.

The Shapes container also manages user properties by employing properties ID's. Properties can be modified by obtaining a new ID from the layout object and replacing the property ID using the Shapes#replace_prop_id method. However it's much more convenient to use the Shape#property, Shape#set_property or Shape#delete_property methods of the Shape object. In both cases however, modifying the properties should be avoided inside an iterator loop.

All shapes inside a shape container can be transformed using Shapes#transform.

With version 0.23, new collection objects entered the stage: Region, Edges and EdgePairs which basically provide a way to store polygons, edges or edge pair objects independently from the shapes container. They are mainly used to implement bulk operations, specifically for the DRC functionality. The cooperate with the shapes container in the sense that they can be inserted into a shapes container which will produce polygons or edges in the layout database (edge pairs are converted to single edges or polygons. These classes are discussed in The Geometry API.

The Shape class

The Shape object provides a unified view to a geometrical primitive inside a Shapes container. It also plays an important role for addressing geometrical primitives inside a Shapes container. A Shape object has general methods and specific methods that apply depending on its identity.

General methods

The Shape#bbox method delivers the bounding box of the geometrical primitive addressed by the Shape object. Please note that the bounding box of a text only contains the single point of the text's origin, not the text drawing itself.

Shape#cell delivers the Cell object that shape lives in. The same way, Shape#layout delivers the Layout object and Shape#shapes the Shapes object.

Shape#property, Shape#set_property and Shape#delete_property allow modification of the user properties of the geometrical primitive. The same can be achieved somewhat less conveniently using a properties ID with the Shape#prop_id attributes' write accessor (Shape#prop_id=). Please note the comments in the description of the Shapes object regarding the interaction of these modifying operations with iterators. Shape#has_prop_id? returns true, if the shape has user properties attached.

Shape#type returns the type code of the shape addressed by the Shape object. This is a detailed code which distinguishes between different internal representations. It's more convenient to use one of the **is_...?** methods. For example Shape#is_box? returns true, if the geometrical primitive is a box. A note about Shape#is_polygon? and Shape#is_simple_polygon?: usually it is not required to distinguish between both. "is_polygon?" will also return true for simple polygons, so it is likely to be sufficient to just ask for "is_polygon?". Shape#is_user_object? returns true, if the primitive is a custom object. Such objects are rarely used and not supported by the Ruby API currently.

Shape#area delivers the area of the shape. The area is zero for a text object. Shape#perimeter delivers the perimeter of the shape. The perimeter is zero for a text object. The Shape object provides an equality operator which delivers true if two Shape objects point to the same primitive.

It is possible to replace a primitive by another one by using the shape assignment methods, i.e. Shape#box=, Shape#path=, Shape#polygon=, Shape#simple_polygon=, Shape#text= and Shape#edge=. Using these methods is equivalent to the using "replace" on the containing Shapes objects. Please see the notes on using "replace" inside iterators there.

Floating-point objects are supported too. For example, Shape#dbox is equivalent to Shape#box, but delivers the object in micrometer units. Shape#dbox= receives a micrometer-unit object. Shape#box_dp1 is equivalent to Shape#box_p1, but gets the first point of the box in micrometer units.

The layer index a shape is on can be obtained with Shape#layer. A shape can be moved to a different layer by assigning a different layer index with Shape#layer=. In that context, layers can also be addressed by layer/datatype or name using a LayerInfo object. The respective methods to address a shape's layer then are Shape#layer_info and Shape#layer_info=.

A shape can be transformed using one of the Shape#transform flavors.

Methods applying for box shapes

A Shape object represents a box if it returns true on Shape#is_box?. The only specific methods that are provided for box type shapes are the Shape#box getter and Shape#box= setter. Shape#box_center, Shape#box_center=, Shape#box_p1, Shape#box_p1=, Shape#box_p2 and Shape#box_p2= get or modify individual aspects of the box.

For the floating-point equivalents in micrometer units see the Shape.

Methods applying for polygon and simple polygon shapes

A Shape object represents a polygon or simple polygon if it returns true on Shape#is_polygon?. If the object is a simple polygon, it will also return true on Shape#is_simple_polygon?. A simple polygon is just a polygon that cannot have holes.

In every case, the Shape#each_edge iterator will deliver all edges (connections between points of the polygon). Shape#each_point_hull will deliver the points of the outer (hull) contour and Shape#each_point_hole will deliver the points of a specific hole contour. Shape#holes will deliver the number of holes. A simple polygon does not have holes and Shape#holes always gives zero.

The Shape#polygon getter delivers a Polygon object. The same way Shape#simple_polygon delivers a SimplePolygon object. A polygon with holes is converted in that case to a simple polygon by introducing cut lines to connect the holes with the outer contour.

The Shape#polygon= and Shape#simple_polygon= setters will replace the current object by the given new one.

For the floating-point equivalents in micrometer units see the Shape.

Methods applying for path shapes

A Shape object represents a path if it returns true on Shape#is_path?. The path's width can be obtained through the Shape#path_width method. The extensions of the path ends can be obtained with Shape#path_bgnext and Shape#path_endext for the start and end extensions. The Path object can be obtained with the Shape#path getter. For the path width and extensions setters are also provided (Shape#path_width=, Shape#path_bgnext= and Shape#path_endext=).

The path length can be obtained with Shape#path_length and includes the begin and end extensions. The round-ended path flag can be obtained with Shape#round_path? flag and set with Shape#round_path=.

The points of the path's spine can be iterated with Shape#each_point. Shape#polygon can be used to obtain the path's contour.

For the floating-point equivalents in micrometer units see the Shape.

Methods applying for text shapes

A Shape object represents a text object if it returns true on Shape#is_text?. The text's text string can be obtained with Shape#text_string. The text's origin and orientation is encoded in a transformation (a Trans object, see Trans) which can be obtained with the Shape#text_trans method. The font code, text size and alignment flags can be obtained with the Shape#text_font, Shape#text_size, Shape#text_halign and Shape#text_valign methods. See the description of the Text object for details about these attributes.

The text representation attributes can be set with Shape#text_font=, Shape#text_size=, Shape#text_halign= and Shape#text_valign=. Shape#text_trans= will modify the text's transformation.

Shape#text will deliver the Text geometrical primitive and Shape#text= allows replacing the shape with the given Text object.

For the floating-point equivalents in micrometer units see the Shape.

Methods applying for edge shapes

A Shape object represents an edge if it returns true on Shape#is_edge?. Edge objects in general are not well supported in KLayout currently. They can be created and manipulated by scripts, but cannot be drawn or modified on the user interface. In GDS files, edges are represented by zero-width paths which is sometimes breaking the conventions of other tools.

The only specific methods that are provided for edge type shapes are the Shape#edge getter and Shape#edge= setter.

For the floating-point equivalents in micrometer units see the Shape.

3.5. The Geometry API

The Geometry API

The central class of the layout database is the Layout class, which provides a concept for layers, shape containers, cells and hierarchy. Separate from that, a set of classes exist, which represent basic shapes and geometrical objects. While shapes embedded in a Layout object are not independent and care has to be taken when manipulating them inside the database API, the free objects are easy to manage, manipulate and in general to work with as they are normal objects in the script interpreter's context.

In addition, the gometry API provides basic objects such as points, edges and transformations for general use throughout the API. Higher objects such as regions and edge collections provide implementations for geometrical algorithms like boolean operations and DRC checks.

Most classes of the geometry API provide a hash value so they can be used as keys in Ruby hashes.

The Point class

The Point object represents an integer coordinate in the 2-dimensional layout space, expressed in database units. That object provides the x and y coordinates through the Point#x and Point#y attributes. Points can be added, subtracted, the euclidian distance and its square can be computed using the Point#distance and Point#sq_distance methods. The ***** operator used with a factor as the second operand will scale both the x and y coordinates.

Points and vectors

Next to points there is a corresponding vector class (Vector). A vector is basically the difference between two points. It is meant to describe the distance and direction between two points. The following rules therefore apply:

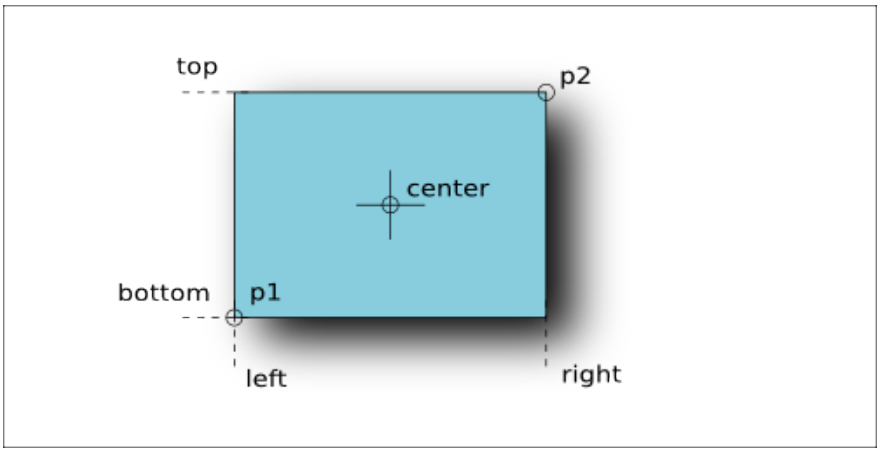
- Subtracting a point from a point renders a vector
- Adding a vector to a point renders a point

As points, vectors have an x and a y component which can be accessed with Vector#x and Vector#y. Vectors offer two functions to compute the vector product (Vector#vprod) and the scalar product (Vector#sprod). For some applications it's sufficient to know the sign of the product. You can get that with Vector#vprod_sign and Vector#sprod_sign respectively.

Vectors don't transform the same way than points. On transformation, only rotation, mirror and scaling (if applicable) is applied. Displacement is not applied. This way, the following two forms are equivalent:

```
(p1 - p2).transformed(t) == p1.transformed(t) - p2.transformed(t)
```

The Box class



The Box object represents a rectangle whose sides are parallel to the axes. The coordinates are integer values and express the rectangle's dimensions in database units. The basic specification consists of two points, giving the lower left and upper right corner. The constructor takes either two points (which are ordered internally) or four coordinates representing the left, bottom, right and top coordinates.

A box has a couple of attributes which are shown in the figure above. The Box#area method delivers the area of the rectangle. A box can be "empty" (non-existing). Such a rectangle can be created by the default constructor without parameters. An empty box basically behaves as a region without a point, i.e. testing the intersection with an empty box always returns false. An empty box returns true on Box#empty?. A box whose lower left point is identical to the upper right one contains just a single point. Such a box returns true on Box#is_point?.

A box supports a couple of operations:

- **Box & Box**: this operator computes the intersection of two boxes. If the boxes do not intersect, an empty box is returned.
- **Box * Box**: computes the "convolution" of two boxes. This operation can basically be viewed as the box which results when the first box is painted with a pen that has the size and displacement of the second box.
- **Box * factor**: scales the box, i.e. multiplies all coordinates with the given factor.
- **Box + Box**: computes the box that encloses both boxes given in the operation.
- **Box + Point**: computes the box that encloses the box and the point given as the second operand. It basically enlarges the first box so it includes the second point as well.
- **contains?(Point)**: returns true, if the point is inside the box or on its edges.
- **enlarge(Point)**: will enlarge the box by the x and y coordinates of the Point. Basically the x value of the point is subtracted from the left side and added to the right. The same way, the y coordinate is added to the top and subtracted from the bottom coordinate.
- **enlarged(Point)**: returns the enlarged box without modifying the box this method is called on (out-of-place operation).
- **move(Point)**: moves the box by the displacement given by the point. Basically the x value of the point is added to the left and right coordinate while the y coordinate is added to the top and bottom coordinates.
- **moved(Point)**: returns the moved box without modifying the box this method is called on (out-of-place operation).
- **inside?(Box)**: returns true, if the box the method is called on is inside the box given by the method's argument.
- **overlaps?(Box)**: returns true, if the given box overlaps with the box the method is called on.
- **touches?(Box)**: returns true, if the given box touches the box the method is called on.
- **transformed(Trans)**: returns the box transformed with the given transformation.
- **transformed(ICplxTrans)**: returns the box transformed with the given complex, integer-based transformation (see ICplxTrans). Note, that if the complex transformation includes a rotation by a non-90-degree angle (for example 45 degree), this operation does not return a rotated box, because by definition a box has edges which are parallel to the axes. Hence the general solution is to convert the box to a polygon:

```
# Wrong result
box = RBA::Box::new(0, 0, 100, 200)
transformed_box = box.transformed(RBA::ICplxTrans::new(1, 45, false, RBA::Vector::new))
# -> (-141,0;71,212)

# Correct result
transformed_box_as_polygon = RBA::Polygon::new(box).transformed(RBA::ICplxTrans::new(1, 45, false,
 RBA::Vector::new))
# -> (0,0;-141,141;-71,212;71,71)
```

- **transformed(CplxTrans)**: behaves like the previous "transformed" method but returns a floating-point coordinate object which is the target coordinate type of the CplxTrans object (see CplxTrans).

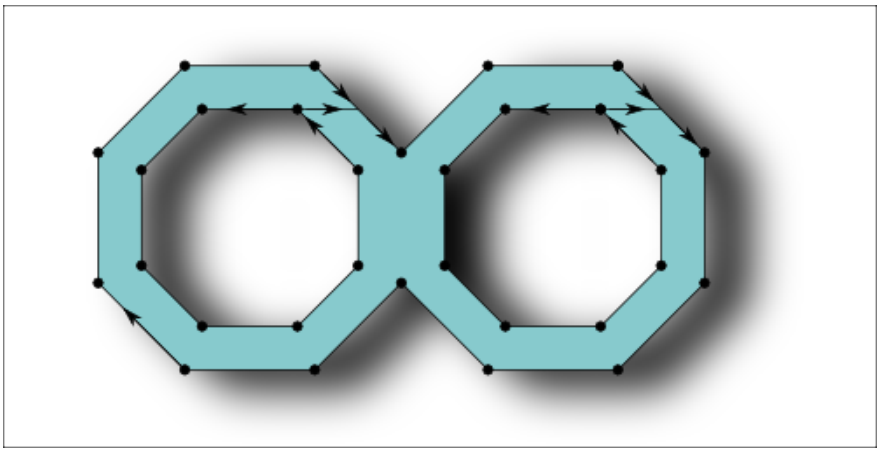
A box object can be constructed from a floating-point object (for floating-point objects see below). Lacking a database unit, no conversion from micrometer units to database units is performed. Instead, the floating-point coordinates are rounded to the nearest integer coordinates:

```
dbox = RBA::DBox::new(2.1, 3.1, 10.7, 11.8)
box = RBA::Box::new(dbox)
# -> (2,3;11,12)
```

An integer box can be turned into a floating-point unit box using Box#to_dtype

Floating-point boxes can be transformed using the DTrans, the DCplxTrans or the VCplxTrans transformations. The latter delivers an integer-type box and provides the reverse flavour transformation to "CplxTrans".

The SimplePolygon class



A SimplePolygon object is a polygon that does not have holes. It consists of a single, closed contour. Such polygons are compatible with the GDS2 format for example. A SimplePolygon object can be created from a Box object or from an array of Point objects. Internally, the points will be ordered into a clockwise orientation.

The class method SimplePolygon#from_dpoly creates a integer-coordinate type SimplePolygon object from a floating-point coordinate type DSimplePolygon object (see below). The floating-point coordinates are rounded to the nearest integer coordinates.

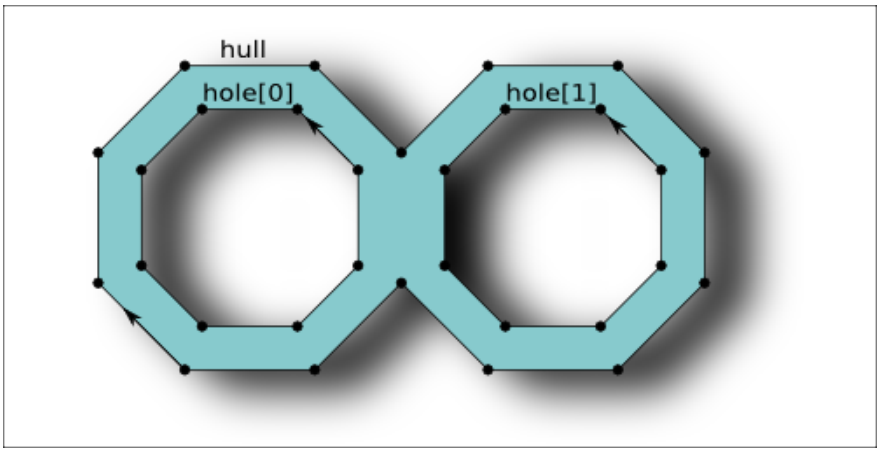
The SimplePolygon#bbox method returns the bounding box of the polyon. SimplePolygon#area will return the area of the polygon. SimplePolygon#num_points returns the number of points, while SimplePolygon#point returns the point for a given index. SimplePolygon#points= replaces the polygon by a new polygon with the given array of points.

The SimplePolygon#each_point iterator will deliver each point in clockwise orienation, starting form the bottom/leftmost one. SimplePolygon#each_edge will deliver all edges of the polygon (connecting every point with the next one).

SimplePolygon#compress will remove points that connect two collinear edges. It has a parameter that controls whether to remove reflecting edges (spikes) as well. SimplePolygon#inside? returns true, if a given point is inside the polygon. SimplePolygon#minkowski_sum computes the Minkowski sum between a polygon and another object in various flavors. SimplePolygon#move will displace the polygon by the distance given by the Point argument. SimplePolygon#moved will return the moved polygon without modifying the polygon it is called on (out-of-place operation). SimplePolygon#transformed will return the transformed polygon, either with a simple or a complex transformation (see the description of the Box object and the section about transformations below for a discussion of transformations). Finally, SimplePolygon#round_corners will apply a corner rounding to a copy of the polygon and return that copy without modifying the polygon.

Please note that using the Point-array constructors it is possible to create polygons with self-intersecting or twisted contours. Such polygons may not behave as expected.

The Polygon class



The Polygon object is basically an extension of the SimplePolygon object and in contrast to that object, supports holes. Polygon objects are not compatible with the GDS2 or OASIS format and will be converted to SimplePolygon objects by introducing cutlines when writing them.

A polygon consists of an outer contour (the hull) and zero to many hole contours. The outer contour like for the SimplePolygon is oriented clockwise while the hole contours are oriented counterclockwise. This orientation is established internally. For the API, contours are represented by arrays of Point objects.

A Polygon differs from a SimplyPolygon by providing methods to modify holes and the hull. Holes can be inserted by using the Polygon#insert_hole method. A hole is identified by an index. The Polygon#holes method returns the number of holes. The hole index runs from 0 to the number of holes minus one.

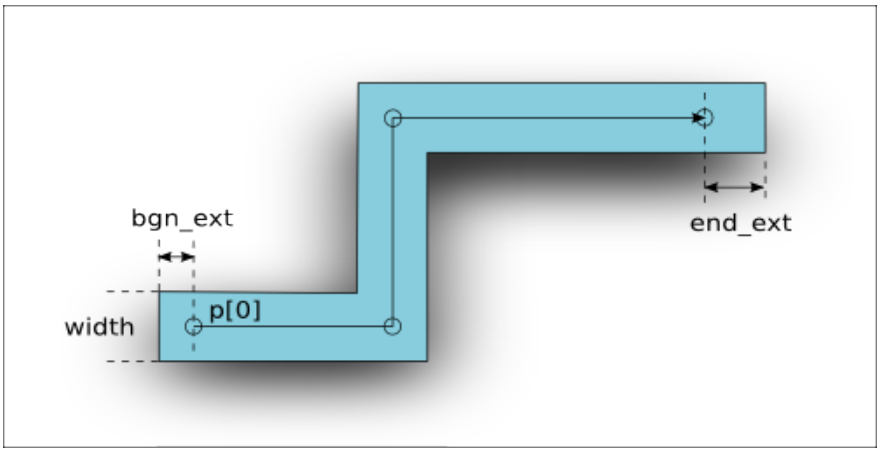
The class method Polygon#from_dpoly creates a integer-coordinate type Polygon object from a floating-point coordinate type DPolygon object (see below). The floating-point coordinates are rounded to the nearest integer coordinates. A constructor is provided that creates a Polygon object from a SimplePolygon object.

Polygon#each_edge will deliver all edges. The orientation of the edges determines whether they belong to a hole or the hull contour. Polygon#each_point_hull will iterated over all points of the hull and Polygon#each_point_hole over the points of the hole with the given index. Polygon#num_points_hull will return the number of points for the hull and Polygon#num_points_hole the number of points for the given hole. Polygon#point_hull will return a specific point from the hull and Polygon#point_hole a specific point for the given hole. Polygon#num_points returns the total number of points.

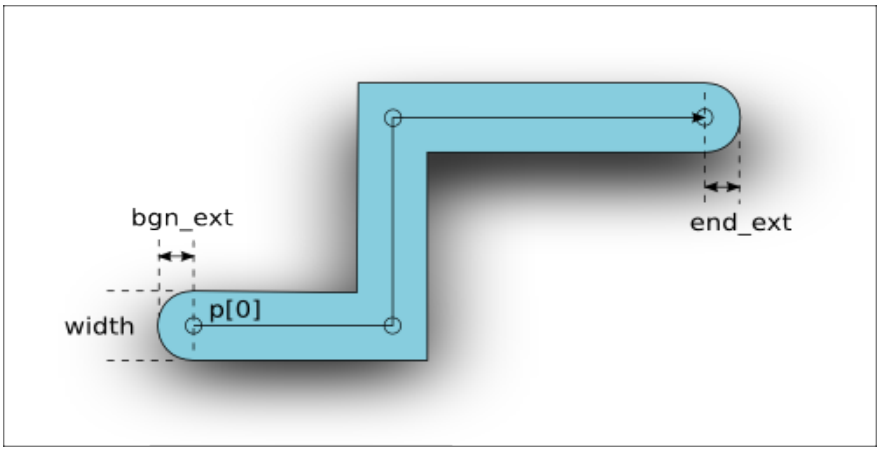
Polygon#resolve_holes will remove all holes and connect them with the hull by introducing cutlines that connect the hole with the hull. This operation introduces new vertexes and hence may apply some distortion due to grid snapping. Polygon#resolved_holes returns the polygon with the holes removed without modifying the object it is called on (out-of-place operation). Polygon#to_simple_polygon basically does the same but returns a SimplePolygon object.

Using Polygon#assign_hull (or Polygon#hull=) and Polygon#assign_hole the hull contour or a hole contour can be replaced with the given array of Point objects. Please note that it is possible to create invalid polygons where the holes are not completely contained in the hull. Such polygons may not behave as expected. The same is true for polygons with self-intersecting or twisted contours.

The Path class



A Path object represents a line with a certain width. The figure above depicts the basic properties of a path. The basic geometry of a path is defined by its spine - a sequence of points that the path follows. By default, a path has rectangular end caps with variable length. The end caps can be round, in which case the extension should be half the path width to avoid paths which are not compatible with the GDS2 format. Round-ended paths return true on Path#is_round?. An example for such a path is depicted in the following figure:



A path with is given in database units. The hull contour of paths with an odd width cannot be represented on-grid and should be avoided. Such path objects are allowed in the GDS2 format, but not in OASIS.

The spine points of a path can be iterated with Path#each_point. Path#num_points returns the number of points. Path#points= allows replacing of the spine with the given array of Point objects. Path#round= sets the "round ended" flag. Path#bbox and Path#area deliver the bounding box and the area, where the area is only approximate and is computed from the spine's length including the extensions times the width for efficiency. For certain acute-angle configurations that value may not be the exact area.

Path#polygon returns the polygon representing the path's hull. Path#simple_polygon returns a SimplePolygon object that represents the hull. Path#move, Path#moved and Path#transformed basically work like for the other objects.

The class method Path#from_dpath creates a integer-coordinate type Path object from a floating-point coordinate type DPath object (see below). The floating-point coordinates are rounded to the nearest integer coordinates.

The Text class

A Text object is basically a point with a label attached. The extension of a text object only includes the point, not the text itself. For display purposes, a text orientation, font and alignment options can be specified.

The location and the orientation of the text are combined in a Trans object. That transformation can be read and written with the Text#trans attribute. The text orientation is not always shown in the drawing. Whether the text is shown in the orientation specified depends on the application settings.

Font number and alignment flags can be read and written using the Text#font, Text#halign and Text#valign attributes. If one of these attributes is not set, the application-provided default is used. The font is currently just a number and is provided to support the respective property of the GDS2 format. For the documentation of the alignment flags see the class documentation for the Text class.

The text string is accessible with the Text#string attribute. Not all characters are supported. Depending on the format, only a subset of the ASCII character set are supported. Sometimes, line-feed control characters are found in text strings. Following the strict OASIS specification for example, such characters are not allowed. The lower and upper case letters and most of the special printing characters of the ASCII character set are usually safe for use in text strings.

Text#move, Text#moved and Text#transformed basically work like for the other objects.

Passing a DText object to the Text constructor creates an integer-coordinate type Text object from a floating-point coordinate type DText object (see below). The floating-point coordinates are rounded to the nearest integer coordinates.

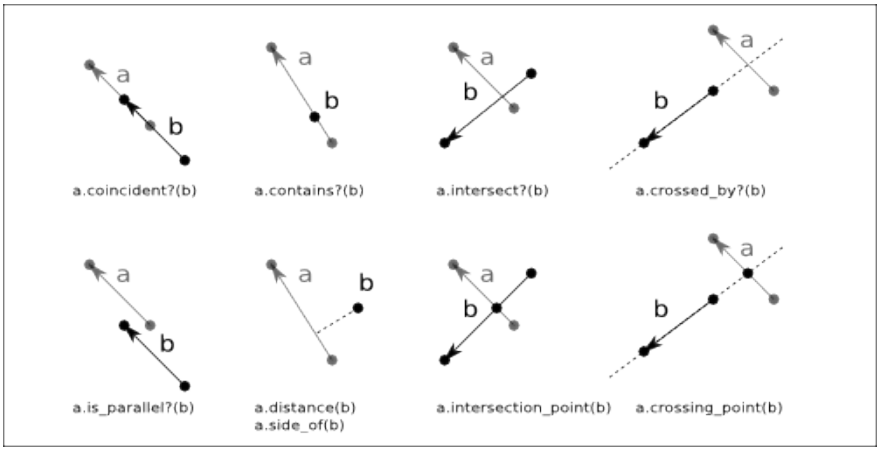
The Edge class

Edge objects are basically connections between two points. Edge objects are provided to support special applications and are mapped to zero-width, two-point paths in the GDS2 format. Edge objects are not supported as editable objects in KLayout currently. Edge objects may be created by script and are useful sometimes to represent the output of a design rule check tool for example.

Edge objects however a frequently used as raw objects in various applications, i.e. as one output option of a boolean operation. Therefore, the Edge class provides a couple of operations on edges, mainly tests for the geometrical relationship of two edges and points in relation to edges. An edge also may represent a straight line through the two endpoints of the edge, i.e. for the Edge#crossed_by? check.

An edge is defined by two points: the start and end point. Edge#p1 is the attribute for the start point, Edge#p2 the attribute for the end point. Various properties deliver extensions of the edge (Edge#dx and Edge#dy for the horizontal and vertical extension, Edge#length and Edge#sq_length for the length and the square of the length, Edge#ortho_length for the Manhattan distance between the points). Edge#swap_points swaps p1 and p2 and effectively inverts the orientation of the edge. Edge#bbox is the bounding box of the edge.

Various methods test the relationship between two edges or an edge and a point. See the following figure for a summary of these methods:



Edge#move, Edge#moved and Edge#transformed basically work like for the other objects. The class method Edge#from_dedge creates a integer-coordinate type Edge object from a floating-point coordinate type DEdge object (see below). The floating-point coordinates are rounded to the nearest integer coordinates.

The floating-point geometrical primitives

Beside the integer-coordinate primitives like Box, Edge, Polygon etc., KLayout provides floating-point coordinate variants as well. These objects require more memory and are subject to floating-point rounding issues and are therefore not employed inside the database. They are provided however, to allow a temporary representation of micron-unit objects or for use int the Marker class for example.

The class names for the floating-point variants is the same the integer-coordinate type prefixed with a "D" (for example, DBox is the floating-point variant of Box). Since floating-point variants support fractional coordinates, scaling with an arbitrary value is not connected

with a loss of accuracy due to rounding. That is why floating-point coordinates are the target type of general transformations including an arbitrary scaling. For example:

```
RBA::Box.new(1,1,2,2)*2.5
# -> (3,3;5,5)
# but:
RBA::DBox.new(1,1,2,2)*2.5
# -> (2.5,2.5;5,5)
```

However, the higher precision of floating-point coordinates comes with subtle issues originating from the finite-precision representation. For example, the value of 0.1 cannot be precisely represented by a floating-point value. The value of 0.1 is approximated and therefore depending on the way it is approximated, 0.1 is not necessarily equal to 0.1. For example (try this in the Ruby console):

```
a = 0.1
b = 1e-6*1e5
a
# -> 0.1
b
# -> 0.1
# but:
a == b
# -> false!
# the reason is:
"%.21g"%a
# -> 0.100000000000000005551
"%.21g"%b
# -> 0.099999999999999916733
```

Because of that, direct comparison of coordinate values should be avoided. The internal precision used is 0.00001. By convention, floating-point type objects are supposed to be used for micrometer-unit objects, hence this precision corresponds to 0.01 nm which corresponds to the tenth of an atom and should be well below physical tolerances.

Some operations which are implemented on integer coordinates (like the removal of holes in polygons) are not available for the floating-point type objects.

All floating-point type objects have a "to_itype" method (i.e. DBox#to_itype) which convert the floating-point type object to the integer-coordinate type object. This method can be given a database unit for scaling from micrometer units. Integer-coordinate type objects can be converted to floating-point type objects the same way through the "to_dtype" method (i.e. Box#to_dtype. A database unit can be passed to this method too for conversion to micrometer units. These methods however require some rounding and are therefore responsible for a potential distortion of the geometry of the object.

For the point and vector object there is also a floating-point equivalent (DPoint and DVector). Both behaves like their integer-coordinate equivalent.

Transformations

Transformations in KLayout are restricted affine transformations. Shear transformations and anisotropic scaling is not supported. All transformation in KLayout follows the conventions implied by the GDS2 and OASIS formats and include in that order:

- Mirroring around the x axis (optional)
- Rotation
- Scaling
- Displacement

For memory performance, a restricted version of that transformation is used if possible. In that restricted version, the rotation angles are confined to a multiple of 90 degree and scaling is not supported. This restricted affine transformation is provided through the Trans class. The 8 possible rotation/mirror variants can be coded in a single rotation/mirror code which is used frequently throughout KLayout (see Transformations in KLayout).

For transforming floating-point coordinates, the DTrans object is provided. The basic difference is that the displacement uses floating-point coordinates (by employing a DVector object).

To support more complex affine transformations include arbitrary-angle rotations and scaling, the complex transformation objects are provided. In addition, the complex transformation object can translate between integer and floating-point coordinate types.

- CplxTrans: takes integer coordinates and delivers floating-point coordinates. Therefore it uses a DVector for the displacement. The inverse of this transformation is a VCplxTrans class (see below).
- DCplxTrans: takes floating-point coordinates and delivers floating-point coordinates. Therefore it also uses a DVector for the displacement.
- ICplxTrans: takes integer coordinates and delivers integer coordinates. Therefore it uses a Vector for the displacement. This transformation is convenient to provide complex transformations for database operations but implies rounding errors due to rounding to integer coordinates on output. It is safe to use however for integer-factor scaling operations for example.
- VCplxTrans: takes floating-point coordinates and integer coordinates. Therefore it also uses a Vector for the displacement. The inverse of this transformation is a CplxTrans object.

Multiplication of a transformation with an object renders the transformed object:

```
t = ... # a transformation
p = ... # some point

# compute the transformed point:
q = t * p
```

Multiplication of two transformations corresponds to concatenation of two transformations:

```
t1 = ... # a transformation
t2 = ... # another transformation

# Multiplication of t2 and t1 renders an equivalent transformation
# that corresponds to "apply t1 first and then t2":
(t2 * t1) * p == t2 * (t1 * p)
```

When multiplying two complex transformations, the resulting transformation type will have the corresponding input and output types. For example when multiplying a VCplxTrans with a CplxTrans, a ICplxTrans object will be created. This is because the first transformation takes integers and the second one delivers integers. Hence the resulting transformation is ICplxTrans.

The Region class

Regions are basically collections of polygons. Regions provide higher functions such as boolean operations and sizing which cannot be implemented on pure polygons because their output may be a number of polygons. A Region is a general representation of a set of points in a two-dimensional area while a polygon is a coherence set of points.

Regions can be created by starting with an empty region and filling the latter with polygons. Regions can also be created from a RecursiveShapeIterator which allows feeding layout data into the region in a very flexible way. In the latter case, boxes and paths will be converted to polygons when feeding them into the region.

Regions feature some important concepts:

- **Merged semantics:** A region can be created from a series of polygons which potentially overlap or touch. In "merged semantics" the region will merge the polygons forming big polygons from touching ones and removing overlaps.
- **Minimum coherence:** In certain cases, the output of merging polygons is ambiguous. In the "kissing corner" case, the touching polygons may be either considered separate ("minimum coherence") or belonging together.
- **strict mode:** In strict mode, some operations are performed even if they are not necessary. For example, an XOR between a region and an empty region will render the first input. Hence the implementation can simply copy the first input in that case. With strict mode, the operation will be performed in every case which is less efficient but renders merged polygons.

The region object is very mighty and easy to use. Here is an example which computes the difference of two boxes (rendering a ring) and sizes the latter:

```
r1 = RBA::Region::new
r1.insert(RBA::Box::new(-2000, -3000, 2000, 3000))

r2 = RBA::Region::new
r2.insert(RBA::Box::new(-1500, -2000, 1500, 2000))

r = (r1 - r2).sized(100)

puts r
```

Using a Region object with input from a cell is almost as simple as this. The following example will take the input from layer 11 and 21 from the top cell and the hierarchy below (as is flat) and compute the intersection in layer 100:

```
ly = RBA::CellView::active.layout

l11 = ly.layer(11, 0)
l21 = ly.layer(21, 0)

r11 = RBA::Region::new(ly.top_cell.begin_shapes_rec(l11))
r21 = RBA::Region::new(ly.top_cell.begin_shapes_rec(l21))

ly.top_cell.shapes(ly.layer(100, 0)).insert(r11 & r21)
```

A variety of operations is implemented on regions:

Region#&, Region#|, Region#- and Region#^ implement boolean operations (AND, OR, NOT and XOR). The operations can be combined with assignment (in-place) using Region#&= etc. Region#+ adds the polygons from another region to self which is basically the same then a boolean OR.

Region#area and Region#bbox deliver the area and bounding box of the region.

Region#each will deliver all original polygons (unless the region was already merged).

Region#each_merged will deliver the merged polygons.

Region#edges will translate the polygons to edges covering their boundaries. If merged semantics is specified, the edges will only cover the outer edges, not inner ones.

Region#enclosing_check, Region#inside_check, Region#isolated_check, Region#notch_check, Region#separation_check, Region#space_check and Region#width_check implement DRC functions. DRC functions deliver EdgePairs edge pair collections, not regions. Each edge pair marks a violation of the given check.

Region#extents replaces each polygon with its bounding box.

Region#grid_check performs an on-grid check returning edge pairs for off-grid markers.

Region#holes identifies holes and delivers a new region with the holes as filled polygons.

Region#hulls identifies holes and delivers a new region without the holes.

Region#insert adds polygons in various flavors.

Region#interacting and Region#not_interacting select polygons interacting (overlapping or touching) or not interacting with polygons from another region.

Region#members_of selects polygons which are contained in the same way in another region.

Region#merge and Region#merged merge the polygons. This feature allows selecting overlapping polygons (minimum wrap count parameter).

Region#minkowski_sum computes the Minkowski sum of the region with other objects (edges, single polygons and other regions).

Region#move, Region#moved, Region#transform and Region#transformed apply geometrical transformations.

Region#rectangles, Region#rectilinear, Region#non_rectangles and Region#non_rectilinear filter out polygons by their appearance.

Region#inside, Region#outside, Region#not_inside and Region#not_outside filter out polygons by their relation to the polygons in the other region.

Region#round_corners and Region#rounded_corners apply corner rounding to polygons.

Region#size and Region#sized will size the polygons (shift edges).

Region#smooth smoothes out coarse steps of the polygons.

Region#snap and Region#snapped apply grid snapping.

Region#with_angle marks polygon vertices which satisfy a certain angle criterion.

Region#with_perimeter, Region#with_area and many more "with_..." methods select polygons based on their properties.

The Edges class

Edges represents a collection of edges which comprise either full polygons (forming closed contours) or parts of polygons. Edges can be derived from Region objects using the Region#edges

A variety of operations is implemented on regions:

Edges#&, Edges#|, Edges#- and Edges#^ implement boolean operations (AND, OR, NOT and XOR). The operations can be combined with assignment (in-place) using Region#&= etc. Edges#+ adds the polygons from another edge set to self which is basically the same then a boolean OR. Boolean AND and NOT are available between edges and regions as well and will deliver the edge parts inside the given region or not inside the given region.

Edges#length and Edges#bbox deliver the total length and bounding box of the edge set.

Edges#each will deliver the edges in the collection.

Edges#centers will deliver the center parts of the edges.

Edges#enclosing_check, Edges#inside_check, Edges#separation_check, Edges#space_check and Edges#width_check implement DRC functions. DRC functions deliver EdgePairs edge pair collections, not edge sets. Each edge pair marks a violation of the given check.

Edges#start_segments and Edges#end_segments replaces each edge with a part at the beginning or end.

Edges#extended, Edges#extended_in and Edges#extended_out create polygons on that represent the edge with a certain width.

Edges#extents returns a region with the bounding boxes of the edges.

Edges#inside_part and Edges#outside_part return the parts of the edge set which are inside or outside a given region. The effect is comparable to the boolean operations but differs at the exact boundary of the polygons of the region.

Edges#interacting and Edges#not_interacting select edges interacting (overlapping or touching) or not interacting with edges of another edge set or polygons from another region.

Edges#members_of selects edges which are contained in the same way in another edge set.

Edges#merge and Edges#merged merge (join) the edges.

Edges#move, Edges#moved, Region#transform and Edges#transformed apply geometrical transformations.

Edges#with_length, Region#with_angle and many more "with_..." methods select edges based on their properties.

The EdgePair class

Edge pairs are handy objects to describe the output of a DRC violation. A space violation marker for example will consist of two edges which mark the opposite parts of the space violation. Such markers are represented by objects of EdgePair.

Edge pairs are simple objects consisting of two edges ("first" and "second"). Polygons can generated from edge pairs covering the marked edges and their connecting files using EdgePair#polygon. Edge pairs can be transformed using EdgePair#transformed.

Edge pairs can be "normalized" using EdgePair#normalized. This method returns the normalized version of the edge pair. Normalization will bring the edge pairs in a form such that when connecting their start and end points a closed loop without intersections is formed. Normalized edge pairs will produce nicer polygons later on.

A floating-point version of the EdgePair class exists as well: DEdgePair.

The EdgePairs class

EdgePairs provides a collection of edge pairs and is the preferred output of DRC functions which deliver one DRC marker for each violation.

EdgePair collections can be conveniently split into individual edges using EdgePairs#edges or converted into polygons covering the markers with EdgePairs#polygons. The first and second edges can be extracted as a Edges edge collection with EdgePairs#first_edges and EdgePairs#second_edges. EdgePairs#extents will deliver a region containing the bounding boxes of the edge pairs.

3.6. Events And Callbacks

Introduction

In some places, the API requires to attach code to an event. An event could be a menu item which is selected or a change of some status which might require some action. The API allows implementation of specific code which is called in that case. This enables us to implement the functionality behind a menu item. In this text we will refer to such functionality by the general term "callback". In general a callback is custom code that is called from the API in contrast to API code that is called from the custom code.

There are basically two ways to attach specific code to a callback:

- **Reimplementation**: some API classes provide "virtual" methods. "virtual" is a C++ term and means a method that can be overridden in a derived class. This technique is employed for example in the "Strategy" design pattern. In strictly typed C++ this is quite a common pattern which allows definition of interfaces and concrete implementations based on those interfaces. Ruby as a dynamic language doesn't care much about classes and their relationship: an object either has a method or it hasn't. So, reimplementation is just a matter of providing the right method. An examples for the strategy pattern is the BrowserSource class (BrowserSource).

- **Events**: events allow attaching a piece of code to an event. In Ruby, such a block is "Proc" object, in "Python" it is a "callable" object ("lambda function" is a term used in both languages for this kind of concept). In case the event is triggered, this attached code is executed. Multiple lambda functions can be attached to the same event and removed from the latter. Events can be cleared of attached code, where only the blocks attached from one language can be cleared together - code attached from Python cannot be cleared from Ruby. An example for events is the Action class (Action) which provides both the reimplementation interface ("triggered" method) and the event interface ("on_triggered"). By the way, Qt signals are mapped to events in KLayout's Qt binding (The Qt Binding).

The "Observer" class which was there prior to KLayout 0.25 has been dropped in favour of the more flexible events. It is no longer supported.

Reimplementation (Strategy Pattern)

The BrowserSource (BrowserSource) class is a nice example for the Strategy pattern. It is used by the BrowserDialog class (BrowserDialog) as a kind of internal HTML server which handles URL's starting with "int:". For this, a script has to provide a class that reimplements the "get(url)" method. In the following example, a BrowserSource is created that takes an URL with an integer index number and delivers a HTML text with a link to the URL with the next index.

Here is the code. This example demonstrates how the "get" method is reimplemented to deliver the actual text.

```
module MyMacro

  include RBA

  class MyBrowserSource < BrowserSource
    def get(url)
      next_url = url.sub(/\d+/) { |num| (num.to_i+1).to_s }
      "This is #{url}. <a href='#{next_url}'>Goto next (#{next_url})</a>"
    end
  end

  dialog = BrowserDialog::new
  dialog.source = MyBrowserSource::new
  dialog.home = "int:0"
  dialog.exec

end
```

```
from pya import BrowserSource, BrowserDialog

class MyBrowserSource(BrowserSource):
  def get(self, url):
```

```
    next_url = "int:" + str(int(url.split(":")[1]) + 1)
    return f"This is {url}. <a href='{next_url}'>Goto next ({next_url})</a>>"

dialog = BrowserDialog()
dialog.home = "int:0"
dialog.source = MyBrowserSource()
dialog.exec_()
```

Ruby even allows reimplementation of a method without deriving a new class, because it allows defining methods per instance:

```
module MyMacro

  include RBA

  source = BrowserSource::new
  def source.get(url)
    next_url = url.sub(/\d+/) { |num| (num.to_i+1).to_s }
    "This is #{url}. <a href='#{next_url}'>Goto next (#{next_url})</a>"
  end

  dialog = BrowserDialog::new
  dialog.source = source
  dialog.home = "int:0"
  dialog.exec

end
```

Events

Events are the callback variant which is the easiest one to use. Using an event it is possible to directly attach a block of code to a callback. An event has a specific signature, i.e. the parameters it provides. The block can obtain this parameters by listing them in its argument list.

Here is a simple example that uses the parameterless "on_triggered" event of the Action class (Action). It puts a new entry into the tool bar and if it is clicked, it displays a message box:

```
module MyMacro

  include RBA

  action = Action::new
  action.on_triggered do
    MessageBox::info("A message", "The action was triggered", MessageBox::Ok)
  end
  action.title = "My Action"

  Application::instance.main_window.menu.insert_item("@toolbar.end", "my_action", action)

end
```

The Python version is:

```
from pya import Action, MessageBox, Application

def on_triggered():
  MessageBox.info("A message", "The action was triggered", MessageBox.Ok)

action = Action()
action.on_triggered = on_triggered
action.title = "My Action"
```

```
Application.instance().main_window().menu().insert_item("@toolbar.end", "my_action", action)
```

Specifying a block to an event will make the event only execute that block. A more flexible way of controlling the code attached to events is available through the += and -= operators:

```
module MyMacro

  include RBA

  code = lambda do
    MessageBox::info("A message", "The action was triggered", MessageBox::Ok)
  end

  action = Action::new
  action.on_triggered += code

  ...

  # to remove the code from the event, use:
  action.on_triggered -= code

  # to replace all event handlers by the one given by "code":
  action.on_triggered = code

  # to clear all event handlers use:
  action.on_triggered.clear
```

Synonyms for the += operator are `add` and `connect`. The latter makes code more familiar for PyQt users. In the same way, synonyms for the `-=` operator are `remove` and `disconnect`.

If the Qt binding is available (see The Qt Binding), Qt signals are implemented as events. This way it's very simple to create a Qt dialog. In following example, the "textChanged" signal of QLineEdit is attached a code block which copies the text of the input field to the label below:

```
module MyMacro

  include RBA

  dialog = QDialog::new(Application::instance.main_window)
  layout = QVBoxLayout::new(dialog)
  input = QLineEdit::new(dialog)
  label = QLabel::new(dialog)
  layout.addWidget(input)
  layout.addWidget(label)

  # implement the textChanged signal as event:
  input.textChanged { |text| label.text = text }

  dialog.exec

end
```

The Python version is:

```
from pya import QDialog, QVBoxLayout, QLineEdit, QLabel, Application

dialog = QDialog(Application.instance().main_window())
layout = QVBoxLayout(dialog)
input = QLineEdit(dialog)
label = QLabel(dialog)
layout.addWidget(input)
layout.addWidget(label)
```

```
def text_changed(text):
  label.text = text

# implement the textChanged signal as event:
input.textChanged = text_changed

dialog.exec_()
```

Using the += operator on the event, multiple handlers can be added to a signal:

```
module MyMacro

  include RBA

  dialog = QDialog::new(Application::instance.main_window)
  layout = QVBoxLayout::new(dialog)
  input = QLineEdit::new(dialog)
  label1 = QLabel::new(dialog)
  label2 = QLabel::new(dialog)
  layout.addWidget(input)
  layout.addWidget(label1)
  layout.addWidget(label2)

  # two signal consumers:
  input.textChanged += lambda { |text| label1.text = text }
  input.textChanged += lambda { |text| label2.text = text.reverse }

  dialog.exec

end
```

with the Python version:

```
from pya import QDialog, QVBoxLayout, QLineEdit, QLabel, Application

dialog = QDialog(Application.instance().main_window())
layout = QVBoxLayout(dialog)
input = QLineEdit(dialog)
label1 = QLabel(dialog)
label2 = QLabel(dialog)
layout.addWidget(input)
layout.addWidget(label1)
layout.addWidget(label2)

def text_changed1(text):
  label1.text = text

def text_changed2(text):
  label2.text = text[::-1]

# two signal consumers:
input.textChanged += text_changed1
input.textChanged += text_changed2

dialog.exec_()
```

3.7. The Ruby Language Binding

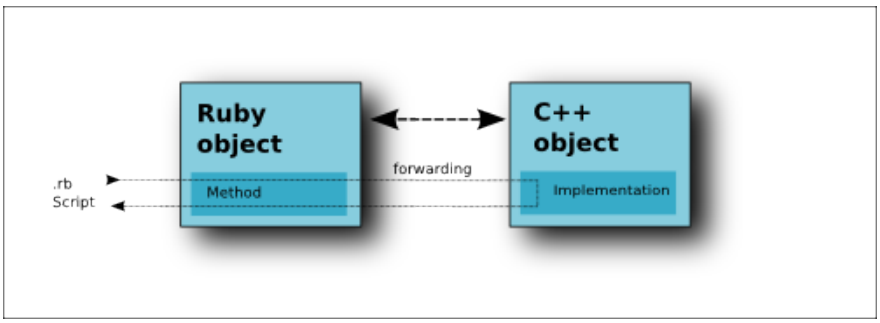
This article covers the basics of the Ruby binding provided by KLayout. The Ruby binding is basically a way to access the native code classes of KLayout through a Ruby interface. KLayout is written in C++, hence the topic covered here is the interface between C++ and Ruby objects. The Ruby API (RBA) is based on the Ruby binding of a selection of C++ classes. RBA is also the framework that implements the Ruby side of the binding. The C++ side is a more generic form which is not strictly confined to a certain programming language. The C++ side of the framework is referred to as GSI (generic scripting interface) in the KLayout sources.

Joining Two Worlds: Ruby and C++

The usual and most simple case of a Ruby/C++ binding is a Ruby wrapper over a C++ object. When Ruby code likes to access a C++ object, the first thing that happens is that a Ruby proxy object is created that is linked to the C++ object. That link can be unidirectional (the Ruby object knows about the C++ object, but the C++ object does not know about the Ruby object) or bidirectional (each know of each other). The kind of linking is important because a bidirectional link is stronger than a unidirectional link and allows lifetime tracking of the other object. For performance reason, not all objects implement the ability of bidirectional links, in particular not the ones that live in the layout database. That has certain consequences we will discuss in the lifetime management section below.

The Ruby proxy object serves as a connection point to the C++ object. It defines methods that correspond to methods in the C++ object. When one of these methods is called, their implementation collects the arguments of the method call and converts them to a binary representation that C++ understands. That process is usually called marshalling. Having done so, the execution continues in C++ space where the GSI framework will use the binary representation of the arguments to call the target method of the C++ object. After the call has returned the same happens on the way back, this time with the return value instead of the arguments. Having converted the return value back into Ruby objects the execution returns to the Ruby script.

The following image illustrates the relationship:



While that operation is simple in theory there are some pitfalls when implementing that scheme. One of them is the inherent compatibility issue between C++ and Ruby's lifetime management. In Ruby, the interpreter knows about all references to a Ruby object. When there are no more references to an object, the object is marked as "no longer used" and deleted. In other words: as long as any reference exists, the object is valid and a reference will never become invalid.

In C++, it is responsibility of the code to explicitly delete an object when it is no longer used. In other words: as long as any reference exists, the object is valid and a reference will never become invalid. Often there is a clear ownership: an object belongs to another object which controls the lifetime of the owned object (aggregation). That scheme is more efficient and predictable but it bears the danger of holding references to objects which are deleted already.

That raises the question how the lifetime of the Ruby proxy object is controlled and how the lifetime of the C++ object is related to that.

Lifetime management

RBA/GSI follows a simple principle that significantly simplifies the implementation: who created an object is responsible for cleaning it up. In other words: a ownership of an object is usually not transferred between C++ and Ruby space. Thus we have to consider two cases: The object is created in Ruby or the object is created in C++ code. Literally the object "lives" in Ruby space or in C++ space. In both cases, there is a pair of objects, but one of them is controlling the other.

Case 1: The object lives in Ruby space

When the object is created in Ruby, the Ruby proxy owns the C++ object and when the Ruby object goes out of scope, not only the Ruby object but also the C++ object is deleted. That means, that except if that case is handled by special measures, a reference to such an

object must not be stored in C++ space, because we will never know when Ruby will delete the object. A reference can be passed safely as an argument of a method however, provided the method does not store the reference somewhere.

But then: how do we then permanently store an object we have created in Ruby? The answer is simply by creating a copy on the C++ side. That is exactly what happens in that piece of code:

```
# creates an object that lives in Ruby space:
box = RBA::Box.new(0, 0, 10, 20)
# insert creates a copy of the box:
cell.shapes(layer).insert(box)
```

That is not an option for heavy objects such as layouts. If such objects need to be stored in C++ space, they are not created in Ruby code. Instead, several methods are provided to create objects that live in C++ space. For example a LayoutView object is not created in Ruby, but rather created inside the MainWindow object with create_layout. After that, the reference is obtained with MainWindow::current_view or MainWindow::view.

An exception to the lifetime control rule given above are Qt objects: a common pattern is to create Qt objects and add them to a container (i.e. widgets to a dialog). This implies a lifetime control transfer from Ruby to C++. RBA handles that case by explicitly transferring control when a QObject or one of the derived objects is created with a parent reference in Ruby code. Qt implements its own mechanism of controlling the lifetime which includes monitoring of the lifetime of child objects. This feature makes transferring the control feasible for these kind of objects. For some Qt methods which are know to transfer the ownership of an object, the ownership is transferred explicitly.

An object living in Ruby space can be explicitly deleted to free resources for example. For this, the "_destroy" method is provided. This method will only deleted the C++ object and not the Ruby object. However, the Ruby object will become invalid and calling a method on such an object will result in an error.

Case 2: the object lives in C++ space

In that case, the Ruby proxy object simply acts as a pointer to a C++ object. An issue arises when the Ruby object is still alive but the C++ object is deleted. In that case, the flavor of the link between the Ruby proxy and C++ object is important: if the link is bidirectional, the C++ object will inform the Ruby proxy that the reference will become invalid. The Ruby proxy will mark itself as being invalid and will block further calls to methods. Object supporting this reference binding are the API classes and "bigger" database objects such as Cell or Layout.

For example:

```
main_window = ... # the RBA::MainWindow object
# returns a reference to a RBA::LayoutView object living in C++ space:
view = main_window.current_view
# deletes all views and also the object we have a reference to
main_window.close_all
# this will fail, because the view is a Ruby proxy that knows that the C++ object
# has been deleted:
view.load_layout(...)
# You can check this by asking "_destroyed?". This will return "true":
view._destroyed?
```

For "lightweight" objects such as the geometry primitives (Box, Polygon etc.), the link is unidirectional and lifetime monitoring is not possible. This situation bears the danger of invalid references with fatal consequences if an attempt is made to call a method then. Fortunately this case is rare and usually mitigated by providing an object clone.

Calling "_destroy" on an object living in C++ space is not safe in general. In some cases, this can have fatal consequences (i.e. destroying the MainWindow object). An exception from that rule are Qt objects because Qt does lifetime monitoring internally and destroying an object from the outside (Ruby) is a valid operation in most cases (although there are exceptions).

Transfer Of Ownership And Object Lifetime

Some C++ methods accept pointers to objects and take over ownership over this object. This happens specifically inside the Qt methods. In that case, the Ruby object has to release ownership over that object. For example, "QApplication::postEvent" takes over the ownership over the event object passed to it and will finally destroy this object:

```
event = RBA::QKeyEvent::new
# takes over ownership over the event object:
RBA::QApplication::postEvent(RBA::MainWindow::instance, event)
...
```

```
# later on, when "event" goes out of scope, the GC will try to
# delete the QKeyEvent object and without further provisions, the
# application will crash!
```

Luckily, there are such provisions. The "postEvent" method is tagged specially, so the interpreter knows that it has to transfer ownership of the event object to Qt.

If that was not the case, one could use "_unmanage" to mark the event object no longer being managed by the script:

```
event = RBA::QKeyEvent::new
event._unmanage
# Now, somebody else is responsible for managing the object's lifetime
```

The reverse is true for methods delivering new objects which the Ruby interpreter is supposed to manage. For example "QLayout::takeAt" returns a free objects which the caller is responsible for deleting. Without further provisions this would lead to a memory leak, because Ruby does not delete the borrowed object:

```
layout = ... # A RBA::QLayout object
child = layout.takeAt(0)
# later on, when child goes out of scope, Ruby needs to delete the object.
# Here is does, because it knows that "takeAt" delivers a free object.
```

If the declaration of "takeAt" was not aware of the return mode, one could use "_manage" to mark the event object as to be managed by the script:

```
obj = createObjectForMe()
event._manage
# Now, when event goes out of scope, the object will be destroyed too.
```

Static And Local Methods, Access

Static C++ methods is simply implemented as class methods while local methods are implemented as instance methods.

RBA also supports binding of protected methods. A Ruby class derived from a C++ class exposed to Ruby can call those methods while code outside that class cannot access those methods. Public methods can be called from anywhere.

Data types, Arguments and Return values

Ruby and C++ feature different types of data. While in Ruby, a variable is of any type, in C++ a variable has a fixed type. This also is the case for arguments of methods and return values. A C++ method requires an argument to be of a certain type. In addition, C++ features pointers, references and a variety of containers. Therefore a mapping of Ruby types to C++ types is required. The following table summarizes the mapping for the simple types:

C++	Ruby	Comment
`(signed, unsigned) char, int, short, long, long long`	`FixNum`	
`float, double`	`Float`	
`const char *, std::string, QString, QByteArray`	`String`	KLayout uses UTF-8 encoding for std::string. Binary strings can be passed to and from QByteArray.
`bool`	`nil, true, false`	When passing a Ruby value to a bool parameter, the Ruby's nil and false values are converted to false. All other values are converted to true. This follows the usual Ruby semantics.
`void *`	`FixNum`	Passing pointers between Ruby and C++ is not possible. But often, a "void *" value is used as a handle or as an arbitrary value. The Ruby binding allows storing of such values as FixNum.

QVariant, tl::Variant (KLayout)	any	Any simple Ruby type that can be mapped to a C++ value can be stored in a QVariant. tl::Variant also supports a selection of complex types (i.e. RBA::Point, RBA::DPoint, RBA::Box, RBA::DBox etc.).

Arguments that expect objects of classes known to RBA can be passed references from Ruby objects. The linear containers (std::vector, QList etc.) are mapped to Ruby arrays. Their values can be any scalar type and objects of known classes. Nested arrays are not supported currently. Since the declaration is uniform in C++ (all members of an array must be of the same type), all members of a Ruby array must be convertible to the target type.

Pointers and references are a special topic for C++ to Ruby binding. Ruby does not have the concept of a reference. Instead, all object values are references by definition. RBA can convert between Ruby variables and pointers/references and also supports "out" parameters.

"void" as return value

While a "void" return value indicates "no return value" in C++, this concept is not common in Ruby. Ruby methods will always return the last value generated in a method.

For consistency, KLayout's Ruby binding returns "self" from methods in this case. This allows chaining of methods in many cases and fosters compact code:

```
// C++
class A {
public:
  virtual void f() { ... }
  virtual void g() { ... }
};

# Ruby
a = A::new.f.g
```

References and pointers to simple types (FixNum, Float, String)

Simple types can be passed as values to arguments expecting pointers and references. RBA will convert the value to a pointer to that value and pass that pointer to the method. Pointer arguments also support the "nil" value which is converted to a null pointer. Beware that not all C++ methods expecting a pointer argument are aware of null pointers and may have trouble digesting that value.

Often, (non-const) reference and pointer arguments are used as "out" parameters, i.e. the method alters the value of the memory location passed by the pointer value. That imposes a problem for the Ruby binding: since Ruby does not pass references for simple types, the value of a variable cannot be altered and the following code does not work as expected:

```
//  C++: use x as an "out" parameter:
void A::f(int &x) { x = 5; }

# Ruby:
x = 1
A::new.f(x)
# x is NOT 5!
```

RBA solves that problem by providing a "boxing" mechanism: a value is stored inside an object which is passed by reference. RBA provides the class Value for that purpose. This class serves as a container for any type and can be used to solve the "out" parameter problem this way:

```
//  C++: use x as an "out" parameter:
void A::f(int &x) { x = 5; }

# Ruby:
x = RBA::Value.new(1)
A::new.f(x)
# x.value is 5 now
```

The RBA::Value object has a attribute "value" which can hold any type. RBA will convert that member into the value required by the method's argument. The method will receive a pointer or reference to that value and can modify that memory location. After the method has returned, the modified value can be accessed by reading the "value" attribute.

Reference and pointer return values are simply converted to copies of the value.

Special pointers: const char *, void *

"const char *" pointers are mapped to Ruby strings. The same is true for "const unsigned char *". The non-const versions "char *" and "unsiged char *" are somewhat ambiguous and are mapped to strings currently.

"void *" is mapped to an integer value representing the address the pointer points at. Since it is not possible to address a value by a pointer in Ruby as well as getting the address of a value, there is noch much use for the "void *" values expect if those values are delivered and digested by C++ methods. This is the case for some "handle" values (i.e. Windows object handles) and some cases, where "void *" stands for "some arbitrary value which can be a pointer or an integer".

Pointers as arrays

In "C style" C++, pointers are sometimes used as the start position of an array and point to a number of items, not only one. Usually there is another parameter telling the number of items the pointer points to. Since there is no declaration for that kind of calling convention, the Ruby binding cannot support that case. Only "char *" and "const char *" are supported and it is assumed that arguments of these type expect a zero-terminated byte string in UTF-8 encoding.

Fortunately that case is rare. Specifically the Qt API uses references to QByteArray, QVector, QList and similar container classes which can be mapped to Ruby arrays.

References and pointers to complex types

References and pointers to complex types and objects of Ruby classes for which a C++ class exists are simply converted to pointers or references to the C++ class. Pointer arguments can also be passed "nil" which renders a null pointer. Again, not all method implementations may be prepared for that value and the application may crash in that case.

Hash arguments and return values

Associative containers (std::map, QHash etc.) are mapped to Ruby hashes. Unlike Ruby, C++ associative containers are strictly typed, so it's important to provide the right key and value pairs.

Default arguments

Some functions provide defaults for certain arguments. If these arguments are omitted, the default value is used instead.

Keyword arguments

Starting with version 3, Ruby supports "real" keyword arguments. Keyword arguments are supported for most methods with the exception of a few built-in ones such as "assign". Keyword arguments can be used when the other, non-optional arguments are given either by positional arguments or other keyword arguments.

Keyword arguments are somewhat more expressive and allow a shorter notation. For example, to instantiate a 45 degree rotation, you can write:

```
t = RBA::CplxTrans::new(rot: 45)
```

Implicit conversions

String arguments

If a method expects a string argument, other types are converted to strings using the "to_s" method. In Python, the equivalent is "str(...)".

Example:

```
# Also accepts a float value for the first string argument -
# it is converted to "2.5"
t = RBA::Text::new(2.5, RBA::Trans::new)
```

Conversion constructors

Conversion constructors are constructors that take an object of a different class and convert it to the target class. Conversion constructors are used implicitly in applicable cases to convert one type to the type requested by the argument.

For example, in the following code, the Region object's "+" operator is used. This expects a Region object as the second parameter, but as there is conversion constructor available which converts a Box to a Region, it is possible to use a Box directly:

```
r = RBA::Region::new(RBA::Box::new(0, 0, 1000, 2000))
r += RBA::Box::new(3000, 0, 4000, 2000)
```

Implicit constructor from lists

When an object is expected for an argument and a list is given, the object constructor is called with the arguments from the list. This specifically allows using size-2 lists instead of Point or Vector arguments. In Python, a "list" can also be a tuple.

In the following example, this mechanism is used for the polygon point list which is expected to be an array of Point objects, but can use size-2 arrays instead. Also, the "moved" method expects a Vector, but here as well, size-2 arrays can be used instead:

```
pts = [ [ 0, 0 ], [ 0, 1000 ], [ 1000, 0 ] ]
poly = RBA::Polygon::new(pts)
poly = poly.moved([ 100, 200 ])
```

Constness

C++ has the concept of "constness". That means that if a pointer or a reference to an object is declared "const", the object cannot be modified. Also, methods can be declared "const" meaning that such methods do no alter the (externally visible) state of an object. C++ ensures constness, because it only allows calling of const methods on const references of objects.

The concept of constness is part of the contract between a caller of a method and the method's implementation: if a method declares an argument to be a const reference or pointer, it tells the caller that it will not modify the object. Similar, returning a const reference is a safe way to expose internal objects because the implementor of the method can be sure that code outside a method will not modify the state of the object returned. Thus, constness is a vital part of a contract and somehow needs to be mapped in the Ruby binding.

Unfortunately that is not as easy as it may look. The problem is basically that Ruby does not have the concept of constness, but it has references. Remember that there is always a pair of Ruby/C++ objects. When a reference to a C++ object is returned into Ruby space, the Ruby counterpart of the object is created and a reference to that object is returned.

But where do we have to attach the constness of the reference? The answer is that there is no other place except the Ruby object. Hence, if a const reference is returned, a "const Ruby object" is created. That object will refuse to execute non-const methods. That way, the const semantics is maintained.

Trouble starts when another non-const reference is returned to the same object. In that case, the Ruby object needs to be reused but this time with non-const semantics. That is a contradiction to the previous const state. RBA solves this issue by switching the object to non-const state in that case and will allow to call non-const methods after that.

In other words: constness is part of the object identity in Ruby and it can change. That actually makes some sense: when I obtained a const reference there may be another way to obtain a non-const reference. Once I have a non-const reference I can modify the object which also is behind the const reference. Thus keeping a const reference is no longer a safety feature and the const reference can be dropped.

To avoid lifetime issues, RBA does not work with references a lot. Objects returned by a const reference are always copied. Only const pointers are kept as const object references in Ruby.

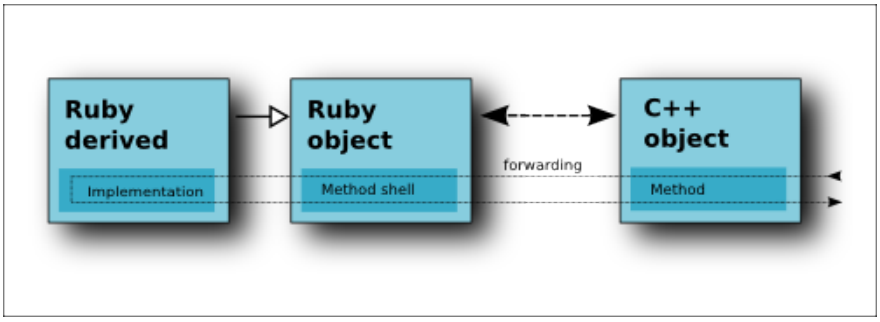
Reimplementing Virtual Methods

The Ruby binding supports reimplementation of virtual C++ methods in derived classes. This works as expected:

```
// C++
class A {
public:
  virtual void f() { }
};
```

```
# Ruby
class B < A
  def f
    # f is called when A::f is called on the C++ side
  end
end
```

Virtual methods are often used as callbacks and provide a reverse call path from C++ to Ruby:



The parameters of the Ruby implementation must match the parameters of the C++ method. Mapping of Ruby to C++ types applies to the Ruby method arguments the same way than for return values of ordinary methods. Virtual functions can also return values. In that case the same mapping rules than for ordinary method arguments apply.

Iterators

A special feature of KLayout's Ruby binding are iterators. C++ iterators are mapped to Ruby iterators. For example:

```
// C++
class A {
public:
  //  begin()..end() are mapped to the "each" method in Ruby:
  iterator begin();
  iterator end();
};

# Ruby
a = A::new
a.each { |i| ... }
```

If no block is given, an Enumerator object is created. Enumerators are a Ruby feature. Enumerators support many convenient methods like sort, inject, collect, select etc. Here is an example:

```
# turns all elements returned by the iterator into strings and sorts them
sorted = a.each.collect(&:to_s).sort
```

Iterators match very well between C++ and Ruby so there are no real issues here. The return type of the iterators is mapped to Ruby's block arguments using the same rules than for values returned from C++ methods.

Exceptions

Raising an error in Ruby is a valid way to terminate the execution of the method. A Ruby error is mapped to a C++ exception which usually is caught in the C++ code and handled properly. There are some cases, where raising an exception can crash the application. That is the case in particular in event handlers of Qt objects. Usually, raising an exception is safe.

Events

Events are a special feature of KLayout's Ruby binding. Events are similar to reimplementations of virtual functions except that no derived class is required and the call is handled by a Ruby block. Events can have return values but using "return" inside a block does not have the expected effect. Instead, the value of the last expression in the block is used. That is a feature of Ruby, not a speciality of RBA.

There is always one receiver for an event. If a new block is assigned to an event, the old block will no longer be called. Here is an example of using events:

```
// C++
class A {
public:
  //  e is an event with an integer argument
  void f(i) { e(i); }
};

# Ruby
a = A::new
a.e { |i| puts i; }
a.f(15)  # calls the block attached to e with the argument 15
```

Events are extensively used for an alternative to Qt slots. The Qt binding of KLayout maps every signal to an event. That means, that it is possible to connect a block to a Qt signal directly at the sender object without having to create a receiver. For example:

```
# Ruby
b = RBA::QPushButton::new
# print a message, when the button is clicked
b.clicked { puts "Ouch." }
```

There is one significant difference between Qt signals and events: A Qt signal can have many receivers while an event always has one block which is executed when the signal is emitted. Connecting signals and slots still is supported with the "connect" method, but it is not possible to define slots on Ruby methods. The events fill that gap and, in the authors opinion, in a much more convenient way.

3.8. Coding PCells In Ruby

A good starting point for Ruby PCells is the PCell sample. Create a macro in the macro development IDE (use the "+" button) and choose "PCell sample" from the templates.

The Sample

We'll do a code walk through that sample here and explain the concepts while doing so. Here is the complete sample:

```
# Sample PCell
#
# This sample PCell implements a library called "MyLib" with a single PCell that
# draws a circle. It demonstrates the basic implementation techniques for a PCell
# and how to use the "guiding shape" feature to implement a handle for the circle
# radius.
#
# NOTE: after changing the code, the macro needs to be rerun to install the new
# implementation. The macro is also set to "auto run" to install the PCell
# when KLayout is run.

module MyLib

  include RBA

  # Remove any definition of our classes (this helps when
  # reexecuting this code after a change has been applied)
  MyLib.constants.member?(:Circle) && remove_const(:Circle)
  MyLib.constants.member?(:MyLib) && remove_const(:MyLib)

  # The PCell declaration for the circle
  class Circle < PCellDeclarationHelper

    include RBA

    def initialize

      # Important: initialize the super class
      super

      # declare the parameters
      param(:l, TypeLayer, "Layer", :default => LayerInfo::new(1, 0))
      param(:s, TypeShape, "", :default => DPoint::new(0, 0))
      param(:r, TypeDouble, "Radius", :default => 0.1)
      param(:n, TypeInt, "Number of points", :default => 64)
      # this hidden parameter is used to determine whether the radius has changed
      # or the "s" handle has been moved
      param(:ru, TypeDouble, "Radius", :default => 0.0, :hidden => true)

    end

    def display_text_impl
      # Provide a descriptive text for the cell
      "Circle(L=#{l.to_s},R=#{'%.3f' % r.to_f})"
    end

    def coerce_parameters_impl

      # We employ coerce_parameters_impl to decide whether the handle or the
      # numeric parameter has changed (by comparing against the effective
      # radius ru) and set ru to the effective radius. We also update the
      # numerical value or the shape, depending on which on has not changed.
      rs = nil
      if s.is_a?(DPoint)
        # compute distance in micron
        rs = s.distance(DPoint::new(0, 0))
```

```
      end
      if rs && (r-ru).abs < 1e-6
        set_ru rs
        set_r rs
      else
        set_ru r
        set_s DPoint::new(-r, 0)
      end

      # n must be larger or equal than 4
      n > 4 || (set_n 4)

    end

    def can_create_from_shape_impl
      # Implement the "Create PCell from shape" protocol: we can use any shape which
      # has a finite bounding box
      shape.is_box? || shape.is_polygon? || shape.is_path?
    end

    def parameters_from_shape_impl
      # Implement the "Create PCell from shape" protocol: we set r and l from the shape's
      # bounding box width and layer
      set_r shape.bbox.width * layout.dbu / 2
      set_l layout.get_info(layer)
    end

    def transformation_from_shape_impl
      # Implement the "Create PCell from shape" protocol: we use the center of the shape's
      # bounding box to determine the transformation
      Trans.new(shape.bbox.center)
    end

    def produce_impl

      # This is the main part of the implementation: create the layout

      # fetch the parameters
      ru_dbu = ru / layout.dbu

      # compute the circle
      pts = []
      da = Math::PI * 2 / n
      n.times do |i|
        pts.push(Point.from_dpoint(DPoint.new(ru_dbu * Math::cos(i * da), ru_dbu * Math::sin(i * da))))
      end

      # create the shape
      cell.shapes(l_layer).insert(Polygon.new(pts))

    end

  end

  # The library where we will put the PCell into
  class MyLib < Library

    def initialize

      # Set the description
      self.description = "My First Library"

      # Create the PCell declarations
      layout.register_pcell("Circle", Circle::new)
      # That would be the place to put in more PCells ...

      # Register us with the name "MyLib".
      # If a library with that name already existed, it will be replaced then.
```

```
      register("MyLib")

    end

  end

  # Instantiate and register the library
  MyLib::new

end
```

Preamble

The first important concepts are PCell class and library. A PCell is provided by implementing a certain class and providing the functionality of the PCell through various methods. In fact there are only three methods which must be implemented. In the sample we use PCellDeclarationHelper as the base class for our PCell. This is a convenience wrapper around the basic interface, PCellDeclaration. Since that interface is too much "C++"-like and is somewhat tedious to use, the PCellDeclarationHelper is the recommended starting point.

Using the same concept, a library is an object derived from the Library class. It is basically a container for PCells and static layout cells. A library has to be initialized (most conveniently in the constructor), registered and initialized once. That makes the library available to the system and it can be used in layouts.

Please note, that the sample PCell is configured for auto-run. This way, the library is installed when KLayout starts and before any layouts are loaded. That way, the library is available for layouts read from the command-line for example.

Let's now start with our code walk:

```
module MyLib

  include RBA

  # Remove any definition of our classes (this helps when
  # reexecuting this code after a change has been applied)
  MyLib.constants.member?(:Circle) && remove_const(:Circle)
  MyLib.constants.member?(:MyLib) && remove_const(:MyLib)
```

It is recommended to put the library code into a separate module. That allows mixing in other modules (in that case RBA) without affecting the main module. The second recommendation is to remove classes which are already defined with the names we are going to create. While developing a PCell is it necessary to frequently rerun the script to register the new version of the library and PCell. If we do not remove the existing class, Ruby will refuse to reopen a class for example if we change the super class or methods we have deleted will still remain. That is avoided by removing the classes before the create them again. In Ruby, a class can be removed by removing the constant with the class name. Note the way, the script checks whether a class is defined by using "member?" on the list of constants. This method should be preferred over "const_defined?" which behaves differently on Ruby 1.8 and Ruby 1.9.

The PCell Class

First we define a PCell class derived from PCellDeclarationHelper. This is the most convenient way to declare a PCell:

```
  # The PCell declaration for the circle
  class Circle < PCellDeclarationHelper

    include RBA
```

Again we include RBA which allows us to use RBA classes inside the PCell without having to write "RBA::" in front of the class names.

The initialization of the object is already a very important step. First, it must initialize the super class. Then it has to declare the PCell parameters. Each PCell has a set of parameters that define the appearance of the PCell. Parameters have a symbolic name, a type, a description and optionally a default value and further attributes. The name is important because it identifies the parameter throughout the system and in layout files as well. It should not be changed. The description is an arbitrary string and can be changed or localized.

Parameters are declared using the "param" method of PCellDeclarationHelper:

```
    def initialize
```

```
    # Important: initialize the super class
    super

    # declare the parameters
    param(:l, TypeLayer, "Layer", :default => LayerInfo::new(1, 0))
    param(:s, TypeShape, "", :default => DPoint::new(0, 0))
    param(:r, TypeDouble, "Radius", :default => 0.1)
    param(:n, TypeInt, "Number of points", :default => 64)
    # this hidden parameter is used to determine whether the radius has changed
    # or the "s" handle has been moved
    param(:ru, TypeDouble, "Radius", :default => 0.0, :hidden => true)

  end
```

In that sample we declared a PCell parameter "l" with type "TypeLayer" which indicates that this is a layer in the layout. "s" is a parameter shape represents the handle and is a shape. A shape is either of type DBox, DText, DPath, DPolygon or DPoint. Shape parameters implement the "guiding shape feature" that KLayout offers to manipulate that parameter graphically. "r" and "n" are simple numerical parameters. All parameters have default values which are set with the "default" symbolic parameter. As a layer, "l" must have a LayerInfo value. "s" is a DPoint which reflects the handle. Since default values not only preset the parameters to a reasonable value but also define the subtype of a parameter (here the DPoint shape), providing a default is strongly recommended. As shapes need to be independent from the database unit for portability, they are expressed in micron units. Hence the use of the "D" forms (DPoint etc.).

"ru" is a special parameter. Because we have two ways to modify the radius (the handle and the numerical value), it is used as a shadow parameter do determine which one of these two values has changed. Depending on that information, either the handle or the radius is updated. Because this parameter should not be shown in the parameter page, it is marked "hidden".

There are some more options for parameters. See the documentation of PCellDeclarationHelper for more details about the further attributes.

The parameter declaration will create accessor methods for each parameter. These accessor methods can be used to get and set the current value of the parameter inside the production method and other methods. For that, it will use the symbolic name of the parameter. The setter is called "set_x" (where x is the parameter name). Although Ruby would allow using "x=" to mimic an assignment, this option leads to some confusion with definition of local variables and was not considered here. The following methods are created in the sample:

- `l, set_l, l_layer`: getter and setter for the current value of "l". l_layer is the layer index in the context of the PCell production method. The layer index can be used to access the layer in the layout or cell.
- `s, set_s`: getter and setter for the current value of "s".
- `r, set_r, n, set_n, ru, set_ru`: same for "r", "n" and "ru".

After the PCell initialization is finished, we can start with the production code. These are the methods that KLayout will call on certain opportunities. The first method that a PCell must implement is the display text callback:

```
  def display_text_impl
    # Provide a descriptive text for the cell
    "Circle(L=#{l.to_s},R=#{'%.3f' % r.to_f})"
  end
```

KLayout will call this method to fetch a formatted string that represents the content of a PCell. This text is used for the cell tree and cell box labels. To avoid confusion, it should start with the name of the PCell. The bracket notation is not mandatory, but it's always a good idea to follow some common style. The information delivered by this method should be short but contain enough information so that a PCell variant can be distinguished from its sibling.

The next method is called whenever something on the parameters has changed. This method allows to adjust the parameters so that they obey certain limitations. It can also raise exceptions for invalid parameter combinations. In our case we use this method to adjust the handle or the numeric radius to the effective value. We also enforce a minimum number of vertex counts for the resulting polygon. Implementing this method in general is optional. By default, no modification of the parameters is done:

```
  def coerce_parameters_impl

    # We employ coerce_parameters_impl to decide whether the handle or the
    # numeric parameter has changed (by comparing against the effective
    # radius ru) and set ru to the effective radius. We also update the
```

```
    # numerical value or the shape, depending on which on has not changed.
    rs = nil
    if s.is_a?(DPoint)
      # compute distance in micron
      rs = s.distance(DPoint::new(0, 0))
    end
    if rs && (r-ru).abs < 1e-6
      set_ru rs
      set_r rs
    else
      set_ru r
      set_s DPoint::new(-r, 0)
    end

    # n must be larger or equal than 4
    n > 4 || (set_n 4)

  end
```

The implementation of the following three methods is optional: they are used to implement the "PCell from shape" protocol. If "Create PCell from shape" is selected in KLayout's Edit menu, it will call "can_create_from_shape_impl" for each known PCell. This method will be given the shape, layout and layer. If this method responds with "true", KLayout offers this PCell as a conversion target in the list. When this PCell has been selected, KLayout calls "parameters_from_shape_impl" and "transformation_from_shape_impl" to obtain the initial parameters and the initial transformation for the new PCell created from that shape. "parameter_from_shape_impl" will use the default values for all parameters unless they are set with the respective setters in the implementation body.

```
  def can_create_from_shape_impl
    # Implement the "Create PCell from shape" protocol: we can use any shape which
    # has a finite bounding box
    shape.is_box? || shape.is_polygon? || shape.is_path?
  end

  def parameters_from_shape_impl
    # Implement the "Create PCell from shape" protocol: we set r and l from the shape's
    # bounding box width and layer
    set_r shape.bbox.width * layout.dbu / 2
    set_l layout.get_info(layer)
  end

  def transformation_from_shape_impl
    # Implement the "Create PCell from shape" protocol: we use the center of the shape's
    # bounding box to determine the transformation
    Trans.new(shape.bbox.center)
  end
```

The most important method is "produce_impl" which actually creates the layout. For that, it can use all methods of Layout and Cell and most other RBA classes. It can even create instances. Although that is possible, it is not recommended to create cells in the production code. This would pretty much degrade performance and lead to a confusing variety of cells. It is possible to use boolean operations by using the methods of EdgeProcessor for example. Some care must be taken to avoid interaction with the user interface, in particular calling methods of LayoutView and MainWindow should be avoided.

The actual layout of the PCell is cached and the production code is called only when the PCell parameters have changed. However, to reduce the risk of performance degradation, the method should run quickly and not spend too much time in long loops or huge data sets.

```
  def produce_impl

    # This is the main part of the implementation: create the layout

    # fetch the parameters
    ru_dbu = ru / layout.dbu

    # compute the circle
    pts = []
    da = Math::PI * 2 / n
    n.times do |i|
```

```
        pts.push(Point.from_dpoint(DPoint.new(ru_dbu * Math::cos(i * da), ru_dbu * Math::sin(i * da))))
      end

      # create the shape
      cell.shapes(l_layer).insert(Polygon.new(pts))

    end

  end
```

Of course, more than one PCell class can be declared. Each PCell type must have an own implementation class which we will use later to create the PCells from.

The Library

The library is the container for the PCells. All important code is packed into the constructor of the library.

```
  # The library where we will put the PCell into
  class MyLib < Library

    def initialize

      # Set the description
      self.description = "My First Library"

      # Create the PCell declarations
      layout.register_pcell("Circle", Circle::new)
      # That would be the place to put in more PCells ...

      # Register us with the name "MyLib".
      # If a library with that name already existed, it will be replaced then.
      register("MyLib")

    end

  end
```

First, a library needs a description that we set with the description setter. Then, we instantiate all PCell classes once and register that instance in the library space.

The library is basically an ordinary Layout object that we can access through the "layout" method. The library can consist of more that PCells - all cells that we put into the layout will become available as library components (more precisely: all top cells). We could use RBA::Layout::read for example to feed the layout with cells from a file.

At the end of the constructor we register our instance inside the system with the given name. To avoid confusion, it is recommended to use the same name for the class and the library.

Finally we only need to instantiate the library:

```
  # Instantiate and register the library
  MyLib::new
```

This line of code will instantiate the library and, through the constructor, instantiate the PCells and register the library. We are done now and can use the library and our PCell.

Debugging The Code

When you have modified the code, you need to rerun the script. That will create the classes again and re-register the PCells and the Library with the new implementation. PCells already living in the layout will be migrated to the new implementation by mapping their parameters by their symbolic names.

The PCell code can be debugged with KLayout's built-in Ruby debugger. If the macro development IDE window is open, just load the PCell code and set a breakpoint. When KLayout calls the PCell implementation, the breakpoint will be triggered. Local variables can be inspected

and modified in the console for example. Single-stepping is supported as well. If the execution is stopped, KLayout will finish the operation with some error message.

It is also possible to print output to the console if the macro development IDE is open. Just use the methods of stdout that Ruby offers or simply "puts".

Please note that while the macro development IDE is opened, macro execution is considerably slower than usually, because the IDE will plug itself into the Ruby interpreter and trace the execution. When the IDE window is closed, Ruby runs at full speed. While in a breakpoint, KLayout's main window is only half alive. Only the IDE is active and the main window will not even repaint correctly. This prevents possible interactions with the executed code.

3.9. The Qt Binding

Starting with 0.22 comes with a large set of Qt classes available through the Ruby binding mechanism. This allows integration of Qt user interfaces with Ruby scripts and to use the Qt API, for example the network or SQL classes. To use the Qt bindings, KLayout must be compiled with Qt binding, i.e.

```
build.sh -with-qtbinding ...
```

The API provided covers the functionality of a certain Qt version. Currently this is Qt 4.6 and Qt 5.5. The API covers the following Qt 4 and Qt 5 modules:

- QtCore: the basic Qt API
- QtGui: the user interface widgets and supporting classes
- QtXml: support for XML
- QtXmlPatterns (Qt5): XML schema and queries
- QtSql: database support
- QtNetwork: various network protocols and supporting classes
- QtDesigner: dynamically load designer files (.ui)
- QtUiTools: dynamically load designer files (.ui)
- QtMultimedia (Qt5): multimedia support
- QtPrintSupport (Qt5): print support
- QtSvg (Qt5): SVG implementation

This article covers the use of the Qt API and special topics related to that. It is recommended to read the article about the Ruby binding (The Ruby Language Binding) for a deeper understanding of the mapping of the Qt API to Ruby.

There is some overlap with the "qtruby" project. This project also makes the Qt API available for Ruby. The approach of "qtruby" is similar. Yet there are some differences, in particular the event feature of KLayout, which allows a convient binding of code blocks to signals.

A First Sample

This is a first sample of how to use the Qt API. To run that sample, open the Macro Development IDE from the "Macros" menu. Add a new macro with the "+" button in the left top tool bar. Choose "General KLayout Macro" from the "General" group as the template. Paste the code above into the macro and run the macro with F5.

```
module MyMacro

  include RBA

  dialog = QDialog::new(Application.instance.main_window)
  dialog.windowTitle = "My Dialog"

  layout = QHBoxLayout::new(dialog)
  dialog.setLayout(layout)

  button = QPushButton.new(dialog)
  layout.addWidget(button)
  button.text = "Click Me"
  button.clicked do
    QMessageBox::information(dialog, "Message", "I was clicked!")
  end
```

```
    dialog.exec

  end
```

The sample creates a `QDialog` with a layout and a button in it. When the button is clicked, a message box appears. This code demonstrates some features of the Ruby binding of the Qt library. For example, the button's text is set with an attribute assignment ("`button.text = ...`") rather than a method call ("`button.setText(...)`").

A noteworthy feature is the event binding which allows associating code blocks with signals. In pure Qt, the "clicked" signal of the button would have to be connected to a slot. This is not possible without creating a receiver object. With events, that receiver is created internally and a code block can be attached to the signal directly:

```
button.clicked do
  QMessageBox::information(dialog, "Message", "I was clicked!")
end
```

That binding includes the ability to receive signal arguments through block arguments.

Binding Details

Given the rules stated in the general Ruby binding documentation (The Ruby Language Binding) the ruby versions of most methods can be derived readily. There are some exceptions however that we will cover here.

First, the C++ to Ruby binding lacks some features that are required for some methods. Those methods cannot be bound. Specifically that concerns:

- Methods that return or require unsupported containers
- Methods that return or require function pointers
- Methods that return or require pointers to pointers or references to pointers
- Methods that require pointers to pass arrays (i.e. `QPolygon::putPoints`)
- Methods that return or require objects which are not available in Ruby for some reason (i.e. `QGenericArgument` or some template classes like `GenericMatrix`)
- Template members
- Methods which are not available on one of the platforms (i.e. `QPrinter::printerSelectionOption`, which is not available on Windows)
- Some operators, like the cast operators
- Methods that require "char *" arguments which will be manipulated (i.e. `QFile::readLineData`)
- Methods that require C++ resources (i.e FILE arguments)
- Methods for which an alternative exists which cannot be distiguished (i.e. variants acceptings `QByteArray` and `QString` - only the `QString` variant is bound in that case)
- Methods and operators which requires a typed argument as disambiguator (i.e. `operator>>`, where the variant is selected by examining the type of the argument. For that case, alternatives exists which explicitly state the type in the name, for example "`read_i32`")

Some template types are made available to Ruby. In particular that is valid for some `QPair` specializations. For example "`QPair<double, double>`" is available as "`QDoublePair`".

The naming of some methods has been aligned to Ruby:

- `isX` is available as `isX?`, i.e. `QAction::isSeparator?`

- `setX` is available as `x=`, i.e. `QAction::iconText=`

In those cases, the original declaration is still available also.

The inheritance hierarchy of classes is mapped to Ruby in most cases. Sometimes that is not possible. For example, if the base class is a template (i.e. `QPolygon`, where the base class is a `QVector<QPoint>`). In that case, methods are provided that implement the features from the base class in the derived class.

Operators are bound to Ruby operators where that makes sense. For example, for `QPoint` the operators are available as expected ("==", "+" etc.).

"`destroy`" and "`create`" have been renamed to "`qt_destroy`" and "`qt_create`" to avoid name clashes with identical methods inherited from the RBA binding. "`destroy`" and "`create`" are standard methods which KLayout's Ruby binding defines for every object exposed to Ruby.

When a Qt object is created in Ruby space with a parent, its ownership is passed to the parent. It is safe however to keep a reference to that object, because KLayout's Ruby binding employs a special Ruby class internally (a proxy) which keeps track of the lifetime of the Qt object. If the parent is destroyed, the Qt object is destroyed as well. The internal Qt object will be notified and the reference to the Qt object will be invalidated. As a consequence, the Ruby proxy will refuse to execute methods on that object.

Destroying a Qt object can be necessary for example to free resources. To perform the equivalent of the C++ delete operator, use the "`destroy`" method that comes with every class exposed to Ruby. After an object is destroyed, the Ruby part of the binding still persists until all references to that object are removed. However, it is no longer possible to call methods on these objects.

The Qt binding significantly benefits from the dynamic binding of C++ objects. If a C++ pointer is returned, this pointer often is a pointer to a base class. Behind the pointer often is an object of a derived class. C++ allows calling of base class methods on that pointer, but not methods of the derived class - the identity of the object is reduced to the base class.

For example, if a method returns a `QWidget` pointer for a `QPushButton`, it is not possible to directly set the buttons text, because the method required for that is not part of the `QWidget` interface. In C++ one would dynamic_cast the pointer to `QWidget` and set the text then.

The Ruby binding automatically upcasts the pointer to the actual object, so the value returned has the real object's identity. In that case, delivering a `QWidget` would render a Ruby object that has a `QPushButton` identity and it's possible to set the text immediately. If the object was not a `QPushButton`, an error would be issued when an attempt is made to call a `QPushButton` method.

Enums

Enum types are available as classes to give them a specific context. Since Ruby does not allow declaration of classes within classes, enums declared inside a class must be declared as separate classes outside that class. The relationship is indicated by the Enum's class name. For example, `QMessageBox::Icon` (C++) is available as the Ruby class `QMessageBox_Icon`. The enum values are defined as constants within that class and the enclosing class. For example `QMessageBox::Critical` which is a value for `QMessageBox::Icon` is available as `QMessageBox_Icon::Critical` and `QMessageBox::Critical` in Ruby.

Starting with version 0.24, the `QFlags` template is supported as a separate class. The name of the class indicates the relationship to the enum class. For example, `QFlags<QMessageBox::Icon>` is available as `QMessageBox_QFlags_Icon`. Enum classes are derived from their respective flags class, so they can serve to initialize arguments expecting flags. It's hardly required to operate with the flags classes directly, since they are created automatically when joining enum's with the "or" (`|`) operator:

```
QMessageBox::Ok                        # A QMessageBox_StandardButton object
QMessageBox::Ok | QMessageBox::Cancel  # A QMessageBox_QFlags_StandardButton object
```

With these definitions, the following is allowed:

```
QMessageBox::information(parent, title, text, QMessageBox::Ok | QMessageBox::Cancel)
QMessageBox::information(parent, title, text, QMessageBox::Ok)
```

Using the designer

It is possible to load a dialog from a UI designer (.ui) file. Have a look at the following sample:

```
module MyMacro

  include RBA
```

```
    ui_file = QFile::new(QFileInfo::new($0).dir.filePath("MyDialog.ui"))
    ui_file.open(QIODevice::ReadOnly)
    dialog = QFormBuilder::new.load(ui_file, Application::instance.main_window)
    ui_file.close

    def dialog.setup
      button.clicked do
        slider.value = (slider.value + 1) % 100
      end
    end

    dialog.setup
    dialog.exec

  end
```

This sample tries to locate a designer file called "`MyDialog.ui`" relative to the macro's path (in `$0`). It uses the QFormBuilder class to load and create the dialog. In that sample, "`MyDialog`" defines a dialog with two widgets: a `QPushButton` ("button") and a `QSlider` ("slider"). Because of the dynamic binding in Ruby, "dialog" will already have the correct class and we don't have to cast the pointer delivered by `QFormBuilder::load` before we can call "exec".

This sample exploits a nice Ruby feature: in Ruby it is possible to dynamically add methods to an instance. This allows extending the `QDialog` object we got from `QFormLoader` by custom code. In our case we add a "setup" method. This method installs the custom logic of the dialog. It makes use of a convenience feature implemented in `QObject`'s Ruby binding: all named child objects of an object are available through accessor methods. Therefore we can access "button" and "slider" by their name to install an event handler that updates the slider value each time the button is clicked.

After calling setup on the dialog we have initialized it and we can show it with "exec".

Behind The Scenes

The mechanism behind the Ruby binding a based on the RBA/GSI framework of KLayout. In order to be able to derive from existing classes, that framework needs to add a kind of interfacing class atop of existing classes. Thus, the framework exposes every Qt class in two ways:

- Directly, without the ability to reimplement virtual methods. This is the way, existing Qt objects are addressed. The Ruby classes for that case are called "X_Native" where "X" is the name of the Qt class (for example, "`QObject_Native`"). When you receive a reference to a Qt object created by C++ code, this reference will have the native class type.
- Indirectly through an interface class. This is the object created when you instantiate a Qt object in Ruby. All virtual methods will be rerouted to the Ruby dispatcher. That allows to reimplement every virtual method, but also adds some overhead to every virtual method call. The name of these classes is identical to the name of the Qt class. In the swig tool, those classes are called "director classes".

The difference between the native and interface classes is important if you test the type of a object. The difference between both cases is the scope. The native classes will always match. The interface classes will only match if the object was created by Ruby code:

```
b = dialog.button
# this will not render true, if the button was created by QFormBuilder for example
b.is_a?(QPushButton)
# this is correct:
b.is_a?(QPushButton_Native)
```

To avoid confusion, the native classes do not appear in the documentation. They would just add another level of inheritance without providing additional methods.

4. Class Index

Per-Module documentation:

- Core Module db
- Core Module lay
- Core Module rdb
- Core Module tl

KLayout classes

AbsoluteProgress	tl	A progress reporter counting progress in absolute units
AbstractMenu	lay	An abstraction for the application menus
AbstractProgress	tl	The abstract progress reporter
Action	lay	The abstraction for an action (i.e. used inside menus)
Annotation	lay	A layout annotation (i.e. ruler)
Application	lay	The application object
BitmapBuffer	lay	A simplistic pixel buffer representing monochrome image
Box	db	A box class with integer coordinates
BrowserDialog	lay	A HTML display and browser dialog
BrowserPanel	lay	A HTML display and browser widget
BrowserSource	lay	The BrowserDialog's source for "int" URL's
ButtonState	lay	The namespace for the button state flags in the mouse events of the Plugin class.
Cell	db	A cell
CellInstArray	db	A single or array cell instance
CellMapping	db	A cell mapping (source to target layout)
CellView	lay	A class describing what is shown inside a layout view
Circuit	db	Circuits are the basic building blocks of the netlist
CompoundRegionOperationNode	db	A base class for compound DRC operations
CompoundRegionOperationNode::Geometri	db	This class represents the CompoundRegionOperationNode::GeometricalOp enum
CompoundRegionOperationNode::LogicalOp	db	This class represents the CompoundRegionOperationNode::LogicalOp enum

CompoundRegionOperationNode::Paramete	db	This class represents the parameter type enum used in \CompoundRegionOperationNode#new_bbox_filter
CompoundRegionOperationNode::RatioParamdbterType		This class represents the parameter type enum used in \CompoundRegionOperationNode#new_ratio_filter
CompoundRegionOperationNode::ResultTy	db	This class represents the CompoundRegionOperationNode::ResultType enum
Connectivity	db	This class specifies connections between different layers.
CplxTrans	db	A complex transformation
Cursor	lay	The namespace for the cursor constants
D25View	lay	The 2.5d View Dialog
DBox	db	A box class with floating-point coordinates
DCellInstArray	db	A single or array cell instance in micrometer units
DCplxTrans	db	A complex transformation
DEdge	db	An edge class
DEdgePair	db	An edge pair (a pair of two edges)
DPath	db	A path class
DPoint	db	A point class with double (floating-point) coordinates
DPolygon	db	A polygon class
DSimplePolygon	db	A simple polygon class
DText	db	A text object
DTrans	db	A simple transformation
DVector	db	A vector class with double (floating-point) coordinates
DeepShapeStore	db	An opaque layout heap for the deep region processor
Device	db	A device inside a circuit.
DeviceAbstract	db	A geometrical device abstract
DeviceAbstractRef	db	Describes an additional device abstract reference for combined devices.
DeviceClass	db	A class describing a specific type of device.
DeviceClassBJT3Transistor	db	A device class for a bipolar transistor.
DeviceClassBJT4Transistor	db	A device class for a 4-terminal bipolar transistor.
DeviceClassCapacitor	db	A device class for a capacitor.

DeviceClassCapacitorWithBulk	db	A device class for a capacitor with a bulk terminal (substrate, well).
DeviceClassDiode	db	A device class for a diode.
DeviceClassFactory	db	A factory for creating specific device classes for the standard device extractors
DeviceClassInductor	db	A device class for an inductor.
DeviceClassMOS3Transistor	db	A device class for a 3-terminal MOS transistor.
DeviceClassMOS4Transistor	db	A device class for a 4-terminal MOS transistor.
DeviceClassResistor	db	A device class for a resistor.
DeviceClassResistorWithBulk	db	A device class for a resistor with a bulk terminal (substrate, well).
DeviceExtractorBJT3Transistor	db	A device extractor for a bipolar transistor (BJT)
DeviceExtractorBJT4Transistor	db	A device extractor for a four-terminal bipolar transistor (BJT)
DeviceExtractorBase	db	The base class for all device extractors.
DeviceExtractorCapacitor	db	A device extractor for a two-terminal capacitor
DeviceExtractorCapacitorWithBulk	db	A device extractor for a capacitor with a bulk terminal
DeviceExtractorDiode	db	A device extractor for a planar diode
DeviceExtractorMOS3Transistor	db	A device extractor for a three-terminal MOS transistor
DeviceExtractorMOS4Transistor	db	A device extractor for a four-terminal MOS transistor
DeviceExtractorResistor	db	A device extractor for a two-terminal resistor
DeviceExtractorResistorWithBulk	db	A device extractor for a resistor with a bulk terminal
DeviceParameterDefinition	db	A parameter descriptor
DeviceReconnectedTerminal	db	Describes a terminal rerouting in combined devices.
DeviceTerminalDefinition	db	A terminal descriptor
Dispatcher	lay	Root of the configuration space in the plugin context and menu dispatcher
Edge	db	An edge class
EdgeFilter	db	A generic edge filter adaptor
EdgeMode	db	This class represents the edge mode type for \Region#edges.
EdgeOperator	db	A generic edge-to-polygon operator
EdgePair	db	An edge pair (a pair of two edges)
EdgePairFilter	db	A generic edge pair filter adaptor

EdgePairOperator	db	A generic edge-pair operator
EdgePairToEdgeOperator	db	A generic edge-pair-to-edge operator
EdgePairToPolygonOperator	db	A generic edge-pair-to-polygon operator
EdgePairs	db	EdgePairs (a collection of edge pairs)
EdgeProcessor	db	The edge processor (boolean, sizing, merge)
EdgeToEdgePairOperator	db	A generic edge-to-edge-pair operator
EdgeToPolygonOperator	db	A generic edge-to-polygon operator
Edges	db	A collection of edges (Not necessarily describing closed contours)
Edges::EdgeType	db	This enum specifies the edge type for edge angle filters.
EmptyClass	tl	
EqualDeviceParameters	db	A device parameter equality comparer.
Executable	tl	A generic executable object
Expression	tl	Evaluation of Expressions
ExpressionContext	tl	Represents the context of an expression evaluation
FileDialog	lay	Various methods to request a file name
GenericDeviceCombiner	db	A class implementing the combination of two devices (parallel or serial mode).
GenericDeviceExtractor	db	The basic class for implementing custom device extractors.
GenericDeviceParameterCompare	db	A class implementing the comparison of device parameters.
GenericNetlistCompareLogger	db	An event receiver for the netlist compare feature.
GlobPattern	tl	A glob pattern matcher
HAlign	db	This class represents the horizontal alignment modes.
HelpDialog	lay	The help dialog
HelpSource	lay	A BrowserSource implementation delivering the help text for the help dialog
ICplxTrans	db	A complex transformation
IMatrix2d	db	A 2d matrix object used mainly for representing rotation and shear transformations (integer coordinate version).
IMatrix3d	db	A 3d matrix object used mainly for representing rotation, shear, displacement and perspective transformations (integer coordinate version).

Image	lay	An image to be stored as a layout annotation
ImageDataMapping	lay	A structure describing the data mapping of an image object
InputDialog	lay	Various methods to open a dialog requesting data entry
InstElement	db	An element in an instantiation path
Instance	db	An instance proxy
Interpreter	tl	A generalization of script interpreters
KeyCode	lay	The namespace for the some key codes.
LEFDEFReaderConfiguration	db	Detailed LEF/DEF reader options
LayerInfo	db	A structure encapsulating the layer properties
LayerMap	db	An object representing an arbitrary mapping of physical layers to logical layers
LayerMapping	db	A layer mapping (source to target layout)
LayerProperties	lay	The layer properties structure
LayerPropertiesIterator	lay	Layer properties iterator
LayerPropertiesNode	lay	A layer properties node structure
LayerPropertiesNodeRef	lay	A class representing a reference to a layer properties node
Layout	db	The layout object
LayoutDiff	db	The layout compare tool
LayoutMetaInfo	db	A piece of layout meta information
LayoutQuery	db	A layout query
LayoutQueryIterator	db	Provides the results of the query
LayoutToNetlist	db	A generic framework for extracting netlists from layouts
LayoutToNetlist::BuildNetHierarchyMode	db	This class represents the LayoutToNetlist::BuildNetHierarchyMode enum
LayoutView	lay	The view object presenting one or more layout objects
LayoutView::SelectionMode	lay	Specifies how selected objects interact with already selected ones.
LayoutViewWidget	lay	
LayoutVsSchematic	db	A generic framework for doing LVS (layout vs. schematic)
Library	db	A Library
LoadLayoutOptions	db	Layout reader options

LoadLayoutOptions::CellConflictResolution	db	This enum specifies how cell conflicts are handled if a layout read into another layout and a cell name conflict arises.
LogEntryData	db	A generic log entry
Logger	tl	A logger
Macro	lay	A macro class
Macro::Format	lay	Specifies the format of a macro
Macro::Interpreter	lay	Specifies the interpreter used for executing a macro
MacroExecutionContext	lay	Support for various debugger features
MacroInterpreter	lay	A custom interpreter for a DSL (domain specific language)
MainWindow	lay	The main application window and central controller object
Manager	db	A transaction manager class
Marker	lay	The floating-point coordinate marker object
Matrix2d	db	A 2d matrix object used mainly for representing rotation and shear transformations.
Matrix3d	db	A 3d matrix object used mainly for representing rotation, shear, displacement and perspective transformations.
MessageBox	lay	Various methods to display message boxes
Metrics	db	This class represents the metrics type for \Region#width and related checks.
Net	db	A single net.
NetElement	db	A net element for the NetTracer net tracing facility
NetPinRef	db	A connection to an outgoing pin of the circuit.
NetSubcircuitPinRef	db	A connection to a pin of a subcircuit.
NetTerminalRef	db	A connection to a terminal of a device.
NetTracer	db	The net tracer feature
NetTracerConnectionInfo	db	Represents a single connection info line for the net tracer technology definition
NetTracerConnectivity	db	A connectivity description for the net tracer
NetTracerSymbolInfo	db	Represents a single symbol info line for the net tracer technology definition
NetTracerTechnologyComponent	db	Represents the technology information for the net tracer.
Netlist	db	The netlist top-level class

NetlistBrowserDialog	lay	Represents the netlist browser dialog.
NetlistCompareLogger	db	A base class for netlist comparer event receivers
NetlistComparer	db	Compares two netlists
NetlistCrossReference	db	Represents the identity mapping between the objects of two netlists.
NetlistCrossReference::CircuitPairData	db	A circuit match entry.
NetlistCrossReference::DevicePairData	db	A device match entry.
NetlistCrossReference::NetPairData	db	A net match entry.
NetlistCrossReference::NetPinRefPair	db	A match entry for a net pin pair.
NetlistCrossReference::NetSubcircuitPinRefPair	db	A match entry for a net subcircuit pin pair.
NetlistCrossReference::NetTerminalRefPair	db	A match entry for a net terminal pair.
NetlistCrossReference::PinPairData	db	A pin match entry.
NetlistCrossReference::Status	db	This class represents the NetlistCrossReference::Status enum
NetlistCrossReference::SubCircuitPairData	db	A subcircuit match entry.
NetlistDeviceExtractorLayerDefinition	db	Describes a layer used in the device extraction
NetlistObject	db	The base class for some netlist objects.
NetlistObjectPath	lay	An object describing the instantiation of a netlist object.
NetlistObjectsPath	lay	An object describing the instantiation of a single netlist object or a pair of those.
NetlistReader	db	Base class for netlist readers
NetlistSpiceReader	db	Implements a netlist Reader for the SPICE format.
NetlistSpiceReaderDelegate	db	Provides a delegate for the SPICE reader for translating device statements
NetlistSpiceWriter	db	Implements a netlist writer for the SPICE format.
NetlistSpiceWriterDelegate	db	Provides a delegate for the SPICE writer for doing special formatting for devices
NetlistWriter	db	Base class for netlist writers
ObjectInstPath	lay	A class describing a selected shape or instance
PCellDeclaration	db	A PCell declaration providing the parameters and code to produce the PCell
PCellDeclarationHelper	db	A helper class to simplify the declaration of a PCell (Python version)

PCellDeclarationHelper	db	A helper class to simplify the declaration of a PCell (Ruby version)
PCellParameterDeclaration	db	A PCell parameter declaration
PCellParameterState	db	Provides access to the attributes of a single parameter within \PCellParameterStates.
PCellParameterState::ParameterStateIcon	db	This enum specifies the icon shown next to the parameter in PCell parameter list.
PCellParameterStates	db	Provides access to the parameter states inside a 'callback' implementation of a PCell
ParentInstArray	db	A parent instance
ParseElementComponentsData	db	Supplies the return value for \NetlistSpiceReaderDelegate#parse_element_components.
ParseElementData	db	Supplies the return value for \NetlistSpiceReaderDelegate#parse_element.
Path	db	A path class
Pin	db	A pin of a circuit.
PixelBuffer	lay	A simplistic pixel buffer representing an image of ARGB32 or RGB32 values
Plugin	lay	The plugin object
PluginFactory	lay	The plugin framework's plugin factory object
Point	db	An integer point class
Polygon	db	A polygon class
PolygonFilter	db	A generic polygon filter adaptor
PolygonOperator	db	A generic polygon operator
PolygonToEdgeOperator	db	A generic polygon-to-edge operator
PolygonToEdgePairOperator	db	A generic polygon-to-edge-pair operator
PreferredOrientation	db	This class represents the PreferredOrientation enum used within polygon decomposition
Progress	tl	A progress reporter
PropertyConstraint	db	This class represents the property constraint for boolean and check functions.
RdbCategory	rdb	A category inside the report database
RdbCell	rdb	A cell inside the report database
RdbItem	rdb	An item inside the report database

RdbItemValue	rdb	A value object inside the report database
RdbReference	rdb	A cell reference inside the report database
Recipe	tl	A facility for providing reproducible recipes
RecursiveInstanceIterator	db	An iterator delivering instances recursively
RecursiveShapeIterator	db	An iterator delivering shapes recursively
Region	db	A region (a potentially complex area consisting of multiple polygons)
Region::OppositeFilter	db	This class represents the opposite error filter mode for \Region#separation and related checks.
Region::RectFilter	db	This class represents the error filter mode on rectangles for \Region#separation and related checks.
RelativeProgress	tl	A progress reporter counting progress in relative units
ReportDatabase	rdb	The report database object
SaveLayoutOptions	db	Options for saving layouts
Severity	db	This enum specifies the severity level for log entries.
Shape	db	An object representing a shape in the layout database
ShapeCollection	db	A base class for the shape collections (\Region, \Edges, \EdgePairs and \Texts)
ShapeProcessor	db	The shape processor (boolean, sizing, merge on shapes)
Shapes	db	A collection of shapes
SimplePolygon	db	A simple polygon class
SubCircuit	db	A subcircuit inside a circuit.
Technology	db	Represents a technology
TechnologyComponent	db	A part of a technology definition
Text	db	A text object
TextFilter	db	A generic text filter adaptor
TextGenerator	db	A text generator class
TextOperator	db	A generic text operator
TextToPolygonOperator	db	A generic text-to-polygon operator
Texts	db	Texts (a collection of texts)
TileOutputReceiver	db	A receiver abstraction for the tiling processor.

TilingProcessor	db	A processor for layout which distributes tasks over tiles
Timer	tl	A timer (stop watch)
Trans	db	A simple transformation
TrapezoidDecompositionMode	db	This class represents the TrapezoidDecompositionMode enum used within trapezoid decomposition
Utils	db	This namespace provides a collection of utility functions
VAlign	db	This class represents the vertical alignment modes.
VCplxTrans	db	A complex transformation
Value	tl	Encapsulates a value (preferably a plain data type) in an object
Vector	db	A integer vector class
ZeroDistanceMode	db	This class represents the zero_distance_mode type for \Region#width and related checks.

4.1. API reference - Class EmptyClass

Notation used in Ruby API documentation

Module: tl

Description:

Public constructors

new EmptyClass ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const EmptyClas other)	Assigns another object to self
[const]	new EmptyClass ptr	**dup**		Creates a copy of self

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const EmptyClass other)

Description: Assigns another object to self

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

	Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
destroyed?	**Signature**: *[const]* bool **destroyed?** **Description**: Returns a value indicating whether the object was already destroyed Use of this method is deprecated. Use _destroyed? instead This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
dup	**Signature**: *[const]* new EmptyClass ptr **dup** **Description**: Creates a copy of self **Python specific notes:** This method also implements '__copy__' and '__deepcopy__'.
is_const_object?	**Signature**: *[const]* bool **is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference Use of this method is deprecated. Use _is_const_object? instead This method returns true, if self is a const reference. In that case, only const methods may be called on self.
new	**Signature**: *[static]* new EmptyClass ptr **new** **Description**: Creates a new object of this class **Python specific notes:** This method is the default initializer of the object.

4.2. API reference - Class Value

Notation used in Ruby API documentation

Module: tl

Description: Encapsulates a value (preferably a plain data type) in an object

This class is provided to 'box' a value (encapsulate the value in an object). This class is required to interface to pointer or reference types in a method call. By using that class, the method can alter the value and thus implement 'out parameter' semantics. The value may be 'nil' which acts as a null pointer in pointer type arguments. This class has been introduced in version 0.22.

Public constructors

new Value ptr	**new**		Constructs a nil object.
new Value ptr	**new**	(variant value)	Constructs a non-nil object with the given value.

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const Value other)	Assigns another object to self
[const]	new Value ptr	**dup**		Creates a copy of self
[const]	string	**to_s**		Convert this object to a string
[const]	variant	**value**		Gets the actual value.
	void	**value=**	(variant value)	Set the actual value.

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead

[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const Value other)

Description: Assigns another object to self

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new Value ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

new

(1) Signature: *[static]* new Value ptr **new**

Description: Constructs a nil object.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new Value ptr **new** (variant value)

Description: Constructs a non-nil object with the given value.

This constructor has been introduced in version 0.22.

Python specific notes:
This method is the default initializer of the object.

to_s

Signature: *[const]* string **to_s**

Description: Convert this object to a string

Python specific notes:
This method is also available as 'str(object)'.

value	**Signature**: *[const]* variant **value** **Description**: Gets the actual value. **Python specific notes:** The object exposes a readable attribute 'value'. This is the getter.
value=	**Signature**: void **value=** (variant value) **Description**: Set the actual value. **Python specific notes:** The object exposes a writable attribute 'value'. This is the setter.

4.3. API reference - Class Interpreter

Notation used in Ruby API documentation

Module: tl

Description: A generalization of script interpreters

The main purpose of this class is to provide cross-language call options. Using the Python interpreter, it is possible to execute Python code from Ruby for example.

The following example shows how to use the interpreter class to execute Python code from Ruby and how to pass values from Ruby to Python and back using the Value wrapper object:

```
pya = RBA::Interpreter::python_interpreter
out_param = RBA::Value::new(17)
pya.define_variable("out_param", out_param)
pya.eval_string(<<END)
print("This is Python now!")
out_param.value = out_param.value + 25
END
puts out_param.value  # gives '42'
```

This class was introduced in version 0.27.5.

Public constructors

new Interpreter ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**define_variable**	(string name, variant value)	Defines a (global) variable with the given name and value
	variant	**eval_expr**	(string string, string filename = nil, int line = 1)	Executes the expression inside the given string and returns the result value
	void	**eval_string**	(string string, string filename = nil, int line = 1)	Executes the code inside the given string

void	load_file	(string path)	Loads the given file into the interpreter

Public static methods and constants

Interpreter ptr	python_interpreter	Gets the instance of the Python interpreter
Interpreter ptr	ruby_interpreter	Gets the instance of the Ruby interpreter

Deprecated methods (protected, public, static, non-static and constructors)

	void	create	Use of this method is deprecated. Use _create instead
	void	destroy	Use of this method is deprecated. Use _destroy instead
[const]	bool	destroyed?	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	is_const_object?	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void _**create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void _**destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool _**destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool _**is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void _**manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is

	known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required. Usually it's not required to call this method. It has been introduced in version 0.24.
_unmanage	**Signature**: void **_unmanage** **Description**: Marks the object as no longer owned by the script side. Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur. Usually it's not required to call this method. It has been introduced in version 0.24.
create	**Signature**: void **create** **Description**: Ensures the C++ object is created Use of this method is deprecated. Use _create instead Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
define_variable	**Signature**: void **define_variable** (string name, variant value) **Description**: Defines a (global) variable with the given name and value You can use the Value class to provide 'out' or 'inout' parameters which can be modified by code executed inside the interpreter and read back by the caller.
destroy	**Signature**: void **destroy** **Description**: Explicitly destroys the object Use of this method is deprecated. Use _destroy instead Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
destroyed?	**Signature**: *[const]* bool **destroyed?** **Description**: Returns a value indicating whether the object was already destroyed Use of this method is deprecated. Use _destroyed? instead This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
eval_expr	**Signature**: variant **eval_expr** (string string, string filename = nil, int line = 1) **Description**: Executes the expression inside the given string and returns the result value Use 'filename' and 'line' to indicate the original source for the error messages.
eval_string	**Signature**: void **eval_string** (string string, string filename = nil, int line = 1) **Description**: Executes the code inside the given string Use 'filename' and 'line' to indicate the original source for the error messages.

is_const_object?	**Signature**: *[const]* bool **is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference Use of this method is deprecated. Use _is_const_object? instead This method returns true, if self is a const reference. In that case, only const methods may be called on self.
load_file	**Signature**: void **load_file** (string path) **Description**: Loads the given file into the interpreter This will execute the code inside the file.
new	**Signature**: *[static]* new Interpreter ptr **new** **Description**: Creates a new object of this class **Python specific notes:** This method is the default initializer of the object.
python_interpreter	**Signature**: *[static]* Interpreter ptr **python_interpreter** **Description**: Gets the instance of the Python interpreter
ruby_interpreter	**Signature**: *[static]* Interpreter ptr **ruby_interpreter** **Description**: Gets the instance of the Ruby interpreter

4.4. API reference - Class Logger

Notation used in Ruby API documentation

Module: tl

Description: A logger

The logger outputs messages to the log channels. If the log viewer is open, the log messages will be shown in the logger view. Otherwise they will be printed to the terminal on Linux for example.

A code example:

```
RBA::Logger::error("An error message")
RBA::Logger::warn("A warning")
```

This class has been introduced in version 0.23.

Public constructors

new Logger ptr	**new**		Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const Logger other)	Assigns another object to self
[const]	new Logger ptr	**dup**		Creates a copy of self

Public static methods and constants

	void	**error**	(string msg)	Writes the given string to the error channel
	void	**info**	(string msg)	Writes the given string to the info channel
	void	**log**	(string msg)	Writes the given string to the log channel
	int	**verbosity**		Returns the verbosity level

	void	verbosity=	(int v)	Sets the verbosity level for the application
	void	warn	(string msg)	Writes the given string to the warning channel

Deprecated methods (protected, public, static, non-static and constructors)

	void	create	Use of this method is deprecated. Use _create instead
	void	destroy	Use of this method is deprecated. Use _destroy instead
[const]	bool	destroyed?	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	is_const_object?	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void _**create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void _**destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool _**destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool _**is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void _**manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const Logger other)

Description: Assigns another object to self

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new Logger ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

error

Signature: *[static]* void **error** (string msg)

Description: Writes the given string to the error channel

The error channel is formatted as an error (i.e. red in the logger window) and output unconditionally.

info

Signature: *[static]* void **info** (string msg)

Description: Writes the given string to the info channel

The info channel is printed as neutral messages unconditionally.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

log

Signature: *[static]* void **log** (string msg)

Description: Writes the given string to the log channel

Log messages are printed as neutral messages and are output only if the verbosity is above 0.

new

Signature: *[static]* new Logger ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

verbosity

Signature: *[static]* int **verbosity**

Description: Returns the verbosity level

The verbosity level is defined by the application (see -d command line option for example). Level 0 is silent, levels 10, 20, 30 etc. denote levels with increasing verbosity. 11, 21, 31 .. are sublevels which also enable timing logs in addition to messages.

Python specific notes:
The object exposes a readable attribute 'verbosity'. This is the getter.

verbosity=

Signature: *[static]* void **verbosity=** (int v)

Description: Sets the verbosity level for the application

See verbosity for a definition of the verbosity levels. Please note that this method changes the verbosity level for the whole application.

Python specific notes:
The object exposes a writable attribute 'verbosity'. This is the setter.

warn

Signature: *[static]* void **warn** (string msg)

Description: Writes the given string to the warning channel

The warning channel is formatted as a warning (i.e. blue in the logger window) and output unconditionally.

4.5. API reference - Class Timer

Notation used in Ruby API documentation

Module: tl

Description: A timer (stop watch)

The timer provides a way to measure CPU time. It provides two basic methods: start and stop. After it has been started and stopped again, the time can be retrieved using the user and sys attributes, i.e.:

```
t = RBA::Timer::new
t.start
# ... do something
t.stop
puts "it took #{t.sys} seconds (kernel), #{t.user} seconds (user) on the CPU"
```

The time is reported in seconds.

This class has been introduced in version 0.23.

Public constructors

new Timer ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const Timer other)	Assigns another object to self
[const]	new Timer ptr	**dup**		Creates a copy of self
	void	**start**		Starts the timer
	void	**stop**		Stops the timer
[const]	double	**sys**		Returns the elapsed CPU time in kernel mode from start to stop in seconds
[const]	string	**to_s**		Produces a string with the currently elapsed times

[const]	double	**user**	Returns the elapsed CPU time in user mode from start to stop in seconds
[const]	double	**wall**	Returns the elapsed real time from start to stop in seconds

Public static methods and constants

unsigned long	**memory_size**	Gets the current memory usage of the process in Bytes

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is

	known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required. Usually it's not required to call this method. It has been introduced in version 0.24.
_unmanage	**Signature**: void **_unmanage** **Description**: Marks the object as no longer owned by the script side. Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur. Usually it's not required to call this method. It has been introduced in version 0.24.
assign	**Signature**: void **assign** (const Timer other) **Description**: Assigns another object to self
create	**Signature**: void **create** **Description**: Ensures the C++ object is created Use of this method is deprecated. Use _create instead Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
destroy	**Signature**: void **destroy** **Description**: Explicitly destroys the object Use of this method is deprecated. Use _destroy instead Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
destroyed?	**Signature**: *[const]* bool **destroyed?** **Description**: Returns a value indicating whether the object was already destroyed Use of this method is deprecated. Use _destroyed? instead This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
dup	**Signature**: *[const]* new Timer ptr **dup** **Description**: Creates a copy of self **Python specific notes:** This method also implements '__copy__' and '__deepcopy__'.
is_const_object?	**Signature**: *[const]* bool **is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference Use of this method is deprecated. Use _is_const_object? instead This method returns true, if self is a const reference. In that case, only const methods may be called on self.

memory_size	**Signature**: *[static]* unsigned long **memory_size** **Description**: Gets the current memory usage of the process in Bytes This method has been introduced in version 0.27.
new	**Signature**: *[static]* new Timer ptr **new** **Description**: Creates a new object of this class **Python specific notes:** This method is the default initializer of the object.
start	**Signature**: void **start** **Description**: Starts the timer
stop	**Signature**: void **stop** **Description**: Stops the timer
sys	**Signature**: *[const]* double **sys** **Description**: Returns the elapsed CPU time in kernel mode from start to stop in seconds
to_s	**Signature**: *[const]* string **to_s** **Description**: Produces a string with the currently elapsed times **Python specific notes:** This method is also available as 'str(object)'.
user	**Signature**: *[const]* double **user** **Description**: Returns the elapsed CPU time in user mode from start to stop in seconds
wall	**Signature**: *[const]* double **wall** **Description**: Returns the elapsed real time from start to stop in seconds This method has been introduced in version 0.26.

4.6. API reference - Class Progress

Notation used in Ruby API documentation

Module: tl

Description: A progress reporter

This is the base class for all progress reporter objects. Progress reporter objects are used to report the progress of some operation and to allow aborting an operation. Progress reporter objects must be triggered periodically, i.e. a value must be set. On the display side, a progress bar usually is used to represent the progress of an operation.

Actual implementations of the progress reporter class are RelativeProgress and AbsoluteProgress.

This class has been introduced in version 0.23.

Public constructors

new Progress ptr	**new**		Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	string	**desc**		Gets the description text of the progress object
	void	**desc=**	(string desc)	Sets the description text of the progress object
	void	**title=**	(string title)	Sets the title text of the progress object

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

	Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
desc	**Signature**: *[const]* string **desc** **Description**: Gets the description text of the progress object **Python specific notes:** The object exposes a readable attribute 'desc'. This is the getter.
desc=	**Signature**: void **desc=** (string desc) **Description**: Sets the description text of the progress object **Python specific notes:** The object exposes a writable attribute 'desc'. This is the setter.
destroy	**Signature**: void **destroy** **Description**: Explicitly destroys the object Use of this method is deprecated. Use _destroy instead Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
destroyed?	**Signature**: *[const]* bool **destroyed?** **Description**: Returns a value indicating whether the object was already destroyed Use of this method is deprecated. Use _destroyed? instead This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
is_const_object?	**Signature**: *[const]* bool **is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference Use of this method is deprecated. Use _is_const_object? instead This method returns true, if self is a const reference. In that case, only const methods may be called on self.
new	**Signature**: *[static]* new Progress ptr **new** **Description**: Creates a new object of this class **Python specific notes:** This method is the default initializer of the object.
title=	**Signature**: void **title=** (string title) **Description**: Sets the title text of the progress object Initially the title is equal to the description. **Python specific notes:** The object exposes a writable attribute 'title'. This is the setter.

4.7. API reference - Class AbstractProgress

Notation used in Ruby API documentation

Module: tl

Description: The abstract progress reporter

Class hierarchy: AbstractProgress » Progress

The abstract progress reporter acts as a 'bracket' for a sequence of operations which are connected logically. For example, a DRC script consists of multiple operations. An abstract progress reportert is instantiated during the run time of the DRC script. This way, the application leaves the UI open while the DRC executes and log messages can be collected.

The abstract progress does not have a value.

This class has been introduced in version 0.27.

Public constructors

new AbstractProgress ptr	**new**	(string desc)		Creates an abstract progress reporter with the given description

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const AbstractPrc other)	Assigns another object to self
[const]	new AbstractProgress ptr	**dup**		Creates a copy of self

Detailed description

_create

Signature: void _create

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void _destroy

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const AbstractProgress other)

Description: Assigns another object to self

dup

Signature: *[const]* new AbstractProgress ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

new

Signature: *[static]* new AbstractProgress ptr **new** (string desc)

Description: Creates an abstract progress reporter with the given description

Python specific notes:
This method is the default initializer of the object.

4.8. API reference - Class RelativeProgress

Notation used in Ruby API documentation

Module: tl

Description: A progress reporter counting progress in relative units

Class hierarchy: RelativeProgress » Progress

A relative progress reporter counts from 0 to some maximum value representing 0 to 100 percent completion of a task. The progress can be configured to have a description text, a title and a format. The "inc" method increments the value, the "set" or "value=" methods set the value to a specific value.

While one of these three methods is called, they will run the event loop in regular intervals. That makes the application respond to mouse clicks, specifically the Cancel button on the progress bar. If that button is clicked, an exception will be raised by these methods.

The progress object must be destroyed explicitly in order to remove the progress status bar.

A code example:

```
p = RBA::RelativeProgress::new("test", 10000000)
begin
  10000000.times { p.inc }
ensure
  p.destroy
end
```

This class has been introduced in version 0.23.

Public constructors

new RelativeProgress ptr	**new**	(string desc, unsigned long max_value)	Creates a relative progress reporter with the given description and maximum value
new RelativeProgress ptr	**new**	(string desc, unsigned long max_value, unsigned long yield_interval)	Creates a relative progress reporter with the given description and maximum value

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const RelativeProgress other)	Assigns another object to self

[const]	new RelativeProgress ptr	**dup**		Creates a copy of self
	void	**format=**	(string format)	sets the output format (sprintf notation) for the progress text
	RelativeProgress	**inc**		Increments the progress value
	void	**set**	(unsigned long value, bool force_yield)	Sets the progress value
	void	**value=**	(unsigned long value)	Sets the progress value

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const RelativeProgress other)

Description: Assigns another object to self

dup

Signature: *[const]* new RelativeProgress ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

format=

Signature: void **format=** (string format)

Description: sets the output format (sprintf notation) for the progress text

Python specific notes:
The object exposes a writable attribute 'format'. This is the setter.

inc

Signature: RelativeProgress **inc**

Description: Increments the progress value

new

(1) Signature: *[static]* new RelativeProgress ptr **new** (string desc, unsigned long max_value)

Description: Creates a relative progress reporter with the given description and maximum value

The reported progress will be 0 to 100% for values between 0 and the maximum value. The values are always integers. Double values cannot be used property.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new RelativeProgress ptr **new** (string desc, unsigned long max_value, unsigned long yield_interval)

Description: Creates a relative progress reporter with the given description and maximum value

The reported progress will be 0 to 100% for values between 0 and the maximum value. The values are always integers. Double values cannot be used property.

The yield interval specifies, how often the event loop will be triggered. When the yield interval is 10 for example, the event loop will be executed every tenth call of inc or set.

Python specific notes:
This method is the default initializer of the object.

set

Signature: void **set** (unsigned long value, bool force_yield)

Description: Sets the progress value

This method is equivalent to value=, but it allows forcing the event loop to be triggered. If "force_yield" is true, the event loop will be triggered always, irregardless of the yield interval specified in the constructor.

value=

Signature: void **value=** (unsigned long value)

Description: Sets the progress value

Python specific notes:
The object exposes a writable attribute 'value'. This is the setter.

4.9. API reference - Class AbsoluteProgress

Notation used in Ruby API documentation

Module: tl

Description: A progress reporter counting progress in absolute units

Class hierarchy: AbsoluteProgress » Progress

An absolute progress reporter counts from 0 upwards without a known limit. A unit value is used to convert the value to a bar value. One unit corresponds to 1% on the bar. For formatted output, a format string can be specified as well as a unit value by which the current value is divided before it is formatted.

The progress can be configured to have a description text, a title and a format. The "inc" method increments the value, the "set" or "value=" methods set the value to a specific value.

While one of these three methods is called, they will run the event loop in regular intervals. That makes the application respond to mouse clicks, specifically the Cancel button on the progress bar. If that button is clicked, an exception will be raised by these methods.

The progress object must be destroyed explicitly in order to remove the progress status bar.

The following sample code creates a progress bar which displays the current count as "Megabytes". For the progress bar, one percent corresponds to 16 kByte:

```
p = RBA::AbsoluteProgress::new("test")
p.format = "%.2f MBytes"
p.unit = 1024*16
p.format_unit = 1024*1024
begin
  10000000.times { p.inc }
ensure
  p.destroy
end
```

This class has been introduced in version 0.23.

Public constructors

new AbsoluteProgress ptr	**new**	(string desc)	Creates an absolute progress reporter with the given description
new AbsoluteProgress ptr	**new**	(string desc, unsigned long yield_interval)	Creates an absolute progress reporter with the given description

Public methods

	void	**_create**	Ensures the C++ object is created
	void	**_destroy**	Explicitly destroys the object
[const]	bool	**_destroyed?**	Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**	Returns a value indicating whether the reference is a const reference
	void	**_manage**	Marks the object as managed by the script side.

	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const AbsoluteProgress other)	Assigns another object to self
[const]	new AbsoluteProgress ptr	**dup**		Creates a copy of self
	void	**format=**	(string format)	sets the output format (sprintf notation) for the progress text
	void	**format_unit=**	(double unit)	Sets the format unit
	AbsoluteProgress	**inc**		Increments the progress value
	void	**set**	(unsigned long value, bool force_yield)	Sets the progress value
	void	**unit=**	(double unit)	Sets the unit
	void	**value=**	(unsigned long value)	Sets the progress value

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

	After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required. Usually it's not required to call this method. It has been introduced in version 0.24.
_unmanage	**Signature**: void **_unmanage** **Description**: Marks the object as no longer owned by the script side. Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur. Usually it's not required to call this method. It has been introduced in version 0.24.
assign	**Signature**: void **assign** (const AbsoluteProgress other) **Description**: Assigns another object to self
dup	**Signature**: *[const]* new AbsoluteProgress ptr **dup** **Description**: Creates a copy of self **Python specific notes:** This method also implements '__copy__' and '__deepcopy__'.
format=	**Signature**: void **format=** (string format) **Description**: sets the output format (sprintf notation) for the progress text **Python specific notes:** The object exposes a writable attribute 'format'. This is the setter.
format_unit=	**Signature**: void **format_unit=** (double unit) **Description**: Sets the format unit This is the unit used for formatted output. The current count is divided by the format unit to render the value passed to the format string. **Python specific notes:** The object exposes a writable attribute 'format_unit'. This is the setter.
inc	**Signature**: AbsoluteProgress **inc** **Description**: Increments the progress value
new	**(1) Signature**: *[static]* new AbsoluteProgress ptr **new** (string desc) **Description**: Creates an absolute progress reporter with the given description **Python specific notes:** This method is the default initializer of the object. **(2) Signature**: *[static]* new AbsoluteProgress ptr **new** (string desc, unsigned long yield_interval) **Description**: Creates an absolute progress reporter with the given description

The yield interval specifies, how often the event loop will be triggered. When the yield interval is 10 for example, the event loop will be executed every tenth call of inc or set.

Python specific notes:
This method is the default initializer of the object.

set

Signature: void **set** (unsigned long value, bool force_yield)

Description: Sets the progress value

This method is equivalent to value=, but it allows forcing the event loop to be triggered. If "force_yield" is true, the event loop will be triggered always, irregardless of the yield interval specified in the constructor.

unit=

Signature: void **unit=** (double unit)

Description: Sets the unit

Specifies the count value corresponding to 1 percent on the progress bar. By default, the current value divided by the unit is used to create the formatted value from the output string. Another attribute is provided (format_unit=) to specify a separate unit for that purpose.

Python specific notes:
The object exposes a writable attribute 'unit'. This is the setter.

value=

Signature: void **value=** (unsigned long value)

Description: Sets the progress value

Python specific notes:
The object exposes a writable attribute 'value'. This is the setter.

4.10. API reference - Class ExpressionContext

Notation used in Ruby API documentation

Module: tl

Description: Represents the context of an expression evaluation

The context provides a variable namespace for the expression evaluation.

This class has been introduced in version 0.26 when Expression was separated into the execution and context part.

Public constructors

new ExpressionContext ptr	**new**		Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const ExpressionCont other)	Assigns another object to self
[const]	new ExpressionContext ptr	**dup**		Creates a copy of self
	variant	**eval**	(string expr)	Compiles and evaluates the given expression in this context
	void	**var**	(string name, variant value)	Defines a variable with the given name and value

Public static methods and constants

void	**global_var**	(string name, variant value)	Defines a global variable with the given name and value

Deprecated methods (protected, public, static, non-static and constructors)

void	**create**		Use of this method is deprecated. Use _create instead

	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const ExpressionContext other)

Description: Assigns another object to self

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new ExpressionContext ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

eval

Signature: variant **eval** (string expr)

Description: Compiles and evaluates the given expression in this context

This method has been introduced in version 0.26.

global_var

Signature: *[static]* void **global_var** (string name, variant value)

Description: Defines a global variable with the given name and value

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

new

Signature: *[static]* new ExpressionContext ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

var

Signature: void **var** (string name, variant value)

Description: Defines a variable with the given name and value

4.11. API reference - Class Expression

Notation used in Ruby API documentation

Module: tl

Description: Evaluation of Expressions

Class hierarchy: Expression » ExpressionContext

This class allows evaluation of expressions. Expressions are used in many places throughout KLayout and provide computation features for various applications. Having a script language, there is no real use for expressions inside a script client. This class is provided mainly for testing purposes.

An expression is 'compiled' into an Expression object and can be evaluated multiple times.

This class has been introduced in version 0.25. In version 0.26 it was separated into execution and context.

Public constructors

new Expression ptr	**new**	(string expr)	Creates an expression evaluator
new Expression ptr	**new**	(string expr, map<string,variant> variables)	Creates an expression evaluator

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	variant	**eval**		Evaluates the current expression and returns the result
	void	**text=**	(string expr)	Sets the given text as the expression.

Public static methods and constants

variant	**eval**	(string expr)	A convience function to evaluate the given expression and directly return the result

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

eval

(1) Signature: variant **eval**

Description: Evaluates the current expression and returns the result

Python specific notes:
This instance method is available as '_inst_eval' in Python.

(2) Signature: *[static]* variant **eval** (string expr)

Description: A convience function to evaluate the given expression and directly return the result

This is a static method that does not require instantiation of the expression object first.

Python specific notes:
This class method is available as '_class_eval' in Python.

new	**(1) Signature**: *[static]* new Expression ptr **new** (string expr) **Description**: Creates an expression evaluator **Python specific notes:** This method is the default initializer of the object. **(2) Signature**: *[static]* new Expression ptr **new** (string expr, map<string,variant> variables) **Description**: Creates an expression evaluator This version of the constructor takes a hash of variables available to the expressions. **Python specific notes:** This method is the default initializer of the object.
text=	**Signature**: void **text=** (string expr) **Description**: Sets the given text as the expression. **Python specific notes:** The object exposes a writable attribute 'text'. This is the setter.

4.12. API reference - Class GlobPattern

Notation used in Ruby API documentation

Module: tl

Description: A glob pattern matcher

This class is provided to make KLayout's glob pattern matching available to scripts too. The intention is to provide an implementation which is compatible with KLayout's pattern syntax.

This class has been introduced in version 0.26.

Public constructors

new GlobPattern ptr	**new**	(string pattern)		Creates a new glob pattern match object

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const GlobPattern other)	Assigns another object to self
[const]	bool	**case_sensitive**		Gets a value indicating whether the glob pattern match is case sensitive.
	void	**case_sensitive=**	(bool case_sensitive)	Sets a value indicating whether the glob pattern match is case sensitive.
[const]	new GlobPattern ptr	**dup**		Creates a copy of self
[const]	bool	**head_match**		Gets a value indicating whether trailing characters are allowed.
	void	**head_match=**	(bool head_match)	Sets a value indicating whether trailing characters are allowed.
[const]	variant	**match**	(string subject)	Matches the subject string against the pattern.

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method

will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const GlobPattern other)

Description: Assigns another object to self

case_sensitive

Signature: *[const]* bool **case_sensitive**

Description: Gets a value indicating whether the glob pattern match is case sensitive.

Python specific notes:
The object exposes a readable attribute 'case_sensitive'. This is the getter.

case_sensitive=

Signature: void **case_sensitive=** (bool case_sensitive)

Description: Sets a value indicating whether the glob pattern match is case sensitive.

Python specific notes:
The object exposes a writable attribute 'case_sensitive'. This is the setter.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new GlobPattern ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

head_match

Signature: *[const]* bool **head_match**

Description: Gets a value indicating whether trailing characters are allowed.

Python specific notes:

	The object exposes a readable attribute 'head_match'. This is the getter.
head_match=	**Signature**: void **head_match=** (bool head_match) **Description**: Sets a value indicating whether trailing characters are allowed. If this predicate is false, the glob pattern needs to match the full subject string. If true, the match function will ignore trailing characters and return true if the front part of the subject string matches. **Python specific notes:** The object exposes a writable attribute 'head_match'. This is the setter.
is_const_object?	**Signature**: *[const]* bool **is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference Use of this method is deprecated. Use _is_const_object? instead This method returns true, if self is a const reference. In that case, only const methods may be called on self.
match	**Signature**: *[const]* variant **match** (string subject) **Description**: Matches the subject string against the pattern. Returns nil if the subject string does not match the pattern. Otherwise returns a list with the substrings captured in round brackets.
new	**Signature**: *[static]* new GlobPattern ptr **new** (string pattern) **Description**: Creates a new glob pattern match object **Python specific notes:** This method is the default initializer of the object.

4.13. API reference - Class Executable

Notation used in Ruby API documentation

Module: tl

Description: A generic executable object

Class hierarchy: Executable

This object is a delegate for implementing the actual function of some generic executable function. In addition to the plain execution, if offers a post-mortem cleanup callback which is always executed, even if execute's implementation is cancelled in the debugger.

Parameters are kept as a generic key/value map.

This class has been introduced in version 0.27.

Public constructors

new Executable ptr	**new**	Creates a new object of this class

Public methods

	void	**_assign**	(const Executable other)	Assigns another object to self
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	new Executable ptr	**_dup**		Creates a copy of self
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const Executable other)	Assigns another object to self
[virtual]	void	**cleanup**		Reimplement this method to provide post-mortem cleanup functionality.
[const]	new Executable ptr	**dup**		Creates a copy of self
[virtual]	variant	**execute**		Reimplement this method to provide the functionality of the executable.

Deprecated methods (protected, public, static, non-static and constructors)

void	**create**	Use of this method is deprecated. Use _create instead

	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_assign

Signature: void **_assign** (const Executable other)

Description: Assigns another object to self

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_dup

Signature: *[const]* new Executable ptr **_dup**

Description: Creates a copy of self

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const Executable other)

Description: Assigns another object to self

cleanup

Signature: *[virtual]* void **cleanup**

Description: Reimplement this method to provide post-mortem cleanup functionality.

This method is always called after execute terminated.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new Executable ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

execute

Signature: *[virtual]* variant **execute**

Description: Reimplement this method to provide the functionality of the executable.

This method is supposed to execute the operation with the given parameters and return the desired output.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

new

Signature: *[static]* new Executable ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

4.14. API reference - Class Recipe

Notation used in Ruby API documentation

Module: tl

Description: A facility for providing reproducible recipes

The idea of this facility is to provide a service by which an object can be reproduced in a parametrized way. The intended use case is a DRC report for example, where the DRC script is the generator.

In this use case, the DRC engine will register a recipe. It will put the serialized version of the recipe into the DRC report. If the user requests a re-run of the DRC, the recipe will be called and the implementation is supposed to deliver a new database.

To register a recipe, reimplement the Recipe class and create an instance. To serialize a recipe, use "generator", to execute the recipe, use "make".

Parameters are kept as a generic key/value map.

This class has been introduced in version 0.26.

Public constructors

new Recipe ptr	**new**	(string name, string description = "")	Creates a new recipe object with the given name and (optional) description

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	string	**description**		Gets the description of the recipe.
[virtual,const]	Executable ptr	**executable**	(map<string,variant> params)	Reimplement this method to provide an executable object for the actual implementation.
	string	**generator**	(map<string,v params)	Delivers the generator string from the given parameters.
[const]	string	**name**		Gets the name of the recipe.

Public static methods and constants

variant	**make**	(string generator, map<string,variant> add_params = {})	Executes the recipe given by the generator string.

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void _**create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void _**destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool _**destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool _**is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void _**manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void _**unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method

will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

description

Signature: *[const]* string **description**

Description: Gets the description of the recipe.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

executable

Signature: *[virtual,const]* Executable ptr **executable** (map<string,variant> params)

Description: Reimplement this method to provide an executable object for the actual implementation.

The reasoning behind this architecture is to supply a cleanup callback. This is useful when the actual function is executed as a script and the script terminates in the debugger. The cleanup callback allows implementing any kind of post-mortem action despite being cancelled in the debugger.

This method has been introduced in version 0.27 and replaces 'execute'.

generator

Signature: string **generator** (map<string,variant> params)

Description: Delivers the generator string from the given parameters.

The generator string can be used with make to re-run the recipe.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

make

Signature: *[static]* variant **make** (string generator, map<string,variant> add_params = {})

Description: Executes the recipe given by the generator string.

The generator string is the one delivered with generator. Additional parameters can be passed in "add_params". They have lower priority than the parameters kept inside the generator string.

name

Signature: *[const]* string **name**

Description: Gets the name of the recipe.

new

Signature: *[static]* new Recipe ptr **new** (string name, string description = "")

Description: Creates a new recipe object with the given name and (optional) description

Python specific notes:
This method is the default initializer of the object.

4.15. API reference - Class PixelBuffer

Notation used in Ruby API documentation

Module: lay

Description: A simplistic pixel buffer representing an image of ARGB32 or RGB32 values

This object is mainly provided for offline rendering of layouts in Qt-less environments. It supports a rectangular pixel space with color values encoded in 32bit integers. It supports transparency through an optional alpha channel. The color format for a pixel is "0xAARRGGBB" where 'AA' is the alpha value which is ignored in non-transparent mode.

This class supports basic operations such as initialization, single-pixel access and I/O to PNG.

This class has been introduced in version 0.28.

Public constructors

new PixelBuffer ptr	**new**	(unsigned int width, unsigned int height)	Creates a pixel buffer object

Public methods

[const]	bool	**!=**	(const PixelBuffer other)	Returns a value indicating whether self is not identical to the other image
[const]	bool	**==**	(const PixelBuffer other)	Returns a value indicating whether self is identical to the other image
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const PixelBuffer other)	Assigns another object to self
[const]	PixelBuffer	**diff**	(const PixelBuffer other)	Creates a difference image
[const]	new PixelBuffer ptr	**dup**		Creates a copy of self
	void	**fill**	(unsigned int color)	Fills the pixel buffer with the given pixel value
	void	**fill**	(QColor color)	Fills the pixel buffer with the given QColor
[const]	unsigned int	**height**		Gets the height of the pixel buffer in pixels

	void	**patch**	(const PixelBuffer other)	Patches another pixel buffer into this one
[const]	unsigned int	**pixel**	(unsigned int x, unsigned int y)	Gets the value of the pixel at position x, y
	void	**set_pixel**	(unsigned int x, unsigned int y, unsigned int c)	Sets the value of the pixel at position x, y
	void	**swap**	(PixelBuffer other)	Swaps data with another PixelBuffer object
[const]	bytes	**to_png_data**		Converts the pixel buffer to a PNG byte stream
[const]	QImage	**to_qimage**		Converts the pixel buffer to a QImage object
[const]	bool	**transparent**		Gets a flag indicating whether the pixel buffer supports an alpha channel
	void	**transparent=**	(bool t)	Sets a flag indicating whether the pixel buffer supports an alpha channel
[const]	unsigned int	**width**		Gets the width of the pixel buffer in pixels
[const]	void	**write_png**	(string file)	Writes the pixel buffer to a PNG file

Public static methods and constants

PixelBuffer	**from_png_data**	(bytes data)	Reads the pixel buffer from a PNG byte stream
PixelBuffer	**from_qimage**	(const QImage qimage)	Creates a pixel buffer object from a QImage object
PixelBuffer	**read_png**	(string file)	Reads the pixel buffer from a PNG file

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=

Signature: *[const]* bool **!=** (const PixelBuffer other)

Description: Returns a value indicating whether self is not identical to the other image

==	**Signature**: *[const]* bool **==** (const PixelBuffer other) **Description**: Returns a value indicating whether self is identical to the other image
_create	**Signature**: void **_create** **Description**: Ensures the C++ object is created Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
_destroy	**Signature**: void **_destroy** **Description**: Explicitly destroys the object Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
_destroyed?	**Signature**: *[const]* bool **_destroyed?** **Description**: Returns a value indicating whether the object was already destroyed This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
_is_const_object?	**Signature**: *[const]* bool **_is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference This method returns true, if self is a const reference. In that case, only const methods may be called on self.
_manage	**Signature**: void **_manage** **Description**: Marks the object as managed by the script side. After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required. Usually it's not required to call this method. It has been introduced in version 0.24.
_unmanage	**Signature**: void **_unmanage** **Description**: Marks the object as no longer owned by the script side. Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur. Usually it's not required to call this method. It has been introduced in version 0.24.
assign	**Signature**: void **assign** (const PixelBuffer other) **Description**: Assigns another object to self

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

diff

Signature: *[const]* PixelBuffer **diff** (const PixelBuffer other)

Description: Creates a difference image

This method is provided to support transfer of image differences - i.e. small updates instead of full images. It works for non-transparent images only and generates an image with transpareny enabled and with the new pixel values for pixels that have changed. The alpha value will be 0 for identical images and 255 for pixels with different values. This way, the difference image can be painted over the original image to generate the new image.

dup

Signature: *[const]* new PixelBuffer ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

fill

(1) Signature: void **fill** (unsigned int color)

Description: Fills the pixel buffer with the given pixel value

(2) Signature: void **fill** (QColor color)

Description: Fills the pixel buffer with the given QColor

from_png_data

Signature: *[static]* PixelBuffer **from_png_data** (bytes data)

Description: Reads the pixel buffer from a PNG byte stream

This method may not be available if PNG support is not compiled into KLayout.

from_qimage

Signature: *[static]* PixelBuffer **from_qimage** (const QImage qimage)

Description: Creates a pixel buffer object from a QImage object

height

Signature: *[const]* unsigned int **height**

Description: Gets the height of the pixel buffer in pixels

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

new

Signature: *[static]* new PixelBuffer ptr **new** (unsigned int width, unsigned int height)

Description: Creates a pixel buffer object

width:	The width in pixels
height:	The height in pixels

The pixels are basically uninitialized. You will need to use fill to initialize them to a certain value.

Python specific notes:
This method is the default initializer of the object.

patch

Signature: void **patch** (const PixelBuffer other)

Description: Patches another pixel buffer into this one

This method is the inverse of diff - it will patch the difference image created by diff into this pixel buffer. Note that this method will not do true alpha blending and requires the other pixel buffer to have the same format than self. Self will be modified by this operation.

pixel

Signature: *[const]* unsigned int **pixel** (unsigned int x, unsigned int y)

Description: Gets the value of the pixel at position x, y

read_png

Signature: *[static]* PixelBuffer **read_png** (string file)

Description: Reads the pixel buffer from a PNG file

This method may not be available if PNG support is not compiled into KLayout.

set_pixel

Signature: void **set_pixel** (unsigned int x, unsigned int y, unsigned int c)

Description: Sets the value of the pixel at position x, y

swap

Signature: void **swap** (PixelBuffer other)

Description: Swaps data with another PixelBuffer object

to_png_data

Signature: *[const]* bytes **to_png_data**

Description: Converts the pixel buffer to a PNG byte stream

This method may not be available if PNG support is not compiled into KLayout.

to_qimage

Signature: *[const]* QImage **to_qimage**

Description: Converts the pixel buffer to a QImage object

transparent	**Signature**: *[const]* bool **transparent** **Description**: Gets a flag indicating whether the pixel buffer supports an alpha channel **Python specific notes:** The object exposes a readable attribute 'transparent'. This is the getter.
transparent=	**Signature**: void **transparent=** (bool t) **Description**: Sets a flag indicating whether the pixel buffer supports an alpha channel By default, the pixel buffer does not support an alpha channel. **Python specific notes:** The object exposes a writable attribute 'transparent'. This is the setter.
width	**Signature**: *[const]* unsigned int **width** **Description**: Gets the width of the pixel buffer in pixels
write_png	**Signature**: *[const]* void **write_png** (string file) **Description**: Writes the pixel buffer to a PNG file This method may not be available if PNG support is not compiled into KLayout.

4.16. API reference - Class BitmapBuffer

Notation used in Ruby API documentation

Module: lay

Description: A simplistic pixel buffer representing monochrome image

This object is mainly provided for offline rendering of layouts in Qt-less environments. It supports a rectangular pixel space with color values encoded in single bits.

This class supports basic operations such as initialization, single-pixel access and I/O to PNG.

This class has been introduced in version 0.28.

Public constructors

new BitmapBuffer ptr	**new**	(unsigned int width, unsigned int height)	Creates a pixel buffer object

Public methods

[const]	bool	**!=**	(const BitmapBuffer other)	Returns a value indicating whether self is not identical to the other image
[const]	bool	**==**	(const BitmapBuffer other)	Returns a value indicating whether self is identical to the other image
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const BitmapBuffer other)	Assigns another object to self
[const]	new BitmapBuffer ptr	**dup**		Creates a copy of self
	void	**fill**	(bool color)	Fills the pixel buffer with the given pixel value
[const]	unsigned int	**height**		Gets the height of the pixel buffer in pixels
[const]	bool	**pixel**	(unsigned int x, unsigned int y)	Gets the value of the pixel at position x, y

	void	**set_pixel**	(unsigned int x, unsigned int y, bool c)	Sets the value of the pixel at position x, y
	void	**swap**	(BitmapBuffer other)	Swaps data with another BitmapBuffer object
[const]	bytes	**to_png_data**		Converts the pixel buffer to a PNG byte stream
[const]	QImage	**to_qimage**		Converts the pixel buffer to a QImage object
[const]	unsigned int	**width**		Gets the width of the pixel buffer in pixels
[const]	void	**write_png**	(string file)	Writes the pixel buffer to a PNG file

Public static methods and constants

	BitmapBuffer	**from_png_data**	(bytes data)	Reads the pixel buffer from a PNG byte stream
	BitmapBuffer	**from_qimage**	(const QImage qimage)	Creates a pixel buffer object from a QImage object
	BitmapBuffer	**read_png**	(string file)	Reads the pixel buffer from a PNG file

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=

Signature: *[const]* bool **!=** (const BitmapBuffer other)

Description: Returns a value indicating whether self is not identical to the other image

==

Signature: *[const]* bool **==** (const BitmapBuffer other)

Description: Returns a value indicating whether self is identical to the other image

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const BitmapBuffer other)

Description: Assigns another object to self

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

	Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
destroyed?	**Signature**: *[const]* bool **destroyed?** **Description**: Returns a value indicating whether the object was already destroyed Use of this method is deprecated. Use _destroyed? instead This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
dup	**Signature**: *[const]* new BitmapBuffer ptr **dup** **Description**: Creates a copy of self **Python specific notes:** This method also implements '__copy__' and '__deepcopy__'.
fill	**Signature**: void **fill** (bool color) **Description**: Fills the pixel buffer with the given pixel value
from_png_data	**Signature**: *[static]* BitmapBuffer **from_png_data** (bytes data) **Description**: Reads the pixel buffer from a PNG byte stream This method may not be available if PNG support is not compiled into KLayout.
from_qimage	**Signature**: *[static]* BitmapBuffer **from_qimage** (const QImage qimage) **Description**: Creates a pixel buffer object from a QImage object
height	**Signature**: *[const]* unsigned int **height** **Description**: Gets the height of the pixel buffer in pixels
is_const_object?	**Signature**: *[const]* bool **is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference Use of this method is deprecated. Use _is_const_object? instead This method returns true, if self is a const reference. In that case, only const methods may be called on self.
new	**Signature**: *[static]* new BitmapBuffer ptr **new** (unsigned int width, unsigned int height) **Description**: Creates a pixel buffer object **width**: The width in pixels **height**: The height in pixels The pixels are basically uninitialized. You will need to use fill to initialize them to a certain value. **Python specific notes:** This method is the default initializer of the object.
pixel	**Signature**: *[const]* bool **pixel** (unsigned int x, unsigned int y) **Description**: Gets the value of the pixel at position x, y

read_png	**Signature**: *[static]* BitmapBuffer **read_png** (string file) **Description**: Reads the pixel buffer from a PNG file This method may not be available if PNG support is not compiled into KLayout.
set_pixel	**Signature**: void **set_pixel** (unsigned int x, unsigned int y, bool c) **Description**: Sets the value of the pixel at position x, y
swap	**Signature**: void **swap** (BitmapBuffer other) **Description**: Swaps data with another BitmapBuffer object
to_png_data	**Signature**: *[const]* bytes **to_png_data** **Description**: Converts the pixel buffer to a PNG byte stream This method may not be available if PNG support is not compiled into KLayout.
to_qimage	**Signature**: *[const]* QImage **to_qimage** **Description**: Converts the pixel buffer to a QImage object
width	**Signature**: *[const]* unsigned int **width** **Description**: Gets the width of the pixel buffer in pixels
write_png	**Signature**: *[const]* void **write_png** (string file) **Description**: Writes the pixel buffer to a PNG file This method may not be available if PNG support is not compiled into KLayout.

4.17. API reference - Class Box

Notation used in Ruby API documentation

Module: db

Description: A box class with integer coordinates

This object represents a box (a rectangular shape).

The definition of the attributes is: p1 is the lower left point, p2 the upper right one. If a box is constructed from two points (or four coordinates), the coordinates are sorted accordingly.

A box can be empty. An empty box represents no area (not even a point). Empty boxes behave neutral with respect to most operations. Empty boxes return true on empty?.

A box can be a point or a single line. In this case, the area is zero but the box still can overlap other boxes for example and it is not empty.

See The Database API for more details about the database objects.

Public constructors

new Box ptr	**new**	(const DBox dbox)	Creates an integer coordinate box from a floating-point coordinate box
new Box ptr	**new**		Creates an empty (invalid) box
new Box ptr	**new**	(int w)	Creates a square with the given dimensions centered around the origin
new Box ptr	**new**	(int w, int h)	Creates a rectangle with given width and height, centered around the origin
new Box ptr	**new**	(int left, int bottom, int right, int top)	Creates a box with four coordinates
new Box ptr	**new**	(const Point lower_left, const Point upper_right)	Creates a box from two points

Public methods

[const]	bool	**!=**	(const Box box)	Returns true if this box is not equal to the other box
[const]	Box	**&**	(const Box box)	Returns the intersection of this box with another box
[const]	Box	*****	(const Box box)	Returns the convolution product from this box with another box
[const]	Box	*****	(double scale_factor)	Returns the scaled box
[const]	Box	**+**	(const Point point)	Joins box with a point
[const]	Box	**+**	(const Box box)	Joins two boxes
[const]	Box	**-**	(const Box box)	Subtraction of boxes

[const]	bool	**<**	(const Box box)	Returns true if this box is 'less' than another box
[const]	bool	**==**	(const Box box)	Returns true if this box is equal to the other box
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	double	**area**		Computes the box area
	void	**assign**	(const Box other)	Assigns another object to self
[const]	Box	**bbox**		Returns the bounding box
[const]	int	**bottom**		Gets the bottom coordinate of the box
	void	**bottom=**	(int c)	Sets the bottom coordinate of the box
[const]	Point	**center**		Gets the center of the box
[const]	bool	**contains?**	(int x, int y)	Returns true if the box contains the given point
[const]	bool	**contains?**	(const Point point)	Returns true if the box contains the given point
[const]	new Box ptr	**dup**		Creates a copy of self
[const]	bool	**empty?**		Returns a value indicating whether the box is empty
	Box	**enlarge**	(int dx, int dy)	Enlarges the box by a certain amount.
	Box	**enlarge**	(int d)	Enlarges the box by a certain amount on all sides.
	Box	**enlarge**	(const Vector enlargement)	Enlarges the box by a certain amount.
[const]	Box	**enlarged**	(int dx, int dy)	Enlarges the box by a certain amount.
[const]	Box	**enlarged**	(int d)	Enlarges the box by a certain amount on all sides.

[const]	Box	**enlarged**	(const Vector enlargement)	Returns the enlarged box.
[const]	unsigned long	**hash**		Computes a hash value
[const]	unsigned int	**height**		Gets the height of the box
[const]	bool	**inside?**	(const Box box)	Tests if this box is inside the argument box
[const]	bool	**is_point?**		Returns true, if the box is a single point
[const]	int	**left**		Gets the left coordinate of the box
	void	**left=**	(int c)	Sets the left coordinate of the box
	Box	**move**	(int dx, int dy)	Moves the box by a certain distance
	Box	**move**	(const Vector distance)	Moves the box by a certain distance
[const]	Box	**moved**	(int dx, int dy)	Moves the box by a certain distance
[const]	Box	**moved**	(const Vector distance)	Returns the box moved by a certain distance
[const]	bool	**overlaps?**	(const Box box)	Tests if this box overlaps the argument box
[const]	Point	**p1**		Gets the lower left point of the box
	void	**p1=**	(const Point p)	Sets the lower left point of the box
[const]	Point	**p2**		Gets the upper right point of the box
	void	**p2=**	(const Point p)	Sets the upper right point of the box
[const]	unsigned long	**perimeter**		Returns the perimeter of the box
[const]	int	**right**		Gets the right coordinate of the box
	void	**right=**	(int c)	Sets the right coordinate of the box
[const]	DBox	**to_dtype**	(double dbu = 1)	Converts the box to a floating-point coordinate box
[const]	string	**to_s**	(double dbu = 0)	Returns a string representing this box
[const]	int	**top**		Gets the top coordinate of the box
	void	**top=**	(int c)	Sets the top coordinate of the box
[const]	bool	**touches?**	(const Box box)	Tests if this box touches the argument box
[const]	Box	**transformed**	(const ICplxTrans t)	Transforms the box with the given complex transformation

[const]	Box	**transformed**	(const Trans t)	Returns the box transformed with the given simple transformation
[const]	DBox	**transformed**	(const CplxTrans t)	Returns the box transformed with the given complex transformation
[const]	unsigned int	**width**		Gets the width of the box

Public static methods and constants

new Box ptr	**from_s**	(string s)	Creates a box object from a string
Box	**world**		Gets the 'world' box

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**		Use of this method is deprecated. Use _create instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[static]	new Box ptr	**from_dbox**	(const DBox dbox)	Use of this method is deprecated. Use new instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=

Signature: *[const]* bool **!=** (const Box box)

Description: Returns true if this box is not equal to the other box

Returns true, if this box and the given box are not equal

&

Signature: *[const]* Box **&** (const Box box)

Description: Returns the intersection of this box with another box

box: The box to take the intersection with

Returns: The intersection box

The intersection of two boxes is the largest box common to both boxes. The intersection may be empty if both boxes to not touch. If the boxes do not overlap but touch the result may be a single line or point with an area of zero. Overwrites this box with the result.

*****

(1) Signature: *[const]* Box ***** (const Box box)

Description: Returns the convolution product from this box with another box

box: The box to convolve with this box.

Returns: The convolved box

The * operator convolves the firstbox with the one given as the second argument. The box resulting from "convolution" is the outer boundary of the union set formed by placing the second box at every point of the first. In other words, the returned box of (p1,p2)*(q1,q2) is (p1+q1,p2+q2).

Python specific notes:
This method also implements '__rmul__'.

(2) Signature: *[const]* Box ***** (double scale_factor)

Description: Returns the scaled box

scale_factor:	The scaling factor
Returns:	The scaled box

The * operator scales the box with the given factor and returns the result.

This method has been introduced in version 0.22.

Python specific notes:
This method also implements '__rmul__'.

\+

(1) Signature: *[const]* Box **+** (const Point point)

Description: Joins box with a point

point:	The point to join with this box.
Returns:	The box joined with the point

The + operator joins a point with the box. The resulting box will enclose both the original box and the point.

(2) Signature: *[const]* Box **+** (const Box box)

Description: Joins two boxes

box:	The box to join with this box.
Returns:	The joined box

The + operator joins the first box with the one given as the second argument. Joining constructs a box that encloses both boxes given. Empty boxes are neutral: they do not change another box when joining. Overwrites this box with the result.

\-

Signature: *[const]* Box **-** (const Box box)

Description: Subtraction of boxes

box:	The box to subtract from this box.
Returns:	The result box

The - operator subtracts the argument box from self. This will return the bounding box of the are covered by self, but not by argument box. Subtracting a box from itself will render an empty box. Subtracting another box from self will modify the first box only if the argument box covers one side entirely.

This feature has been introduced in version 0.29.

<

Signature: *[const]* bool **<** (const Box box)

Description: Returns true if this box is 'less' than another box

Returns true, if this box is 'less' with respect to first and second point (in this order)

==	**Signature**: *[const]* bool **==** (const Box box) **Description**: Returns true if this box is equal to the other box Returns true, if this box and the given box are equal
_create	**Signature**: void **_create** **Description**: Ensures the C++ object is created Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
_destroy	**Signature**: void **_destroy** **Description**: Explicitly destroys the object Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
_destroyed?	**Signature**: *[const]* bool **_destroyed?** **Description**: Returns a value indicating whether the object was already destroyed This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
_is_const_object?	**Signature**: *[const]* bool **_is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference This method returns true, if self is a const reference. In that case, only const methods may be called on self.
_manage	**Signature**: void **_manage** **Description**: Marks the object as managed by the script side. After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required. Usually it's not required to call this method. It has been introduced in version 0.24.
_unmanage	**Signature**: void **_unmanage** **Description**: Marks the object as no longer owned by the script side. Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur. Usually it's not required to call this method. It has been introduced in version 0.24.
area	**Signature**: *[const]* double **area** **Description**: Computes the box area

Returns the box area or 0 if the box is empty

assign

Signature: void **assign** (const Box other)

Description: Assigns another object to self

bbox

Signature: *[const]* Box **bbox**

Description: Returns the bounding box

This method is provided for consistency of the shape API is returns the box itself.

This method has been introduced in version 0.27.

bottom

Signature: *[const]* int **bottom**

Description: Gets the bottom coordinate of the box

Python specific notes:
The object exposes a readable attribute 'bottom'. This is the getter.

bottom=

Signature: void **bottom=** (int c)

Description: Sets the bottom coordinate of the box

Python specific notes:
The object exposes a writable attribute 'bottom'. This is the setter.

center

Signature: *[const]* Point **center**

Description: Gets the center of the box

contains?

(1) Signature: *[const]* bool **contains?** (int x, int y)

Description: Returns true if the box contains the given point

Returns: true if the point is inside the box.

Tests whether a point (x, y) is inside the box. It also returns true if the point is exactly on the box contour.

(2) Signature: *[const]* bool **contains?** (const Point point)

Description: Returns true if the box contains the given point

p: The point to test against.

Returns: true if the point is inside the box.

Tests whether a point is inside the box. It also returns true if the point is exactly on the box contour.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new Box ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

empty?

Signature: *[const]* bool **empty?**

Description: Returns a value indicating whether the box is empty

An empty box may be created with the default constructor for example. Such a box is neutral when combining it with other boxes and renders empty boxes if used in box intersections and false in geometrical relationship tests.

enlarge

(1) Signature: Box **enlarge** (int dx, int dy)

Description: Enlarges the box by a certain amount.

Returns: A reference to this box.

This is a convenience method which takes two values instead of a Vector object. This method has been introduced in version 0.23.

(2) Signature: Box **enlarge** (int d)

Description: Enlarges the box by a certain amount on all sides.

Returns: A reference to this box.

This is a convenience method which takes one values instead of two values. It will apply the given enlargement in both directions. This method has been introduced in version 0.28.

(3) Signature: Box **enlarge** (const Vector enlargement)

Description: Enlarges the box by a certain amount.

enlargement: The grow or shrink amount in x and y direction

Returns: A reference to this box.

Enlarges the box by x and y value specified in the vector passed. Positive values with grow the box, negative ones will shrink the box. The result may be an empty box if the box disappears. The amount specifies the grow or shrink per edge. The width and height will change by twice the amount. Does not check for coordinate overflows.

enlarged

(1) Signature: *[const]* Box **enlarged** (int dx, int dy)

Description: Enlarges the box by a certain amount.

Returns: The enlarged box.

This is a convenience method which takes two values instead of a Vector object. This method has been introduced in version 0.23.

(2) Signature: *[const]* Box **enlarged** (int d)

Description: Enlarges the box by a certain amount on all sides.

Returns: The enlarged box.

This is a convenience method which takes one values instead of two values. It will apply the given enlargement in both directions. This method has been introduced in version 0.28.

(3) Signature: *[const]* Box **enlarged** (const Vector enlargement)

Description: Returns the enlarged box.

enlargement: The grow or shrink amount in x and y direction

Returns: The enlarged box.

Enlarges the box by x and y value specified in the vector passed. Positive values with grow the box, negative ones will shrink the box. The result may be an empty box if the box disappears. The amount specifies the grow or shrink per edge. The width and height will change by twice the amount. Does not modify this box. Does not check for coordinate overflows.

from_dbox

Signature: *[static]* new Box ptr **from_dbox** (const DBox dbox)

Description: Creates an integer coordinate box from a floating-point coordinate box

Use of this method is deprecated. Use new instead

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_dbox'.

Python specific notes:
This method is the default initializer of the object.

from_s

Signature: *[static]* new Box ptr **from_s** (string s)

Description: Creates a box object from a string

Creates the object from a string representation (as returned by to_s)

This method has been added in version 0.23.

hash

Signature: *[const]* unsigned long **hash**

Description: Computes a hash value

Returns a hash value for the given box. This method enables boxes as hash keys.

This method has been introduced in version 0.25.

Python specific notes:
This method is also available as 'hash(object)'.

height

Signature: *[const]* unsigned int **height**

Description: Gets the height of the box

inside?

Signature: *[const]* bool **inside?** (const Box box)

Description: Tests if this box is inside the argument box

Returns true, if this box is inside the given box, i.e. the box intersection renders this box

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_point?

Signature: *[const]* bool **is_point?**

Description: Returns true, if the box is a single point

left

Signature: *[const]* int **left**

Description: Gets the left coordinate of the box

Python specific notes:
The object exposes a readable attribute 'left'. This is the getter.

left=

Signature: void **left=** (int c)

Description: Sets the left coordinate of the box

Python specific notes:
The object exposes a writable attribute 'left'. This is the setter.

move

(1) Signature: Box **move** (int dx, int dy)

Description: Moves the box by a certain distance

Returns: A reference to this box.

This is a convenience method which takes two values instead of a Point object. This method has been introduced in version 0.23.

(2) Signature: Box **move** (const Vector distance)

Description: Moves the box by a certain distance

distance: The offset to move the box.

Returns: A reference to this box.

Moves the box by a given offset and returns the moved box. Does not check for coordinate overflows.

moved

(1) Signature: *[const]* Box **moved** (int dx, int dy)

Description: Moves the box by a certain distance

Returns: The moved box.

This is a convenience method which takes two values instead of a Point object. This method has been introduced in version 0.23.

(2) Signature: *[const]* Box **moved** (const Vector distance)

Description: Returns the box moved by a certain distance

distance: The offset to move the box.

Returns: The moved box.

Moves the box by a given offset and returns the moved box. Does not modify this box. Does not check for coordinate overflows.

new

(1) Signature: *[static]* new Box ptr **new** (const DBox dbox)

Description: Creates an integer coordinate box from a floating-point coordinate box

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_dbox'.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new Box ptr **new**

Description: Creates an empty (invalid) box

Empty boxes don't modify a box when joined with it. The intersection between an empty and any other box is also an empty box. The width, height, p1 and p2 attributes of an empty box are undefined. Use empty? to get a value indicating whether the box is empty.

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new Box ptr **new** (int w)

Description: Creates a square with the given dimensions centered around the origin

Note that for integer-unit boxes, the dimension has to be an even number to avoid rounding.

This convenience constructor has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(4) Signature: *[static]* new Box ptr **new** (int w, int h)

Description: Creates a rectangle with given width and height, centered around the origin

Note that for integer-unit boxes, the dimensions have to be an even number to avoid rounding.

This convenience constructor has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(5) Signature: *[static]* new Box ptr **new** (int left, int bottom, int right, int top)

Description: Creates a box with four coordinates

Four coordinates are given to create a new box. If the coordinates are not provided in the correct order (i.e. right < left), these are swapped.

Python specific notes:
This method is the default initializer of the object.

(6) Signature: *[static]* new Box ptr **new** (const Point lower_left, const Point upper_right)

Description: Creates a box from two points

Two points are given to create a new box. If the coordinates are not provided in the correct order (i.e. right < left), these are swapped.

Python specific notes:
This method is the default initializer of the object.

overlaps?

Signature: *[const]* bool **overlaps?** (const Box box)

Description: Tests if this box overlaps the argument box

Returns true, if the intersection box of this box with the argument box exists and has a non-vanishing area

p1

Signature: *[const]* Point **p1**

Description: Gets the lower left point of the box

Python specific notes:
The object exposes a readable attribute 'p1'. This is the getter.

p1=

Signature: void **p1=** (const Point p)

Description: Sets the lower left point of the box

Python specific notes:
The object exposes a writable attribute 'p1'. This is the setter.

p2

Signature: *[const]* Point **p2**

Description: Gets the upper right point of the box

Python specific notes:
The object exposes a readable attribute 'p2'. This is the getter.

p2=

Signature: void **p2=** (const Point p)

Description: Sets the upper right point of the box

Python specific notes:
The object exposes a writable attribute 'p2'. This is the setter.

perimeter

Signature: *[const]* unsigned long **perimeter**

Description: Returns the perimeter of the box

This method is equivalent to 2*(width+height). For empty boxes, this method returns 0.

This method has been introduced in version 0.23.

right

Signature: *[const]* int **right**

Description: Gets the right coordinate of the box

Python specific notes:
The object exposes a readable attribute 'right'. This is the getter.

right=

Signature: void **right=** (int c)

Description: Sets the right coordinate of the box

Python specific notes:
The object exposes a writable attribute 'right'. This is the setter.

to_dtype

Signature: *[const]* DBox **to_dtype** (double dbu = 1)

Description: Converts the box to a floating-point coordinate box

The database unit can be specified to translate the integer-coordinate box into a floating-point coordinate box in micron units. The database unit is basically a scaling factor.

This method has been introduced in version 0.25.

to_s

Signature: *[const]* string **to_s** (double dbu = 0)

Description: Returns a string representing this box

This string can be turned into a box again by using from_s . If a DBU is given, the output units will be micrometers.

The DBU argument has been added in version 0.27.6.

Python specific notes:
This method is also available as 'str(object)'.

top

Signature: *[const]* int **top**

Description: Gets the top coordinate of the box

Python specific notes:
The object exposes a readable attribute 'top'. This is the getter.

top=

Signature: void **top=** (int c)

Description: Sets the top coordinate of the box

Python specific notes:
The object exposes a writable attribute 'top'. This is the setter.

touches?

Signature: *[const]* bool **touches?** (const Box box)

Description: Tests if this box touches the argument box

Two boxes touch if they overlap or their boundaries share at least one common point. Touching is equivalent to a non-empty intersection ('!(b1 & b2).empty?').

transformed

(1) Signature: *[const]* Box **transformed** (const ICplxTrans t)

Description: Transforms the box with the given complex transformation

t:	The magnifying transformation to apply
Returns:	The transformed box (in this case an integer coordinate box)

This method has been introduced in version 0.18.

(2) Signature: *[const]* Box **transformed** (const Trans t)

Description: Returns the box transformed with the given simple transformation

t:	The transformation to apply
Returns:	The transformed box

(3) Signature: *[const]* DBox **transformed** (const CplxTrans t)

Description: Returns the box transformed with the given complex transformation

t:	The magnifying transformation to apply
Returns:	The transformed box (a DBox now)

width

Signature: *[const]* unsigned int **width**

Description: Gets the width of the box

world

Signature: *[static]* Box **world**

Description: Gets the 'world' box

The world box is the biggest box that can be represented. So it is basically 'all'. The world box behaves neutral on intersections for example. In other operations such as displacement or transformations, the world box may render unexpected results because of coordinate overflow.

The world box can be used

- for comparison ('==', '!=', '<')
- in union and intersection ('+' and '&')
- in relations (contains?, overlaps?, touches?)
- as 'all' argument in region queries

This method has been introduced in version 0.28.

4.18. API reference - Class DBox

Notation used in Ruby API documentation

Module: db

Description: A box class with floating-point coordinates

This object represents a box (a rectangular shape).

The definition of the attributes is: p1 is the lower left point, p2 the upper right one. If a box is constructed from two points (or four coordinates), the coordinates are sorted accordingly.

A box can be empty. An empty box represents no area (not even a point). Empty boxes behave neutral with respect to most operations. Empty boxes return true on empty?.

A box can be a point or a single line. In this case, the area is zero but the box still can overlap other boxes for example and it is not empty.

See The Database API for more details about the database objects.

Public constructors

new DBox ptr	**new**	(const Box box)	Creates a floating-point coordinate box from an integer coordinate box
new DBox ptr	**new**		Creates an empty (invalid) box
new DBox ptr	**new**	(double w)	Creates a square with the given dimensions centered around the origin
new DBox ptr	**new**	(double w, double h)	Creates a rectangle with given width and height, centered around the origin
new DBox ptr	**new**	(double left, double bottom, double right, double top)	Creates a box with four coordinates
new DBox ptr	**new**	(const DPoint lower_left, const DPoint upper_right)	Creates a box from two points

Public methods

[const]	bool	**!=**	(const DBox box)	Returns true if this box is not equal to the other box
[const]	DBox	**&**	(const DBox box)	Returns the intersection of this box with another box
[const]	DBox	*****	(const DBox box)	Returns the convolution product from this box with another box
[const]	DBox	*****	(double scale_factor)	Returns the scaled box
[const]	DBox	**+**	(const DPoint point)	Joins box with a point
[const]	DBox	**+**	(const DBox box)	Joins two boxes
[const]	DBox	**-**	(const DBox box)	Subtraction of boxes

[const]	bool	**<**	(const DBox box)	Returns true if this box is 'less' than another box
[const]	bool	**==**	(const DBox box)	Returns true if this box is equal to the other box
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	double	**area**		Computes the box area
	void	**assign**	(const DBox other)	Assigns another object to self
[const]	DBox	**bbox**		Returns the bounding box
[const]	double	**bottom**		Gets the bottom coordinate of the box
	void	**bottom=**	(double c)	Sets the bottom coordinate of the box
[const]	DPoint	**center**		Gets the center of the box
[const]	bool	**contains?**	(double x, double y)	Returns true if the box contains the given point
[const]	bool	**contains?**	(const DPoint point)	Returns true if the box contains the given point
[const]	new DBox ptr	**dup**		Creates a copy of self
[const]	bool	**empty?**		Returns a value indicating whether the box is empty
	DBox	**enlarge**	(double dx, double dy)	Enlarges the box by a certain amount.
	DBox	**enlarge**	(double d)	Enlarges the box by a certain amount on all sides.
	DBox	**enlarge**	(const DVector enlargement)	Enlarges the box by a certain amount.
[const]	DBox	**enlarged**	(double dx, double dy)	Enlarges the box by a certain amount.

[const]	DBox	**enlarged**	(double d)	Enlarges the box by a certain amount on all sides.
[const]	DBox	**enlarged**	(const DVector enlargement)	Returns the enlarged box.
[const]	unsigned long	**hash**		Computes a hash value
[const]	double	**height**		Gets the height of the box
[const]	bool	**inside?**	(const DBox box)	Tests if this box is inside the argument box
[const]	bool	**is_point?**		Returns true, if the box is a single point
[const]	double	**left**		Gets the left coordinate of the box
	void	**left=**	(double c)	Sets the left coordinate of the box
	DBox	**move**	(double dx, double dy)	Moves the box by a certain distance
	DBox	**move**	(const DVector distance)	Moves the box by a certain distance
[const]	DBox	**moved**	(double dx, double dy)	Moves the box by a certain distance
[const]	DBox	**moved**	(const DVector distance)	Returns the box moved by a certain distance
[const]	bool	**overlaps?**	(const DBox box)	Tests if this box overlaps the argument box
[const]	DPoint	**p1**		Gets the lower left point of the box
	void	**p1=**	(const DPoint p)	Sets the lower left point of the box
[const]	DPoint	**p2**		Gets the upper right point of the box
	void	**p2=**	(const DPoint p)	Sets the upper right point of the box
[const]	double	**perimeter**		Returns the perimeter of the box
[const]	double	**right**		Gets the right coordinate of the box
	void	**right=**	(double c)	Sets the right coordinate of the box
[const]	Box	**to_itype**	(double dbu = 1)	Converts the box to an integer coordinate box
[const]	string	**to_s**	(double dbu = 0)	Returns a string representing this box
[const]	double	**top**		Gets the top coordinate of the box
	void	**top=**	(double c)	Sets the top coordinate of the box
[const]	bool	**touches?**	(const DBox box)	Tests if this box touches the argument box

[const]	Box	**transformed**	(const VCplxTrans t)	Transforms the box with the given complex transformation
[const]	DBox	**transformed**	(const DTrans t)	Returns the box transformed with the given simple transformation
[const]	DBox	**transformed**	(const DCplxTrans t)	Returns the box transformed with the given complex transformation
[const]	double	**width**		Gets the width of the box

Public static methods and constants

	new DBox ptr	**from_s**	(string s)	Creates a box object from a string
	DBox	**world**		Gets the 'world' box

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**		Use of this method is deprecated. Use _create instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[static]	new DBox ptr	**from_ibox**	(const Box box)	Use of this method is deprecated. Use new instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=

Signature: *[const]* bool **!=** (const DBox box)

Description: Returns true if this box is not equal to the other box

Returns true, if this box and the given box are not equal

&

Signature: *[const]* DBox **&** (const DBox box)

Description: Returns the intersection of this box with another box

box: The box to take the intersection with

Returns: The intersection box

The intersection of two boxes is the largest box common to both boxes. The intersection may be empty if both boxes to not touch. If the boxes do not overlap but touch the result may be a single line or point with an area of zero. Overwrites this box with the result.

*****

(1) Signature: *[const]* DBox ***** (const DBox box)

Description: Returns the convolution product from this box with another box

box: The box to convolve with this box.

Returns: The convolved box

The * operator convolves the firstbox with the one given as the second argument. The box resulting from "convolution" is the outer boundary of the union set formed by placing the second box at every point of the first. In other words, the returned box of (p1,p2)*(q1,q2) is (p1+q1,p2+q2).

Python specific notes:
This method also implements '__rmul__'.

(2) Signature: *[const]* DBox ***** (double scale_factor)

Description: Returns the scaled box

scale_factor: The scaling factor

Returns: The scaled box

The * operator scales the box with the given factor and returns the result.

This method has been introduced in version 0.22.

Python specific notes:
This method also implements '__rmul__'.

\+

(1) Signature: *[const]* DBox **+** (const DPoint point)

Description: Joins box with a point

point: The point to join with this box.

Returns: The box joined with the point

The + operator joins a point with the box. The resulting box will enclose both the original box and the point.

(2) Signature: *[const]* DBox **+** (const DBox box)

Description: Joins two boxes

box: The box to join with this box.

Returns: The joined box

The + operator joins the first box with the one given as the second argument. Joining constructs a box that encloses both boxes given. Empty boxes are neutral: they do not change another box when joining. Overwrites this box with the result.

\-

Signature: *[const]* DBox **-** (const DBox box)

Description: Subtraction of boxes

box: The box to subtract from this box.

Returns: The result box

The - operator subtracts the argument box from self. This will return the bounding box of the are covered by self, but not by argument box. Subtracting a box from itself will render an empty box. Subtracting another box from self will modify the first box only if the argument box covers one side entirely.

This feature has been introduced in version 0.29.

<

Signature: *[const]* bool **<** (const DBox box)

Description: Returns true if this box is 'less' than another box

	Returns true, if this box is 'less' with respect to first and second point (in this order)
==	**Signature**: *[const]* bool **==** (const DBox box) **Description**: Returns true if this box is equal to the other box Returns true, if this box and the given box are equal
_create	**Signature**: void **_create** **Description**: Ensures the C++ object is created Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
_destroy	**Signature**: void **_destroy** **Description**: Explicitly destroys the object Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
_destroyed?	**Signature**: *[const]* bool **_destroyed?** **Description**: Returns a value indicating whether the object was already destroyed This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
_is_const_object?	**Signature**: *[const]* bool **_is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference This method returns true, if self is a const reference. In that case, only const methods may be called on self.
_manage	**Signature**: void **_manage** **Description**: Marks the object as managed by the script side. After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required. Usually it's not required to call this method. It has been introduced in version 0.24.
_unmanage	**Signature**: void **_unmanage** **Description**: Marks the object as no longer owned by the script side. Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur. Usually it's not required to call this method. It has been introduced in version 0.24.
area	**Signature**: *[const]* double **area** **Description**: Computes the box area

Returns the box area or 0 if the box is empty

assign

Signature: void **assign** (const DBox other)

Description: Assigns another object to self

bbox

Signature: *[const]* DBox **bbox**

Description: Returns the bounding box

This method is provided for consistency of the shape API is returns the box itself.

This method has been introduced in version 0.27.

bottom

Signature: *[const]* double **bottom**

Description: Gets the bottom coordinate of the box

Python specific notes:
The object exposes a readable attribute 'bottom'. This is the getter.

bottom=

Signature: void **bottom=** (double c)

Description: Sets the bottom coordinate of the box

Python specific notes:
The object exposes a writable attribute 'bottom'. This is the setter.

center

Signature: *[const]* DPoint **center**

Description: Gets the center of the box

contains?

(1) Signature: *[const]* bool **contains?** (double x, double y)

Description: Returns true if the box contains the given point

Returns: true if the point is inside the box.

Tests whether a point (x, y) is inside the box. It also returns true if the point is exactly on the box contour.

(2) Signature: *[const]* bool **contains?** (const DPoint point)

Description: Returns true if the box contains the given point

p: The point to test against.

Returns: true if the point is inside the box.

Tests whether a point is inside the box. It also returns true if the point is exactly on the box contour.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new DBox ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

empty?

Signature: *[const]* bool **empty?**

Description: Returns a value indicating whether the box is empty

An empty box may be created with the default constructor for example. Such a box is neutral when combining it with other boxes and renders empty boxes if used in box intersections and false in geometrical relationship tests.

enlarge

(1) Signature: DBox **enlarge** (double dx, double dy)

Description: Enlarges the box by a certain amount.

Returns: A reference to this box.

This is a convenience method which takes two values instead of a Vector object. This method has been introduced in version 0.23.

(2) Signature: DBox **enlarge** (double d)

Description: Enlarges the box by a certain amount on all sides.

Returns: A reference to this box.

This is a convenience method which takes one values instead of two values. It will apply the given enlargement in both directions. This method has been introduced in version 0.28.

(3) Signature: DBox **enlarge** (const DVector enlargement)

Description: Enlarges the box by a certain amount.

enlargement: The grow or shrink amount in x and y direction

Returns: A reference to this box.

Enlarges the box by x and y value specified in the vector passed. Positive values with grow the box, negative ones will shrink the box. The result may be an empty box if the box disappears. The amount specifies the grow or shrink per edge. The width and height will change by twice the amount. Does not check for coordinate overflows.

enlarged

(1) Signature: *[const]* DBox **enlarged** (double dx, double dy)

Description: Enlarges the box by a certain amount.

Returns: The enlarged box.

This is a convenience method which takes two values instead of a Vector object. This method has been introduced in version 0.23.

(2) Signature: *[const]* DBox **enlarged** (double d)

Description: Enlarges the box by a certain amount on all sides.

Returns: The enlarged box.

This is a convenience method which takes one values instead of two values. It will apply the given enlargement in both directions. This method has been introduced in version 0.28.

(3) Signature: *[const]* DBox **enlarged** (const DVector enlargement)

Description: Returns the enlarged box.

enlargement: The grow or shrink amount in x and y direction

Returns: The enlarged box.

Enlarges the box by x and y value specified in the vector passed. Positive values with grow the box, negative ones will shrink the box. The result may be an empty box if the box disappears. The amount specifies the grow or shrink per edge. The width and height will change by twice the amount. Does not modify this box. Does not check for coordinate overflows.

from_ibox

Signature: *[static]* new DBox ptr **from_ibox** (const Box box)

Description: Creates a floating-point coordinate box from an integer coordinate box

Use of this method is deprecated. Use new instead

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_ibox'.

Python specific notes:
This method is the default initializer of the object.

from_s

Signature: *[static]* new DBox ptr **from_s** (string s)

Description: Creates a box object from a string

Creates the object from a string representation (as returned by to_s)

This method has been added in version 0.23.

hash

Signature: *[const]* unsigned long **hash**

Description: Computes a hash value

Returns a hash value for the given box. This method enables boxes as hash keys.

This method has been introduced in version 0.25.

Python specific notes:
This method is also available as 'hash(object)'.

height

Signature: *[const]* double **height**

Description: Gets the height of the box

inside?

Signature: *[const]* bool **inside?** (const DBox box)

Description: Tests if this box is inside the argument box

Returns true, if this box is inside the given box, i.e. the box intersection renders this box

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_point?

Signature: *[const]* bool **is_point?**

Description: Returns true, if the box is a single point

left

Signature: *[const]* double **left**

Description: Gets the left coordinate of the box

Python specific notes:
The object exposes a readable attribute 'left'. This is the getter.

left=

Signature: void **left=** (double c)

Description: Sets the left coordinate of the box

Python specific notes:
The object exposes a writable attribute 'left'. This is the setter.

move

(1) Signature: DBox **move** (double dx, double dy)

Description: Moves the box by a certain distance

Returns: A reference to this box.

This is a convenience method which takes two values instead of a Point object. This method has been introduced in version 0.23.

(2) Signature: DBox **move** (const DVector distance)

Description: Moves the box by a certain distance

distance: The offset to move the box.

Returns: A reference to this box.

Moves the box by a given offset and returns the moved box. Does not check for coordinate overflows.

moved

(1) Signature: *[const]* DBox **moved** (double dx, double dy)

Description: Moves the box by a certain distance

Returns: The moved box.

This is a convenience method which takes two values instead of a Point object. This method has been introduced in version 0.23.

(2) Signature: *[const]* DBox **moved** (const DVector distance)

Description: Returns the box moved by a certain distance

distance: The offset to move the box.

Returns: The moved box.

Moves the box by a given offset and returns the moved box. Does not modify this box. Does not check for coordinate overflows.

new

(1) Signature: *[static]* new DBox ptr **new** (const Box box)

Description: Creates a floating-point coordinate box from an integer coordinate box

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_ibox'.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new DBox ptr **new**

Description: Creates an empty (invalid) box

Empty boxes don't modify a box when joined with it. The intersection between an empty and any other box is also an empty box. The width, height, p1 and p2 attributes of an empty box are undefined. Use empty? to get a value indicating whether the box is empty.

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new DBox ptr **new** (double w)

Description: Creates a square with the given dimensions centered around the origin

Note that for integer-unit boxes, the dimension has to be an even number to avoid rounding.

This convenience constructor has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(4) Signature: *[static]* new DBox ptr **new** (double w, double h)

Description: Creates a rectangle with given width and height, centered around the origin

Note that for integer-unit boxes, the dimensions have to be an even number to avoid rounding.

This convenience constructor has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(5) Signature: *[static]* new DBox ptr **new** (double left, double bottom, double right, double top)

Description: Creates a box with four coordinates

Four coordinates are given to create a new box. If the coordinates are not provided in the correct order (i.e. right < left), these are swapped.

Python specific notes:
This method is the default initializer of the object.

(6) Signature: *[static]* new DBox ptr **new** (const DPoint lower_left, const DPoint upper_right)

Description: Creates a box from two points

Two points are given to create a new box. If the coordinates are not provided in the correct order (i.e. right < left), these are swapped.

Python specific notes:
This method is the default initializer of the object.

overlaps?

Signature: *[const]* bool **overlaps?** (const DBox box)

Description: Tests if this box overlaps the argument box

Returns true, if the intersection box of this box with the argument box exists and has a non-vanishing area

p1

Signature: *[const]* DPoint **p1**

Description: Gets the lower left point of the box

Python specific notes:
The object exposes a readable attribute 'p1'. This is the getter.

p1=

Signature: void **p1=** (const DPoint p)

Description: Sets the lower left point of the box

Python specific notes:
The object exposes a writable attribute 'p1'. This is the setter.

p2

Signature: *[const]* DPoint **p2**

Description: Gets the upper right point of the box

Python specific notes:
The object exposes a readable attribute 'p2'. This is the getter.

p2=

Signature: void **p2=** (const DPoint p)

Description: Sets the upper right point of the box

Python specific notes:
The object exposes a writable attribute 'p2'. This is the setter.

perimeter

Signature: *[const]* double **perimeter**

Description: Returns the perimeter of the box

This method is equivalent to 2*(width+height). For empty boxes, this method returns 0.

This method has been introduced in version 0.23.

right

Signature: *[const]* double **right**

Description: Gets the right coordinate of the box

Python specific notes:
The object exposes a readable attribute 'right'. This is the getter.

right=

Signature: void **right=** (double c)

Description: Sets the right coordinate of the box

Python specific notes:
The object exposes a writable attribute 'right'. This is the setter.

to_itype

Signature: *[const]* Box **to_itype** (double dbu = 1)

Description: Converts the box to an integer coordinate box

The database unit can be specified to translate the floating-point coordinate box in micron units to an integer-coordinate box in database units. The boxes coordinates will be divided by the database unit.

This method has been introduced in version 0.25.

to_s

Signature: *[const]* string **to_s** (double dbu = 0)

Description: Returns a string representing this box

This string can be turned into a box again by using from_s . If a DBU is given, the output units will be micrometers.

The DBU argument has been added in version 0.27.6.

Python specific notes:
This method is also available as 'str(object)'.

top

Signature: *[const]* double **top**

Description: Gets the top coordinate of the box

Python specific notes:
The object exposes a readable attribute 'top'. This is the getter.

top=

Signature: void **top=** (double c)

Description: Sets the top coordinate of the box

Python specific notes:
The object exposes a writable attribute 'top'. This is the setter.

touches?

Signature: *[const]* bool **touches?** (const DBox box)

Description: Tests if this box touches the argument box

Two boxes touch if they overlap or their boundaries share at least one common point. Touching is equivalent to a non-empty intersection ('!(b1 & b2).empty?').

transformed

(1) Signature: *[const]* Box **transformed** (const VCplxTrans t)

Description: Transforms the box with the given complex transformation

t: The magnifying transformation to apply

Returns: The transformed box (in this case an integer coordinate box)

This method has been introduced in version 0.25.

(2) Signature: *[const]* DBox **transformed** (const DTrans t)

Description: Returns the box transformed with the given simple transformation

t: The transformation to apply

Returns: The transformed box

(3) Signature: *[const]* DBox **transformed** (const DCplxTrans t)

Description: Returns the box transformed with the given complex transformation

t: The magnifying transformation to apply

Returns: The transformed box (a DBox now)

width

Signature: *[const]* double **width**

Description: Gets the width of the box

world

Signature: *[static]* DBox **world**

Description: Gets the 'world' box

The world box is the biggest box that can be represented. So it is basically 'all'. The world box behaves neutral on intersections for example. In other operations such as displacement or transformations, the world box may render unexpected results because of coordinate overflow.

The world box can be used

- for comparison ('==', '!=', '<')
- in union and intersection ('+' and '&')
- in relations (contains?, overlaps?, touches?)
- as 'all' argument in region queries

This method has been introduced in version 0.28.

4.19. API reference - Class Cell

Notation used in Ruby API documentation

Module: db

Description: A cell

A cell object consists of a set of shape containers (called layers), a set of child cell instances and auxiliary information such as the parent instance list. A cell is identified through an index given to the cell upon instantiation. Cell instances refer to single instances or array instances. Both are encapsulated in the same object, the CellInstArray object. In the simple case, this object refers to a single instance. In the general case, this object may refer to a regular array of cell instances as well.

Starting from version 0.16, the child_inst and erase_inst methods are no longer available since they were using index addressing which is no longer supported. Instead, instances are now addressed with the Instance reference objects.

See The Database API for more details about the database objects like the Cell class.

Public constructors

new Cell ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**add_meta_info**	(const LayoutMetaInfo info)	Adds meta information to the cell
[const]	string	**basic_name**		Returns the name of the library or PCell or the real name of the cell
[const]	Box	**bbox**		Gets the bounding box of the cell
[const]	Box	**bbox**	(unsigned int layer_index)	Gets the per-layer bounding box of the cell
[const]	RecursiveInstanceIt	**begin_instances_rec**		Delivers a recursive instance iterator for the instances below the cell
[const]	RecursiveInstanceIterator	**begin_instances_rec_overlapping**	(DBox region)	Delivers a recursive instance iterator for the instances below the cell using a region search
[const]	RecursiveInstanceIt	**begin_instances_rec**	(DBox region)	Delivers a recursive instance iterator for the instances below the cell using a region

				search, with the region given in micrometer units
[const]	RecursiveInstanceIterator	**begin_instances_rec_touching**	(DBox region)	Delivers a recursive instance iterator for the instances below the cell
[const]	RecursiveInstanceIt	**begin_instances_rec_**	(DBox region)	Delivers a recursive instance iterator for the instances below the cell using a region search, with the region given in micrometer units
[const]	RecursiveShapeIterator	**begin_shapes_rec**	(unsigned int layer)	Delivers a recursive shape iterator for the shapes below the cell on the given layer
[const]	RecursiveShapeIter	**begin_shapes_rec_ov**	(unsigned int layer, Box region)	Delivers a recursive shape iterator for the shapes below the cell on the given layer using a region search
[const]	RecursiveShapeIterator	**begin_shapes_rec_overlapping**	(unsigned int layer, DBox region)	Delivers a recursive shape iterator for the shapes below the cell on the given layer using a region search, with the region given in micrometer units
[const]	RecursiveShapeIter	**begin_shapes_rec_to**	(unsigned int layer, Box region)	Delivers a recursive shape iterator for the shapes below the cell on the given layer using a region search
[const]	RecursiveShapeIterator	**begin_shapes_rec_touching**	(unsigned int layer, DBox region)	Delivers a recursive shape iterator for the shapes below the cell on the given layer using a region search, with the region given in micrometer units
[const]	unsigned int[]	**called_cells**		Gets a list of all called cells
[const]	unsigned int[]	**caller_cells**		Gets a list of all caller cells
[const]	unsigned int	**cell_index**		Gets the cell index
	Instance	**change_pcell_parameter**	(const Instance instance, string name, variant value)	Changes a single parameter for an individual PCell instance given by name
	Instance	**change_pcell_parame**	(const Instance instance, map<string,variant> dict)	Changes the given parameter for an individual PCell instance
	Instance	**change_pcell_parameters**	(const Instance instance, variant[] parameters)	Changes the parameters for an individual PCell instance
[const]	unsigned long	**child_cells**		Gets the number of child cells
[const]	unsigned long	**child_instances**		Gets the number of child instances
	void	**clear**	(unsigned int layer_index)	Clears the shapes on the given layer

	void	clear		Clears the cell (deletes shapes and instances)
	void	clear_insts		Clears the instance list
	void	clear_meta_info		Clears the meta information of the cell
	void	clear_shapes		Clears all shapes in the cell
	void	copy	(unsigned int src, unsigned int dest)	Copies the shapes from the source to the target layer
	void	copy	(Cell ptr src_cell, unsigned int src_layer, unsigned int dest)	Copies shapes from another cell to the target layer in this cell
	void	copy_instances	(const Cell source_cell)	Copies the instances of child cells in the source cell to this cell
	void	copy_meta_info	(const Cell ptr other)	Copies the meta information from the other cell into this cell
	void	copy_shapes	(const Cell source_cell)	Copies the shapes from the given cell into this cell
	void	copy_shapes	(const Cell source_cell, const LayerMapping layer_mapping)	Copies the shapes from the given cell into this cell
	unsigned int[]	copy_tree	(const Cell source_cell)	Copies the cell tree of the given cell into this cell
	void	copy_tree_shapes	(const Cell source_cell, const CellMapping cell_mapping)	Copies the shapes from the given cell and the cell tree below into this cell or subcells of this cell
	void	copy_tree_shapes	(const Cell source_cell, const CellMapping cell_mapping, const LayerMapping layer_mapping)	Copies the shapes from the given cell and the cell tree below into this cell or subcells of this cell with layer mapping
[const]	DBox	dbbox		Gets the bounding box of the cell in micrometer units
[const]	DBox	dbbox	(unsigned int layer_index)	Gets the per-layer bounding box of the cell in micrometer units
	void	delete		Deletes this cell
	void	delete_property	(variant key)	Deletes the user property with the given key
[const]	string	display_title		Returns a nice looking name for display purposes
[const]	Cell ptr	dup		Creates a copy of the cell
[const,iter]	unsigned int	each_child_cell		Iterates over all child cells

[iter]	Instance	each_inst		Iterates over all child instances (which may actually be instance arrays)
[const,iter]	LayoutMetaInfo	each_meta_info		Iterates over the meta information of the cell
[const,iter]	Instance	each_overlapping_inst	(const Box b)	Gets the instances overlapping the given rectangle
[const,iter]	Instance	each_overlapping_ins	(const DBox b)	Gets the instances overlapping the given rectangle, with the rectangle in micrometer units
[const,iter]	Shape	each_overlapping_shape	(unsigned int layer_index, const Box box, unsigned int flags)	Iterates over all shapes of a given layer that overlap the given box
[const,iter]	Shape	each_overlapping_sh	(unsigned int layer_index, const Box box)	Iterates over all shapes of a given layer that overlap the given box
[const,iter]	Shape	each_overlapping_shape	(unsigned int layer_index, const DBox box, unsigned int flags)	Iterates over all shapes of a given layer that overlap the given box, with the box given in micrometer units
[const,iter]	Shape	each_overlapping_sh	(unsigned int layer_index, const DBox box)	Iterates over all shapes of a given layer that overlap the given box, with the box given in micrometer units
[const,iter]	unsigned int	each_parent_cell		Iterates over all parent cells
[const,iter]	ParentInstArray	each_parent_inst		Iterates over the parent instance list (which may actually be instance arrays)
[const,iter]	Shape	each_shape	(unsigned int layer_index, unsigned int flags)	Iterates over all shapes of a given layer
[const,iter]	Shape	each_shape	(unsigned int layer_index)	Iterates over all shapes of a given layer
[const,iter]	Instance	each_touching_inst	(const Box b)	Gets the instances touching the given rectangle
[const,iter]	Instance	each_touching_inst	(const DBox b)	Gets the instances touching the given rectangle, with the rectangle in micrometer units
[const,iter]	Shape	each_touching_shape	(unsigned int layer_index, const Box box, unsigned int flags)	Iterates over all shapes of a given layer that touch the given box
[const,iter]	Shape	each_touching_shape	(unsigned int layer_index, const Box box)	Iterates over all shapes of a given layer that touch the given box

[const,iter]	Shape	**each_touching_shape**	(unsigned int layer_index, const DBox box, unsigned int flags)	Iterates over all shapes of a given layer that touch the given box, with the box given in micrometer units
[const,iter]	Shape	**each_touching_shape**	(unsigned int layer_index, const DBox box)	Iterates over all shapes of a given layer that touch the given box, with the box given in micrometer units
	void	**erase**	(const Instance inst)	Erases the instance given by the Instance object
	void	**fill_region**	(const Region region, unsigned int fill_cell_index, const Box fc_box, const Point ptr origin = (0, 0), Region ptr remaining_parts = nil, const Vector fill_margin = 0,0, Region ptr remaining_polygons = nil, const Box glue_box = ())	Fills the given region with cells of the given type (extended version)
	void	**fill_region**	(const Region region, unsigned int fill_cell_index, const Box fc_bbox, const Vector row_step, const Vector column_step, const Point ptr origin = (0, 0), Region ptr remaining_parts = nil, const Vector fill_margin = 0,0, Region ptr remaining_polygons = nil, const Box glue_box = ())	Fills the given region with cells of the given type (skew step version)
	void	**fill_region_multi**	(const Region region, unsigned int fill_cell_index, const Box fc_bbox, const Vector row_step, const Vector column_step, const Vector fill_margin = 0,0, Region ptr remaining_polygons = nil,	Fills the given region with cells of the given type in enhanced mode with iterations

			const Box glue_box = ())	
	void	**flatten**	(bool prune)	Flattens the given cell
	void	**flatten**	(int levels, bool prune)	Flattens the given cell
	void	**ghost_cell=**	(bool flag)	Sets the "ghost cell" flag
[const]	bool	**has_prop_id?**		Returns true, if the cell has user properties
[const]	unsigned int	**hierarchy_levels**		Returns the number of hierarchy levels below
	Instance	**insert**	(const Instance inst)	Inserts a cell instance given by another reference
	Instance	**insert**	(const CellInstArray cell_inst_array)	Inserts a cell instance (array)
	Instance	**insert**	(const DCellInstArray cell_inst_array)	Inserts a cell instance (array) given in micron units
	Instance	**insert**	(const DCellInstArray cell_inst_array, unsigned long property_id)	Inserts a cell instance (array) given in micron units with properties
	Instance	**insert**	(const CellInstArray cell_inst_array, unsigned long property_id)	Inserts a cell instance (array) with properties
[const]	bool	**is_empty?**		Returns a value indicating whether the cell is empty
[const]	bool	**is_ghost_cell?**		Returns a value indicating whether the cell is a "ghost cell"
[const]	bool	**is_leaf?**		Gets a value indicating whether the cell is a leaf cell
[const]	bool	**is_library_cell?**		Returns true, if the cell is a proxy cell pointing to a library cell
[const]	bool	**is_pcell_variant?**		Returns true, if this cell is a pcell variant
[const]	bool	**is_pcell_variant?**	(const Instance instance)	Returns true, if this instance is a PCell variant
[const]	bool	**is_proxy?**		Returns true, if the cell presents some external entity
[const]	bool	**is_top?**		Gets a value indicating whether the cell is a top-level cell
[const]	bool	**is_valid?**	(const Instance instance)	Tests if the given Instance object is still pointing to a valid object

	Layout ptr	**layout**		Returns a reference to the layout where the cell resides
[const]	const Layout ptr	**layout**		Returns a reference to the layout where the cell resides (const references)
[const]	Library ptr	**library**		Returns a reference to the library from which the cell is imported
[const]	unsigned int	**library_cell_index**		Returns the index of the cell in the layout of the library (if it's a library proxy)
	void	**merge_meta_info**	(const Cell ptr other)	Merges the meta information from the other cell into this cell
	new LayoutMetaInfo ptr	**meta_info**	(string name)	Gets the meta information for a given name
	variant	**meta_info_value**	(string name)	Gets the meta information value for a given name
	void	**move**	(unsigned int src, unsigned int dest)	Moves the shapes from the source to the target layer
	void	**move**	(Cell ptr src_cell, unsigned int src_layer, unsigned int dest)	Moves shapes from another cell to the target layer in this cell
	void	**move_instances**	(Cell source_cell)	Moves the instances of child cells in the source cell to this cell
	void	**move_shapes**	(Cell source_cell)	Moves the shapes from the given cell into this cell
	void	**move_shapes**	(Cell source_cell, const LayerMapping layer_mapping)	Moves the shapes from the given cell into this cell
	unsigned int[]	**move_tree**	(Cell source_cell)	Moves the cell tree of the given cell into this cell
	void	**move_tree_shapes**	(Cell source_cell, const CellMapping cell_mapping)	Moves the shapes from the given cell and the cell tree below into this cell or subcells of this cell
	void	**move_tree_shapes**	(Cell source_cell, const CellMapping cell_mapping, const LayerMapping layer_mapping)	Moves the shapes from the given cell and the cell tree below into this cell or subcells of this cell with layer mapping
[const]	string	**name**		Gets the cell's name
	void	**name=**	(string name)	Renames the cell
[const]	unsigned long	**parent_cells**		Gets the number of parent cells

[const]	const PCellDeclaration ptr	**pcell_declaration**		Returns a reference to the PCell declaration
[const]	const PCellDeclaration ptr	**pcell_declaration**	(const Instance instance)	Returns the PCell declaration of a pcell instance
[const]	unsigned int	**pcell_id**		Returns the PCell ID if the cell is a pcell variant
[const]	Library ptr	**pcell_library**		Returns the library where the PCell is declared if this cell is a PCell and it is not defined locally.
[const]	variant	**pcell_parameter**	(string name)	Gets a PCell parameter by name if the cell is a PCell variant
[const]	variant	**pcell_parameter**	(const Instance instance, string name)	Returns a PCell parameter by name for a pcell instance
[const]	variant[]	**pcell_parameters**		Returns the PCell parameters for a pcell variant
[const]	variant[]	**pcell_parameters**	(const Instance instance)	Returns the PCell parameters for a pcell instance
[const]	map<string,variant>	**pcell_parameters_by_**		Returns the PCell parameters for a pcell variant as a name to value dictionary
[const]	map<string,variant>	**pcell_parameters_by_name**	(const Instance instance)	Returns the PCell parameters for a pcell instance as a name to value dictionary
[const]	unsigned long	**prop_id**		Gets the properties ID associated with the cell
	void	**prop_id=**	(unsigned long id)	Sets the properties ID associated with the cell
	variant	**property**	(variant key)	Gets the user property with the given key
	void	**prune_cell**		Deletes the cell plus subcells not used otherwise
	void	**prune_cell**	(int levels)	Deletes the cell plus subcells not used otherwise
	void	**prune_subcells**		Deletes all sub cells of the cell which are not used otherwise
	void	**prune_subcells**	(int levels)	Deletes all sub cells of the cell which are not used otherwise down to the specified level of hierarchy
[const]	string	**qname**		Returns the library-qualified name
	unsigned int[]	**read**	(string file_name,	Reads a layout file into this cell

			const LoadLayoutOptions options)	
	unsigned int[]	**read**	(string file_name)	Reads a layout file into this cell
	void	**refresh**		Refreshes a proxy cell
	void	**remove_meta_info**	(string name)	Removes meta information from the cell
	Instance	**replace**	(const Instance instance, const CellInstArray cell_inst_array)	Replaces a cell instance (array) with a different one
	Instance	**replace**	(const Instance instance, const CellInstArray cell_inst_array, unsigned long property_id)	Replaces a cell instance (array) with a different one with properties
	Instance	**replace**	(const Instance instance, const DCellInstArray cell_inst_array)	Replaces a cell instance (array) with a different one, given in micrometer units
	Instance	**replace**	(const Instance instance, const DCellInstArray cell_inst_array, unsigned long property_id)	Replaces a cell instance (array) with a different one and new properties, where the cell instance is given in micrometer units
	Instance	**replace_prop_id**	(const Instance instance, unsigned long property_id)	Replaces (or install) the properties of a cell
	void	**set_property**	(variant key, variant value)	Sets the user property with the given key to the given value
	Shapes	**shapes**	(unsigned int layer_index)	Returns the shapes list of the given layer
[const]	const Shapes ptr	**shapes**	(unsigned int layer_index)	Returns the shapes list of the given layer (const version)
	void	**swap**	(unsigned int layer_index1, unsigned int layer_index2)	Swaps the layers given
	Instance	**transform**	(const Instance instance, const Trans trans)	Transforms the instance with the given transformation
	Instance	**transform**	(const Instance instance,	Transforms the instance with the given complex integer transformation

			const ICplxTrans trans)	
	Instance	**transform**	(const Instance instance, const DTrans trans)	Transforms the instance with the transformation given in micrometer units
	Instance	**transform**	(const Instance instance, const DCplxTrans trans)	Transforms the instance with the given complex floating-point transformation given in micrometer units
	void	**transform**	(const Trans trans)	Transforms the cell by the given integer transformation
	void	**transform**	(const ICplxTrans trans)	Transforms the cell by the given complex integer transformation
	void	**transform**	(const DTrans trans)	Transforms the cell by the given, micrometer-unit transformation
	void	**transform**	(const DCplxTrans trans)	Transforms the cell by the given, micrometer-unit transformation
	Instance	**transform_into**	(const Instance instance, const Trans trans)	Transforms the instance into a new coordinate system with the given transformation
	Instance	**transform_into**	(const Instance instance, const ICplxTrans trans)	Transforms the instance into a new coordinate system with the given complex integer transformation
	void	**transform_into**	(const Trans trans)	Transforms the cell into a new coordinate system with the given transformation
	void	**transform_into**	(const ICplxTrans trans)	Transforms the cell into a new coordinate system with the given complex integer transformation
	Instance	**transform_into**	(const Instance instance, const DTrans trans)	Transforms the instance into a new coordinate system with the given transformation where the transformation is in micrometer units
	Instance	**transform_into**	(const Instance instance, const DCplxTrans trans)	Transforms the instance into a new coordinate system with the given complex transformation where the transformation is in micrometer units
	void	**transform_into**	(const DTrans trans)	Transforms the cell into a new coordinate system with the given transformation where the transformation is in micrometer units
	void	**transform_into**	(const DCplxTrans trans)	Transforms the cell into a new coordinate system with the given complex integer transformation where the transformation is in micrometer units
[const]	void	**write**	(string file_name)	Writes the cell to a layout file
[const]	void	**write**	(string file_name,	Writes the cell to a layout file

			const SaveLayoutOptions options)	

Deprecated methods (protected, public, static, non-static and constructors)

[const]	Box	**bbox_per_layer**	(unsigned int layer_index)	Use of this method is deprecated. Use bbox instead
	void	**create**		Use of this method is deprecated. Use _create instead
[const]	DBox	**dbbox_per_layer**	(unsigned int layer_index)	Use of this method is deprecated. Use dbbox instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

add_meta_info

Signature: void **add_meta_info** (const LayoutMetaInfo info)

Description: Adds meta information to the cell

See LayoutMetaInfo for details about cells and meta information.

This method has been introduced in version 0.28.8.

basic_name

Signature: *[const]* string **basic_name**

Description: Returns the name of the library or PCell or the real name of the cell

For non-proxy cells (see is_proxy?), this method simply returns the cell name. For proxy cells, this method returns the PCells definition name or the library cell name. This name may differ from the actual cell's name because to ensure that cell names are unique, KLayout may assign different names to the actual cell compared to the source cell.

This method has been introduced in version 0.22.

bbox

(1) Signature: *[const]* Box **bbox**

Description: Gets the bounding box of the cell

Returns: The bounding box of the cell

The bounding box is computed over all layers. To compute the bounding box over single layers, use bbox with a layer index argument.

(2) Signature: *[const]* Box **bbox** (unsigned int layer_index)

Description: Gets the per-layer bounding box of the cell

Returns: The bounding box of the cell considering only the given layer

The bounding box is the box enclosing all shapes on the given layer.

'bbox' is the preferred synonym since version 0.28.

bbox_per_layer

Signature: *[const]* Box **bbox_per_layer** (unsigned int layer_index)

Description: Gets the per-layer bounding box of the cell

Returns: The bounding box of the cell considering only the given layer

Use of this method is deprecated. Use bbox instead

The bounding box is the box enclosing all shapes on the given layer.

'bbox' is the preferred synonym since version 0.28.

begin_instances_rec

Signature: *[const]* RecursiveInstanceIterator **begin_instances_rec**

Description: Delivers a recursive instance iterator for the instances below the cell

Returns: A suitable iterator

For details see the description of the RecursiveInstanceIterator class.

This method has been added in version 0.27.

begin_instances_rec_overlapping

(1) Signature: *[const]* RecursiveInstanceIterator **begin_instances_rec_overlapping** (Box region)

Description: Delivers a recursive instance iterator for the instances below the cell using a region search

region: The search region

Returns: A suitable iterator

For details see the description of the RecursiveInstanceIterator class. This version gives an iterator delivering instances whose bounding box overlaps the given region.

This method has been added in version 0.27.

(2) Signature: *[const]* RecursiveInstanceIterator **begin_instances_rec_overlapping** (DBox region)

Description: Delivers a recursive instance iterator for the instances below the cell using a region search, with the region given in micrometer units

region: The search region as DBox object in micrometer units

Returns: A suitable iterator

For details see the description of the RecursiveInstanceIterator class. This version gives an iterator delivering instances whose bounding box overlaps the given region.

This variant has been added in version 0.27.

begin_instances_rec_touching

(1) Signature: *[const]* RecursiveInstanceIterator **begin_instances_rec_touching** (Box region)

Description: Delivers a recursive instance iterator for the instances below the cell

region: The search region

Returns: A suitable iterator

For details see the description of the RecursiveInstanceIterator class. This version gives an iterator delivering instances whose bounding box touches the given region.

This method has been added in version 0.27.

(2) Signature: *[const]* RecursiveInstanceIterator **begin_instances_rec_touching** (DBox region)

Description: Delivers a recursive instance iterator for the instances below the cell using a region search, with the region given in micrometer units

region: The search region as DBox object in micrometer units

Returns: A suitable iterator

For details see the description of the RecursiveInstanceIterator class. This version gives an iterator delivering instances whose bounding box touches the given region.

This variant has been added in version 0.27.

begin_shapes_rec

Signature: *[const]* RecursiveShapeIterator **begin_shapes_rec** (unsigned int layer)

Description: Delivers a recursive shape iterator for the shapes below the cell on the given layer

layer:	The layer from which to get the shapes
Returns:	A suitable iterator

For details see the description of the RecursiveShapeIterator class.

This method has been added in version 0.23.

begin_shapes_rec_overlapping

(1) Signature: *[const]* RecursiveShapeIterator **begin_shapes_rec_overlapping** (unsigned int layer, Box region)

Description: Delivers a recursive shape iterator for the shapes below the cell on the given layer using a region search

layer:	The layer from which to get the shapes
region:	The search region
Returns:	A suitable iterator

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box overlaps the given region.

This method has been added in version 0.23.

(2) Signature: *[const]* RecursiveShapeIterator **begin_shapes_rec_overlapping** (unsigned int layer, DBox region)

Description: Delivers a recursive shape iterator for the shapes below the cell on the given layer using a region search, with the region given in micrometer units

layer:	The layer from which to get the shapes
region:	The search region as DBox object in micrometer units
Returns:	A suitable iterator

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box overlaps the given region.

This variant has been added in version 0.25.

begin_shapes_rec_touching

(1) Signature: *[const]* RecursiveShapeIterator **begin_shapes_rec_touching** (unsigned int layer, Box region)

Description: Delivers a recursive shape iterator for the shapes below the cell on the given layer using a region search

layer:	The layer from which to get the shapes
region:	The search region
Returns:	A suitable iterator

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box touches the given region.

This method has been added in version 0.23.

(2) Signature: *[const]* RecursiveShapeIterator **begin_shapes_rec_touching** (unsigned int layer, DBox region)

Description: Delivers a recursive shape iterator for the shapes below the cell on the given layer using a region search, with the region given in micrometer units

layer:	The layer from which to get the shapes

region: The search region as DBox object in micrometer units

Returns: A suitable iterator

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box touches the given region.

This variant has been added in version 0.25.

called_cells

Signature: *[const]* unsigned int[] **called_cells**

Description: Gets a list of all called cells

Returns: A list of cell indices.

This method determines all cells which are called either directly or indirectly by the cell. It returns an array of cell indexes. Use the 'cell' method of Layout to retrieve the corresponding Cell object.

This method has been introduced in version 0.19.

caller_cells

Signature: *[const]* unsigned int[] **caller_cells**

Description: Gets a list of all caller cells

Returns: A list of cell indices.

This method determines all cells which call this cell either directly or indirectly. It returns an array of cell indexes. Use the 'cell' method of Layout to retrieve the corresponding Cell object.

This method has been introduced in version 0.19.

cell_index

Signature: *[const]* unsigned int **cell_index**

Description: Gets the cell index

Returns: The cell index of the cell

change_pcell_parameter

Signature: Instance **change_pcell_parameter** (const Instance instance, string name, variant value)

Description: Changes a single parameter for an individual PCell instance given by name

Returns: The new instance (the old may be invalid)

This will set the PCell parameter named 'name' to the given value for the instance addressed by 'instance'. If no parameter with that name exists, the method will do nothing.

This method has been introduced in version 0.23.

change_pcell_parameters

(1) Signature: Instance **change_pcell_parameters** (const Instance instance, map<string,variant> dict)

Description: Changes the given parameter for an individual PCell instance

Returns: The new instance (the old may be invalid)

This version receives a dictionary of names and values. It will change the parameters given by the names to the values given by the values of the dictionary. The functionality is similar to the same function with an array, but more convenient to use. Values with unknown names are ignored.

This method has been introduced in version 0.24.

(2) Signature: Instance **change_pcell_parameters** (const Instance instance, variant[] parameters)

Description: Changes the parameters for an individual PCell instance

Returns: The new instance (the old may be invalid)

If necessary, this method creates a new variant and replaces the given instance by an instance of this variant.

The parameters are given in the order the parameters are declared. Use pcell_declaration on the instance to get the PCell declaration object of the cell. That PCellDeclaration object delivers the parameter declaration with its 'get_parameters' method. Each parameter in the variant list passed to the second list of values corresponds to one parameter declaration.

There is a more convenient method (change_pcell_parameter) that changes a single parameter by name.

This method has been introduced in version 0.22.

child_cells

Signature: *[const]* unsigned long **child_cells**

Description: Gets the number of child cells

The number of child cells (not child instances!) is returned. CAUTION: this method is SLOW, in particular if many instances are present.

child_instances

Signature: *[const]* unsigned long **child_instances**

Description: Gets the number of child instances

Returns: Returns the number of cell instances

clear

(1) Signature: void **clear** (unsigned int layer_index)

Description: Clears the shapes on the given layer

(2) Signature: void **clear**

Description: Clears the cell (deletes shapes and instances)

This method has been introduced in version 0.23.

clear_insts

Signature: void **clear_insts**

Description: Clears the instance list

clear_meta_info

Signature: void **clear_meta_info**

Description: Clears the meta information of the cell

See LayoutMetaInfo for details about cells and meta information.

This method has been introduced in version 0.28.8.

clear_shapes

Signature: void **clear_shapes**

Description: Clears all shapes in the cell

copy

(1) Signature: void **copy** (unsigned int src, unsigned int dest)

Description: Copies the shapes from the source to the target layer

src: The layer index of the source layer

dest: The layer index of the destination layer

The destination layer is not overwritten. Instead, the shapes are added to the shapes of the destination layer. If source are target layer are identical, this method does nothing. This method will copy shapes within the cell. To copy shapes from another cell to this cell, use the copy method with the cell parameter.

This method has been introduced in version 0.19.

(2) Signature: void **copy** (Cell ptr src_cell, unsigned int src_layer, unsigned int dest)

Description: Copies shapes from another cell to the target layer in this cell

src_cell:	The cell where to take the shapes from
src_layer:	The layer index of the layer from which to take the shapes
dest:	The layer index of the destination layer

This method will copy all shapes on layer 'src_layer' of cell 'src_cell' to the layer 'dest' of this cell. The destination layer is not overwritten. Instead, the shapes are added to the shapes of the destination layer. If the source cell lives in a layout with a different database unit than that current cell is in, the shapes will be transformed accordingly. The same way, shape properties are transformed as well. Note that the shape transformation may require rounding to smaller coordinates. This may result in a slight distortion of the original shapes, in particular when transforming into a layout with a bigger database unit.

copy_instances

Signature: void **copy_instances** (const Cell source_cell)

Description: Copies the instances of child cells in the source cell to this cell

source_cell:	The cell where the instances are copied from

The source cell must reside in the same layout than this cell. The instances of child cells inside the source cell are copied to this cell. No new cells are created, just new instances are created to already existing cells in the target cell.

The instances will be added to any existing instances in the cell.

More elaborate methods of copying hierarchy trees between layouts or duplicating trees are provided through the copy_tree_shapes (in cooperation with the CellMapping class) or copy_tree methods.

This method has been added in version 0.23.

copy_meta_info

Signature: void **copy_meta_info** (const Cell ptr other)

Description: Copies the meta information from the other cell into this cell

See LayoutMetaInfo for details about cells and meta information. The meta information from this cell will be replaced by the meta information from the other cell.

This method has been introduced in version 0.28.16.

copy_shapes

(1) Signature: void **copy_shapes** (const Cell source_cell)

Description: Copies the shapes from the given cell into this cell

source_cell:	The cell from where to copy shapes

All shapes are copied from the source cell to this cell. Instances are not copied.

The source cell can reside in a different layout. In this case, the shapes are copied over from the other layout into this layout. Database unit conversion is done automatically if the database units differ between the layouts. Note that this may lead to grid snapping effects if the database unit of the target layout is not an integer fraction of the source layout.

If source and target layout are different, the layers of the source and target layout are identified by their layer/datatype number or name (if no layer/datatype is present). The shapes will be added to any shapes already in the cell.

This method has been added in version 0.23.

(2) Signature: void **copy_shapes** (const Cell source_cell, const LayerMapping layer_mapping)

Description: Copies the shapes from the given cell into this cell

source_cell: The cell from where to copy shapes

layer_mapping: A LayerMapping object that specifies which layers are copied and where

All shapes on layers specified in the layer mapping object are copied from the source cell to this cell. Instances are not copied. The target layer is taken from the mapping table.

The shapes will be added to any shapes already in the cell.

This method has been added in version 0.23.

copy_tree

Signature: unsigned int[] **copy_tree** (const Cell source_cell)

Description: Copies the cell tree of the given cell into this cell

source_cell: The cell from where to copy the cell tree

Returns: A list of indexes of newly created cells

The complete cell tree of the source cell is copied to the target cell plus all shapes in that tree are copied as well. This method will basically duplicate the cell tree of the source cell.

The source cell may reside in a separate layout. This method therefore provides a way to copy over complete cell trees from one layout to another.

The shapes and instances will be added to any shapes or instances already in the cell.

This method has been added in version 0.23.

copy_tree_shapes

(1) Signature: void **copy_tree_shapes** (const Cell source_cell, const CellMapping cell_mapping)

Description: Copies the shapes from the given cell and the cell tree below into this cell or subcells of this cell

source_cell: The starting cell from where to copy shapes

cell_mapping: The cell mapping object that determines how cells are identified between source and target layout

This method is provided if source and target cell reside in different layouts. If will copy the shapes from all cells below the given source cell, but use a cell mapping object that provides a specification how cells are identified between the layouts. Cells in the source tree, for which no mapping is provided, will be flattened - their shapes will be propagated into parent cells for which a mapping is provided.

The cell mapping object provides various methods to map cell trees between layouts. See the CellMapping class for details about the mapping methods available. The cell mapping object is also responsible for creating a proper hierarchy of cells in the target layout if that is required.

Layers are identified between the layouts by the layer/datatype number of name if no layer/datatype number is present.

The shapes copied will be added to any shapes already in the cells.

This method has been added in version 0.23.

(2) Signature: void **copy_tree_shapes** (const Cell source_cell, const CellMapping cell_mapping, const LayerMapping layer_mapping)

Description: Copies the shapes from the given cell and the cell tree below into this cell or subcells of this cell with layer mapping

source_cell: The cell from where to copy shapes and instances

cell_mapping: The cell mapping object that determines how cells are identified between source and target layout

This method is provided if source and target cell reside in different layouts. If will copy the shapes from all cells below the given source cell, but use a cell mapping object that provides a specification how cells are identified between the layouts. Cells in the source tree, for which no mapping is

provided, will be flattened - their shapes will be propagated into parent cells for which a mapping is provided.

The cell mapping object provides various methods to map cell trees between layouts. See the CellMapping class for details about the mapping methods available. The cell mapping object is also responsible for creating a proper hierarchy of cells in the target layout if that is required.

In addition, the layer mapping object can be specified which maps source to target layers. This feature can be used to restrict the copy operation to a subset of layers or to convert shapes to different layers in that step.

The shapes copied will be added to any shapes already in the cells.

This method has been added in version 0.23.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

dbbox

(1) Signature: *[const]* DBox **dbbox**

Description: Gets the bounding box of the cell in micrometer units

Returns: The bounding box of the cell

The bounding box is computed over all layers. To compute the bounding box over single layers, use dbbox with a layer index argument.

This method has been introduced in version 0.25.

(2) Signature: *[const]* DBox **dbbox** (unsigned int layer_index)

Description: Gets the per-layer bounding box of the cell in micrometer units

Returns: The bounding box of the cell considering only the given layer

The bounding box is the box enclosing all shapes on the given layer.

This method has been introduced in version 0.25. 'dbbox' is the preferred synonym since version 0.28.

dbbox_per_layer

Signature: *[const]* DBox **dbbox_per_layer** (unsigned int layer_index)

Description: Gets the per-layer bounding box of the cell in micrometer units

Returns: The bounding box of the cell considering only the given layer

Use of this method is deprecated. Use dbbox instead

The bounding box is the box enclosing all shapes on the given layer.

This method has been introduced in version 0.25. 'dbbox' is the preferred synonym since version 0.28.

delete

Signature: void **delete**

Description: Deletes this cell

This deletes the cell but not the sub cells of the cell. These subcells will likely become new top cells unless they are used otherwise. All instances of this cell are deleted as well. Hint: to delete multiple cells, use "delete_cells" which is far more efficient in this case.

After the cell has been deleted, the Cell object becomes invalid. Do not access methods or attributes of this object after deleting the cell.

This method has been introduced in version 0.23.

delete_property

Signature: void **delete_property** (variant key)

Description: Deletes the user property with the given key

This method is a convenience method that deletes the property with the given key. It does nothing if no property with that key exists. Using that method is more convenient than creating a new property set with a new ID and assigning that properties ID. This method may change the properties ID.

This method has been introduced in version 0.23.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

display_title

Signature: *[const]* string **display_title**

Description: Returns a nice looking name for display purposes

For example, this name include PCell parameters for PCell proxy cells.

This method has been introduced in version 0.22.

dup

Signature: *[const]* Cell ptr **dup**

Description: Creates a copy of the cell

This method will create a copy of the cell. The new cell will be member of the same layout the original cell was member of. The copy will inherit all shapes and instances, but get a different cell_index and a modified name as duplicate cell names are not allowed in the same layout.

This method has been introduced in version 0.27.

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

each_child_cell

Signature: *[const,iter]* unsigned int **each_child_cell**

Description: Iterates over all child cells

This iterator will report the child cell indices, not every instance.

each_inst

Signature: *[iter]* Instance **each_inst**

Description: Iterates over all child instances (which may actually be instance arrays)

Starting with version 0.15, this iterator delivers Instance objects rather than CellInstArray objects.

each_meta_info

Signature: *[const,iter]* LayoutMetaInfo **each_meta_info**

Description: Iterates over the meta information of the cell

See LayoutMetaInfo for details about cells and meta information.

This method has been introduced in version 0.28.8.

each_overlapping_inst

(1) Signature: *[const,iter]* Instance **each_overlapping_inst** (const Box b)

Description: Gets the instances overlapping the given rectangle

b: The region to iterate over

This will iterate over all child cell instances overlapping with the given rectangle b.

Starting with version 0.15, this iterator delivers Instance objects rather than CellInstArray objects.

(2) Signature: *[const,iter]* Instance **each_overlapping_inst** (const DBox b)

Description: Gets the instances overlapping the given rectangle, with the rectangle in micrometer units

b: The region to iterate over

This will iterate over all child cell instances overlapping with the given rectangle b. This method is identical to the each_overlapping_inst version that takes a Box object, but instead of taking database unit coordinates in will take a micrometer unit DBox object.

This variant has been introduced in version 0.25.

each_overlapping_shape

(1) Signature: *[const,iter]* Shape **each_overlapping_shape** (unsigned int layer_index, const Box box, unsigned int flags)

Description: Iterates over all shapes of a given layer that overlap the given box

flags: An "or"-ed combination of the S.. constants of the Shapes class

box: The box by which to query the shapes

layer_index: The layer on which to run the query

(2) Signature: *[const,iter]* Shape **each_overlapping_shape** (unsigned int layer_index, const Box box)

Description: Iterates over all shapes of a given layer that overlap the given box

box: The box by which to query the shapes

layer_index: The layer on which to run the query

This call is equivalent to each_overlapping_shape(layer_index,box,RBA::Shapes::SAll). This convenience method has been introduced in version 0.16.

(3) Signature: *[const,iter]* Shape **each_overlapping_shape** (unsigned int layer_index, const DBox box, unsigned int flags)

Description: Iterates over all shapes of a given layer that overlap the given box, with the box given in micrometer units

flags: An "or"-ed combination of the S.. constants of the Shapes class

box: The box by which to query the shapes as a DBox object in micrometer units

layer_index: The layer on which to run the query

(4) Signature: *[const,iter]* Shape **each_overlapping_shape** (unsigned int layer_index, const DBox box)

Description: Iterates over all shapes of a given layer that overlap the given box, with the box given in micrometer units

box: The box by which to query the shapes as a DBox object in micrometer units

layer_index: The layer on which to run the query

This call is equivalent to each_overlapping_shape(layer_index,box,RBA::Shapes::SAll). This convenience method has been introduced in version 0.16.

each_parent_cell

Signature: *[const,iter]* unsigned int **each_parent_cell**

Description: Iterates over all parent cells

This iterator will iterate over the parent cells, just returning their cell index.

each_parent_inst

Signature: *[const,iter]* ParentInstArray **each_parent_inst**

Description: Iterates over the parent instance list (which may actually be instance arrays)

The parent instances are basically inversions of the instances. Using parent instances it is possible to determine how a specific cell is called from where.

each_shape

(1) Signature: *[const,iter]* Shape **each_shape** (unsigned int layer_index, unsigned int flags)

Description: Iterates over all shapes of a given layer

flags: An "or"-ed combination of the S.. constants of the Shapes class

layer_index: The layer on which to run the query

This iterator is equivalent to 'shapes(layer).each'.

(2) Signature: *[const,iter]* Shape **each_shape** (unsigned int layer_index)

Description: Iterates over all shapes of a given layer

layer_index: The layer on which to run the query

This call is equivalent to each_shape(layer_index,RBA::Shapes::SAll). This convenience method has been introduced in version 0.16.

each_touching_inst

(1) Signature: *[const,iter]* Instance **each_touching_inst** (const Box b)

Description: Gets the instances touching the given rectangle

b: The region to iterate over

This will iterate over all child cell instances overlapping with the given rectangle b.

Starting with version 0.15, this iterator delivers Instance objects rather than CellInstArray objects.

(2) Signature: *[const,iter]* Instance **each_touching_inst** (const DBox b)

Description: Gets the instances touching the given rectangle, with the rectangle in micrometer units

b: The region to iterate over

This will iterate over all child cell instances touching the given rectangle b. This method is identical to the each_touching_inst version that takes a Box object, but instead of taking database unit coordinates in will take a micrometer unit DBox object.

This variant has been introduced in version 0.25.

each_touching_shape

(1) Signature: *[const,iter]* Shape **each_touching_shape** (unsigned int layer_index, const Box box, unsigned int flags)

Description: Iterates over all shapes of a given layer that touch the given box

flags:	An "or"-ed combination of the S.. constants of the Shapes class
box:	The box by which to query the shapes
layer_index:	The layer on which to run the query

(2) Signature: *[const,iter]* Shape **each_touching_shape** (unsigned int layer_index, const Box box)

Description: Iterates over all shapes of a given layer that touch the given box

box:	The box by which to query the shapes
layer_index:	The layer on which to run the query

This call is equivalent to each_touching_shape(layer_index,box,RBA::Shapes::SAll). This convenience method has been introduced in version 0.16.

(3) Signature: *[const,iter]* Shape **each_touching_shape** (unsigned int layer_index, const DBox box, unsigned int flags)

Description: Iterates over all shapes of a given layer that touch the given box, with the box given in micrometer units

flags:	An "or"-ed combination of the S.. constants of the Shapes class
box:	The box by which to query the shapes as a DBox object in micrometer units
layer_index:	The layer on which to run the query

(4) Signature: *[const,iter]* Shape **each_touching_shape** (unsigned int layer_index, const DBox box)

Description: Iterates over all shapes of a given layer that touch the given box, with the box given in micrometer units

box:	The box by which to query the shapes as a DBox object in micrometer units
layer_index:	The layer on which to run the query

This call is equivalent to each_touching_shape(layer_index,box,RBA::Shapes::SAll). This convenience method has been introduced in version 0.16.

erase

Signature: void **erase** (const Instance inst)

Description: Erases the instance given by the Instance object

This method has been introduced in version 0.16. It can only be used in editable mode.

fill_region

(1) Signature: void **fill_region** (const Region region, unsigned int fill_cell_index, const Box fc_box, const Point ptr origin = (0, 0), Region ptr remaining_parts = nil, const Vector fill_margin = 0,0, Region ptr remaining_polygons = nil, const Box glue_box = ())

Description: Fills the given region with cells of the given type (extended version)

region:	The region to fill
fill_cell_index:	The fill cell to place
fc_box:	The fill cell's footprint
origin:	The global origin of the fill pattern or nil to allow local (per-polygon) optimization
remaining_parts:	See explanation below
fill_margin:	See explanation below
remaining_polygons:	See explanation below
glue_box:	Guarantees fill cell compatibility to neighbor regions in enhanced mode

This method creates a regular pattern of fill cells to cover the interior of the given region as far as possible. This process is also known as tiling. This implementation supports rectangular (not necessarily square) tile cells. The tile cell's footprint is given by the fc_box parameter and the cells will be arranged with their footprints forming a seamless array.

The algorithm supports a global fill raster as well as local (per-polygon) origin optimization. In the latter case the origin of the regular raster is optimized per individual polygon of the fill region. To enable optimization, pass 'nil' to the 'origin' argument.

The implementation will basically try to find a repetition pattern of the tile cell's footprint and produce instances which fit entirely into the fill region.

There is also a version available which offers skew step vectors as a generalization of the orthogonal ones.

If the 'remaining_parts' argument is non-nil, the corresponding region will receive the parts of the polygons which are not covered by tiles. Basically the tiles are subtracted from the original polygons. A margin can be specified which is applied separately in x and y direction before the subtraction is done ('fill_margin' parameter).

If the 'remaining_polygons' argument is non-nil, the corresponding region will receive all polygons from the input region which could not be filled and where there is no chance of filling because not a single tile will fit into them.

'remaining_parts' and 'remaining_polygons' can be identical with the input. In that case the input will be overwritten with the respective output. Otherwise, the respective polygons are added to these regions.

This allows setting up a more elaborate fill scheme using multiple iterations and local origin-optimization ('origin' is nil):

```
r = ...        # region to fill
c = ...        # cell in which to produce the fill cells
fc_index = ... # fill cell index
fc_box = ...   # fill cell footprint

fill_margin = RBA::Point::new(0, 0)   # x/y distance between tile cells with
 different origin

# Iteration: fill a region and fill the remaining parts as long as there is
 anything left.
# Polygons not worth being considered further are dropped (last argument is
 nil).
while !r.is_empty?
  c.fill_region(r, fc_index, fc_box, nil, r, fill_margin, nil)
```

```
end
```

The glue box parameter supports fill cell array compatibility with neighboring regions. This is specifically useful when putting the fill_cell method into a tiling processor. Fill cell array compatibility means that the fill cell array continues over tile boundaries. This is easy with an origin: you can chose the origin identically over all tiles which is sufficient to guarantee fill cell array compatibility across the tiles. However there is no freedom of choice of the origin then and fill cell placement may not be optimal. To enable the origin for the tile boundary only, a glue box can given. The origin will then be used only when the polygons to fill not entirely inside and not at the border of the glue box. Hence, while a certain degree of freedom is present for the placement of fill cells inside the glue box, the fill cells are guaranteed to be placed at the raster implied by origin at the glue box border and beyond. To ensure fill cell compatibility inside the tiling processor, it is sufficient to use the tile box as the glue box.

This method has been introduced in version 0.23 and enhanced in version 0.27.

(2) Signature: void **fill_region** (const Region region, unsigned int fill_cell_index, const Box fc_bbox, const Vector row_step, const Vector column_step, const Point ptr origin = (0, 0), Region ptr remaining_parts = nil, const Vector fill_margin = 0,0, Region ptr remaining_polygons = nil, const Box glue_box = ())

Description: Fills the given region with cells of the given type (skew step version)

region:	The region to fill
fill_cell_index:	The fill cell to place
fc_bbox:	The fill cell's box to place
row_step:	The 'rows' step vector
column_step:	The 'columns' step vector
origin:	The global origin of the fill pattern or nil to allow local (per-polygon) optimization
remaining_parts:	See explanation in other version
fill_margin:	See explanation in other version
remaining_polygons:	See explanation in other version

This version is similar to the version providing an orthogonal fill, but it offers more generic stepping of the fill cell. The step pattern is defined by an origin and two vectors (row_step and column_step) which span the axes of the fill cell pattern.

The fill box and the step vectors are decoupled which means the fill box can be larger or smaller than the step pitch - it can be overlapping and there can be space between the fill box instances. Fill boxes are placed where they fit entirely into a polygon of the region. The fill boxes lower left corner is the reference for the fill pattern and aligns with the origin if given.

This variant has been introduced in version 0.27.

fill_region_multi

Signature: void **fill_region_multi** (const Region region, unsigned int fill_cell_index, const Box fc_bbox, const Vector row_step, const Vector column_step, const Vector fill_margin = 0,0, Region ptr remaining_polygons = nil, const Box glue_box = ())

Description: Fills the given region with cells of the given type in enhanced mode with iterations

This version operates like fill_region, but repeats the fill generation until no further fill cells can be placed. As the fill pattern origin changes between the iterations, narrow regions can be filled which cannot with a fixed fill pattern origin. The fill_margin parameter is important as it controls the distance between fill cells with a different origin and therefore introduces a safety distance between pitch-incompatible arrays.

The origin is ignored unless a glue box is given. See fill_region for a description of this concept.

This method has been introduced in version 0.27.

flatten

(1) Signature: void **flatten** (bool prune)

Description: Flattens the given cell

prune: Set to true to remove orphan cells.

This method propagates all shapes from the hierarchy below into the given cell. It also removes the instances of the cells from which the shapes came from, but does not remove the cells themselves if prune is set to false. If prune is set to true, these cells are removed if not used otherwise.

A version of this method exists which allows one to specify the number of hierarchy levels to which subcells are considered.

This method has been introduced in version 0.23.

(2) Signature: void **flatten** (int levels, bool prune)

Description: Flattens the given cell

levels: The number of hierarchy levels to flatten (-1: all, 0: none, 1: one level etc.)

prune: Set to true to remove orphan cells.

This method propagates all shapes from the specified number of hierarchy levels below into the given cell. It also removes the instances of the cells from which the shapes came from, but does not remove the cells themselves if prune is set to false. If prune is set to true, these cells are removed if not used otherwise.

This method has been introduced in version 0.23.

ghost_cell=

Signature: void **ghost_cell=** (bool flag)

Description: Sets the "ghost cell" flag

See is_ghost_cell? for a description of this property.

This method has been introduced in version 0.20.

Python specific notes:
The object exposes a writable attribute 'ghost_cell'. This is the setter.

has_prop_id?

Signature: *[const]* bool **has_prop_id?**

Description: Returns true, if the cell has user properties

This method has been introduced in version 0.23.

hierarchy_levels

Signature: *[const]* unsigned int **hierarchy_levels**

Description: Returns the number of hierarchy levels below

This method returns the number of call levels below the current cell. If there are no child cells, this method will return 0, if there are only direct children, it will return 1.

CAUTION: this method may be expensive!

insert

(1) Signature: Instance **insert** (const Instance inst)

Description: Inserts a cell instance given by another reference

Returns: An Instance object representing the new instance

This method allows one to copy instances taken from a reference (an Instance object). This method is not suited to inserting instances from other Layouts into this cell. For this purpose, the hierarchical copy methods of Layout have to be used.

It has been added in version 0.16.

(2) Signature: Instance **insert** (const CellInstArray cell_inst_array)

Description: Inserts a cell instance (array)

Returns: An Instance object representing the new instance

With version 0.16, this method returns an Instance object that represents the new instance. It's use is discouraged in readonly mode, since it invalidates other Instance references.

(3) Signature: Instance **insert** (const DCellInstArray cell_inst_array)

Description: Inserts a cell instance (array) given in micron units

Returns: An Instance object representing the new instance

This method inserts an instance array, similar to insert with a CellInstArray parameter. But in this version, the argument is a cell instance array given in micrometer units. It is translated to database units internally.

This variant has been introduced in version 0.25.

(4) Signature: Instance **insert** (const DCellInstArray cell_inst_array, unsigned long property_id)

Description: Inserts a cell instance (array) given in micron units with properties

Returns: An Instance object representing the new instance

This method inserts an instance array, similar to insert with a CellInstArray parameter and a property set ID. But in this version, the argument is a cell instance array given in micrometer units. It is translated to database units internally.

This variant has been introduced in version 0.25.

(5) Signature: Instance **insert** (const CellInstArray cell_inst_array, unsigned long property_id)

Description: Inserts a cell instance (array) with properties

Returns: An Instance object representing the new instance

The property Id must be obtained from the Layout object's property_id method which associates a property set with a property Id. With version 0.16, this method returns an Instance object that represents the new instance. It's use is discouraged in readonly mode, since it invalidates other Instance references.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_empty?

Signature: *[const]* bool **is_empty?**

Description: Returns a value indicating whether the cell is empty

An empty cell is a cell not containing instances nor any shapes.

This method has been introduced in version 0.20.

is_ghost_cell?

Signature: *[const]* bool **is_ghost_cell?**

Description: Returns a value indicating whether the cell is a "ghost cell"

The ghost cell flag is used by the GDS reader for example to indicate that the cell is not located inside the file. Upon writing the reader can determine whether to write the cell or not. To satisfy the references inside the layout, a dummy cell is created in this case which has the "ghost cell" flag set to true.

This method has been introduced in version 0.20.

Python specific notes:
The object exposes a readable attribute 'ghost_cell'. This is the getter.

is_leaf?

Signature: *[const]* bool **is_leaf?**

Description: Gets a value indicating whether the cell is a leaf cell

A cell is a leaf cell if there are no child instantiations.

is_library_cell?

Signature: *[const]* bool **is_library_cell?**

Description: Returns true, if the cell is a proxy cell pointing to a library cell

If the cell is imported from some library, this attribute returns true. Please note, that this attribute can combine with is_pcell? for PCells imported from a library.

This method has been introduced in version 0.22.

is_pcell_variant?

(1) Signature: *[const]* bool **is_pcell_variant?**

Description: Returns true, if this cell is a pcell variant

this method returns true, if this cell represents a pcell with a distinct set of parameters (a PCell proxy). This also is true, if the PCell is imported from a library.

Technically, PCells imported from a library are library proxies which are pointing to PCell variant proxies. This scheme can even proceed over multiple indirections, i.e. a library using PCells from another library.

This method has been introduced in version 0.22.

(2) Signature: *[const]* bool **is_pcell_variant?** (const Instance instance)

Description: Returns true, if this instance is a PCell variant

This method returns true, if this instance represents a PCell with a distinct set of parameters. This method also returns true, if it is a PCell imported from a library.

This method has been introduced in version 0.22.

is_proxy?

Signature: *[const]* bool **is_proxy?**

Description: Returns true, if the cell presents some external entity

A cell may represent some data which is imported from some other source, i.e. a library. Such cells are called "proxy cells". For a library reference, the proxy cell is some kind of pointer to the library and the cell within the library.

For PCells, this data can even be computed through some script. A PCell proxy represents all instances with a given set of parameters.

Proxy cells cannot be modified, except that pcell parameters can be modified and PCell instances can be recomputed.

This method has been introduced in version 0.22.

is_top?

Signature: *[const]* bool **is_top?**

Description: Gets a value indicating whether the cell is a top-level cell

A cell is a top-level cell if there are no parent instantiations.

is_valid?

Signature: *[const]* bool **is_valid?** (const Instance instance)

Description: Tests if the given Instance object is still pointing to a valid object

This method has been introduced in version 0.16. If the instance represented by the given reference has been deleted, this method returns false. If however, another instance has been inserted already that occupies the original instances position, this method will return true again.

layout

(1) Signature: Layout ptr **layout**

Description: Returns a reference to the layout where the cell resides

this method has been introduced in version 0.22.

(2) Signature: *[const]* const Layout ptr **layout**

Description: Returns a reference to the layout where the cell resides (const references)

this method has been introduced in version 0.22.

library

Signature: *[const]* Library ptr **library**

Description: Returns a reference to the library from which the cell is imported

if the cell is not imported from a library, this reference is nil.

this method has been introduced in version 0.22.

library_cell_index

Signature: *[const]* unsigned int **library_cell_index**

Description: Returns the index of the cell in the layout of the library (if it's a library proxy)

Together with the library method, it is possible to locate the source cell of a library proxy. The source cell can be retrieved from a cell "c" with

```
c.library.layout.cell(c.library_cell_index)
```

This cell may be itself a proxy, i.e. for pcell libraries, where the library cells are pcell variants which itself are proxies to a pcell.

This method has been introduced in version 0.22.

merge_meta_info

Signature: void **merge_meta_info** (const Cell ptr other)

Description: Merges the meta information from the other cell into this cell

See LayoutMetaInfo for details about cells and meta information. Existing keys in this cell will be overwritten by the respective values from the other cell. New keys will be added.

This method has been introduced in version 0.28.16.

meta_info

Signature: new LayoutMetaInfo ptr **meta_info** (string name)

Description: Gets the meta information for a given name

See LayoutMetaInfo for details about cells and meta information.

If no meta information with the given name exists, a default object with empty fields will be returned.

This method has been introduced in version 0.28.8.

meta_info_value

Signature: variant **meta_info_value** (string name)

Description: Gets the meta information value for a given name

See LayoutMetaInfo for details about cells and meta information.

If no meta information with the given name exists, a nil value will be returned. A more generic version that delivers all fields of the meta information is meta_info.

This method has been introduced in version 0.28.8.

move

(1) Signature: void **move** (unsigned int src, unsigned int dest)

Description: Moves the shapes from the source to the target layer

src:	The layer index of the source layer
dest:	The layer index of the destination layer

The destination layer is not overwritten. Instead, the shapes are added to the shapes of the destination layer. This method will move shapes within the cell. To move shapes from another cell to this cell, use the copy method with the cell parameter.

This method has been introduced in version 0.19.

(2) Signature: void **move** (Cell ptr src_cell, unsigned int src_layer, unsigned int dest)

Description: Moves shapes from another cell to the target layer in this cell

src_cell:	The cell where to take the shapes from
src_layer:	The layer index of the layer from which to take the shapes
dest:	The layer index of the destination layer

This method will move all shapes on layer 'src_layer' of cell 'src_cell' to the layer 'dest' of this cell. The destination layer is not overwritten. Instead, the shapes are added to the shapes of the destination layer. If the source cell lives in a layout with a different database unit than that current cell is in, the shapes will be transformed accordingly. The same way, shape properties are transformed as well. Note that the shape transformation may require rounding to smaller coordinates. This may result in a slight distortion of the original shapes, in particular when transforming into a layout with a bigger database unit.

move_instances

Signature: void **move_instances** (Cell source_cell)

Description: Moves the instances of child cells in the source cell to this cell

source_cell:	The cell where the instances are moved from

The source cell must reside in the same layout than this cell. The instances of child cells inside the source cell are moved to this cell. No new cells are created, just new instances are created to already existing cells in the target cell.

The instances will be added to any existing instances in the cell.

More elaborate methods of moving hierarchy trees between layouts are provided through the move_tree_shapes (in cooperation with the CellMapping class) or move_tree methods.

This method has been added in version 0.23.

move_shapes

(1) Signature: void **move_shapes** (Cell source_cell)

Description: Moves the shapes from the given cell into this cell

source_cell:	The cell from where to move shapes

All shapes are moved from the source cell to this cell. Instances are not moved.

The source cell can reside in a different layout. In this case, the shapes are moved over from the other layout into this layout. Database unit conversion is done automatically if the database units

differ between the layouts. Note that this may lead to grid snapping effects if the database unit of the target layout is not an integer fraction of the source layout.

If source and target layout are different, the layers of the source and target layout are identified by their layer/datatype number or name (if no layer/datatype is present). The shapes will be added to any shapes already in the cell.

This method has been added in version 0.23.

(2) Signature: void **move_shapes** (Cell source_cell, const LayerMapping layer_mapping)

Description: Moves the shapes from the given cell into this cell

source_cell:	The cell from where to move shapes
layer_mapping:	A LayerMapping object that specifies which layers are moved and where

All shapes on layers specified in the layer mapping object are moved from the source cell to this cell. Instances are not moved. The target layer is taken from the mapping table.

The shapes will be added to any shapes already in the cell.

This method has been added in version 0.23.

move_tree

Signature: unsigned int[] **move_tree** (Cell source_cell)

Description: Moves the cell tree of the given cell into this cell

source_cell:	The cell from where to move the cell tree
Returns:	A list of indexes of newly created cells

The complete cell tree of the source cell is moved to the target cell plus all shapes in that tree are moved as well. This method will basically rebuild the cell tree of the source cell and empty the source cell.

The source cell may reside in a separate layout. This method therefore provides a way to move over complete cell trees from one layout to another.

The shapes and instances will be added to any shapes or instances already in the cell.

This method has been added in version 0.23.

move_tree_shapes

(1) Signature: void **move_tree_shapes** (Cell source_cell, const CellMapping cell_mapping)

Description: Moves the shapes from the given cell and the cell tree below into this cell or subcells of this cell

source_cell:	The starting cell from where to move shapes
cell_mapping:	The cell mapping object that determines how cells are identified between source and target layout

This method is provided if source and target cell reside in different layouts. If will move the shapes from all cells below the given source cell, but use a cell mapping object that provides a specification how cells are identified between the layouts. Cells in the source tree, for which no mapping is provided, will be flattened - their shapes will be propagated into parent cells for which a mapping is provided.

The cell mapping object provides various methods to map cell trees between layouts. See the CellMapping class for details about the mapping methods available. The cell mapping object is also responsible for creating a proper hierarchy of cells in the target layout if that is required.

Layers are identified between the layouts by the layer/datatype number of name if no layer/datatype number is present.

The shapes moved will be added to any shapes already in the cells.

This method has been added in version 0.23.

(2) Signature: void **move_tree_shapes** (Cell source_cell, const CellMapping cell_mapping, const LayerMapping layer_mapping)

Description: Moves the shapes from the given cell and the cell tree below into this cell or subcells of this cell with layer mapping

source_cell:	The cell from where to move shapes and instances
cell_mapping:	The cell mapping object that determines how cells are identified between source and target layout

This method is provided if source and target cell reside in different layouts. If will move the shapes from all cells below the given source cell, but use a cell mapping object that provides a specification how cells are identified between the layouts. Cells in the source tree, for which no mapping is provided, will be flattened - their shapes will be propagated into parent cells for which a mapping is provided.

The cell mapping object provides various methods to map cell trees between layouts. See the CellMapping class for details about the mapping methods available. The cell mapping object is also responsible for creating a proper hierarchy of cells in the target layout if that is required.

In addition, the layer mapping object can be specified which maps source to target layers. This feature can be used to restrict the move operation to a subset of layers or to convert shapes to different layers in that step.

The shapes moved will be added to any shapes already in the cells.

This method has been added in version 0.23.

name

Signature: *[const]* string **name**

Description: Gets the cell's name

This may be an internal name for proxy cells. See basic_name for the formal name (PCell name or library cell name).

This method has been introduced in version 0.22.

Python specific notes:
The object exposes a readable attribute 'name'. This is the getter.

name=

Signature: void **name=** (string name)

Description: Renames the cell

Renaming a cell may cause name clashes, i.e. the name may be identical to the name of another cell. This does not have any immediate effect, but the cell needs to be renamed, for example when writing the layout to a GDS file.

This method has been introduced in version 0.22.

Python specific notes:
The object exposes a writable attribute 'name'. This is the setter.

new

Signature: *[static]* new Cell ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

parent_cells

Signature: *[const]* unsigned long **parent_cells**

Description: Gets the number of parent cells

The number of parent cells (cells which reference our cell) is reported.

pcell_declaration

(1) Signature: *[const]* const PCellDeclaration ptr **pcell_declaration**

Description: Returns a reference to the PCell declaration

If this cell is not a PCell variant, this method returns nil. PCell variants are proxy cells which are PCell incarnations for a specific parameter set. The PCellDeclaration object allows one to retrieve PCell parameter definitions for example.

This method has been introduced in version 0.22.

(2) Signature: *[const]* const PCellDeclaration ptr **pcell_declaration** (const Instance instance)

Description: Returns the PCell declaration of a pcell instance

If the instance is not a PCell instance, this method returns nil. The PCellDeclaration object allows one to retrieve PCell parameter definitions for example.

This method has been introduced in version 0.22.

pcell_id

Signature: *[const]* unsigned int **pcell_id**

Description: Returns the PCell ID if the cell is a pcell variant

This method returns the ID which uniquely identifies the PCell within the layout where it's declared. It can be used to retrieve the PCell declaration or to create new PCell variants.

The method will be rarely used. It's more convenient to use pcell_declaration to directly retrieve the PCellDeclaration object for example.

This method has been introduced in version 0.22.

pcell_library

Signature: *[const]* Library ptr **pcell_library**

Description: Returns the library where the PCell is declared if this cell is a PCell and it is not defined locally.

A PCell often is not declared within the current layout but in some library. This method returns a reference to that library, which technically is the last of the chained library proxies. If this cell is not a PCell or it is not located in a library, this method returns nil.

This method has been introduced in version 0.22.

pcell_parameter

(1) Signature: *[const]* variant **pcell_parameter** (string name)

Description: Gets a PCell parameter by name if the cell is a PCell variant

If the cell is a PCell variant, this method returns the parameter with the given name. If the cell is not a PCell variant or the name is not a valid PCell parameter name, the return value is nil.

This method has been introduced in version 0.25.

(2) Signature: *[const]* variant **pcell_parameter** (const Instance instance, string name)

Description: Returns a PCell parameter by name for a pcell instance

If the given instance is a PCell instance, this method returns the value of the PCell parameter with the given name. If the instance is not a PCell instance or the name is not a valid PCell parameter name, this method returns nil.

This method has been introduced in version 0.25.

pcell_parameters

(1) Signature: *[const]* variant[] **pcell_parameters**

Description: Returns the PCell parameters for a pcell variant

If the cell is a PCell variant, this method returns a list of values for the PCell parameters. If the cell is not a PCell variant, this method returns an empty list. This method also returns the PCell parameters if the cell is a PCell imported from a library.

This method has been introduced in version 0.22.

(2) Signature: *[const]* variant[] **pcell_parameters** (const Instance instance)

Description: Returns the PCell parameters for a pcell instance

If the given instance is a PCell instance, this method returns a list of values for the PCell parameters. If the instance is not a PCell instance, this method returns an empty list.

This method has been introduced in version 0.22.

pcell_parameters_by_name

(1) Signature: *[const]* map<string,variant> **pcell_parameters_by_name**

Description: Returns the PCell parameters for a pcell variant as a name to value dictionary

If the cell is a PCell variant, this method returns a dictionary of values for the PCell parameters with the parameter names as the keys. If the cell is not a PCell variant, this method returns an empty dictionary. This method also returns the PCell parameters if the cell is a PCell imported from a library.

This method has been introduced in version 0.24.

(2) Signature: *[const]* map<string,variant> **pcell_parameters_by_name** (const Instance instance)

Description: Returns the PCell parameters for a pcell instance as a name to value dictionary

If the given instance is a PCell instance, this method returns a dictionary of values for the PCell parameters with the parameter names as the keys. If the instance is not a PCell instance, this method returns an empty dictionary.

This method has been introduced in version 0.24.

prop_id

Signature: *[const]* unsigned long **prop_id**

Description: Gets the properties ID associated with the cell

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a readable attribute 'prop_id'. This is the getter.

prop_id=

Signature: void **prop_id=** (unsigned long id)

Description: Sets the properties ID associated with the cell

This method is provided, if a properties ID has been derived already. Usually it's more convenient to use delete_property, set_property or property.

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a writable attribute 'prop_id'. This is the setter.

property

Signature: variant **property** (variant key)

Description: Gets the user property with the given key

This method is a convenience method that gets the property with the given key. If no property with that key exists, it will return nil. Using that method is more convenient than using the layout object and the properties ID to retrieve the property value. This method has been introduced in version 0.23.

prune_cell

(1) Signature: void **prune_cell**

Description: Deletes the cell plus subcells not used otherwise

This deletes the cell and also all sub cells of the cell which are not used otherwise. All instances of this cell are deleted as well. A version of this method exists which allows one to specify the number of hierarchy levels to which subcells are considered.

After the cell has been deleted, the Cell object becomes invalid. Do not access methods or attributes of this object after deleting the cell.

This method has been introduced in version 0.23.

(2) Signature: void **prune_cell** (int levels)

Description: Deletes the cell plus subcells not used otherwise

levels:	The number of hierarchy levels to consider (-1: all, 0: none, 1: one level etc.)

This deletes the cell and also all sub cells of the cell which are not used otherwise. The number of hierarchy levels to consider can be specified as well. One level of hierarchy means that only the direct children of the cell are deleted with the cell itself. All instances of this cell are deleted as well.

After the cell has been deleted, the Cell object becomes invalid. Do not access methods or attributes of this object after deleting the cell.

This method has been introduced in version 0.23.

prune_subcells

(1) Signature: void **prune_subcells**

Description: Deletes all sub cells of the cell which are not used otherwise

This deletes all sub cells of the cell which are not used otherwise. All instances of the deleted cells are deleted as well. A version of this method exists which allows one to specify the number of hierarchy levels to which subcells are considered.

This method has been introduced in version 0.23.

(2) Signature: void **prune_subcells** (int levels)

Description: Deletes all sub cells of the cell which are not used otherwise down to the specified level of hierarchy

levels:	The number of hierarchy levels to consider (-1: all, 0: none, 1: one level etc.)

This deletes all sub cells of the cell which are not used otherwise. All instances of the deleted cells are deleted as well. It is possible to specify how many levels of hierarchy below the given root cell are considered.

This method has been introduced in version 0.23.

qname

Signature: *[const]* string **qname**

Description: Returns the library-qualified name

Library cells will be indicated by returning a qualified name composed of the library name, a dot and the basic cell name. For example: "Basic.TEXT" will be the qname of the TEXT cell of the Basic library. For non-library cells, the qname is identical to the basic name (see name).

This method has been introduced in version 0.25.

read

(1) Signature: unsigned int[] **read** (string file_name, const LoadLayoutOptions options)

Description: Reads a layout file into this cell

file_name:	The path of the file to read
options:	The reader options to use

Returns: The indexes of the cells created during the reading (new child cells)

The format of the file will be determined from the file name. The layout will be read into the cell, potentially creating new layers and a subhierarchy of cells below this cell.

This feature is equivalent to the following code:

```
def Cell.read(file_name, options)
  layout = RBA::Layout::new
  layout.read(file_name, options)
  cm = RBA::CellMapping::new
  cm.for_single_cell_full(self, layout.top_cell)
  self.move_tree_shapes(layout.top_cell)
end
```

See move_tree_shapes and CellMapping for more details and how to implement more elaborate schemes.

This method has been introduced in version 0.28.

(2) Signature: unsigned int[] **read** (string file_name)

Description: Reads a layout file into this cell

This version uses the default options for reading the file.

This method has been introduced in version 0.28.

refresh

Signature: void **refresh**

Description: Refreshes a proxy cell

If the cell is a PCell variant, this method recomputes the PCell. If the cell is a library proxy, this method reloads the information from the library, but not the library itself. Note that if the cell is an PCell variant for a PCell coming from a library, this method will not recompute the PCell. Instead, you can use Library#refresh to recompute all PCells from that library.

You can use Layout#refresh to refresh all cells from a layout.

This method has been introduced in version 0.22.

remove_meta_info

Signature: void **remove_meta_info** (string name)

Description: Removes meta information from the cell

See LayoutMetaInfo for details about cells and meta information.

This method has been introduced in version 0.28.8.

replace

(1) Signature: Instance **replace** (const Instance instance, const CellInstArray cell_inst_array)

Description: Replaces a cell instance (array) with a different one

Returns: An Instance object representing the new instance

This method has been introduced in version 0.16. It can only be used in editable mode. The instance given by the instance object (first argument) is replaced by the given instance (second argument). The new object will not have any properties.

(2) Signature: Instance **replace** (const Instance instance, const CellInstArray cell_inst_array, unsigned long property_id)

Description: Replaces a cell instance (array) with a different one with properties

Returns: An Instance object representing the new instance

This method has been introduced in version 0.16. It can only be used in editable mode. The instance given by the instance object (first argument) is replaced by the given instance (second argument) with the given properties Id. The property Id must be obtained from the Layout object's property_id method which associates a property set with a property Id. The new object will not have any properties.

(3) Signature: Instance **replace** (const Instance instance, const DCellInstArray cell_inst_array)

Description: Replaces a cell instance (array) with a different one, given in micrometer units

Returns: An Instance object representing the new instance

This method is identical to the corresponding replace variant with a CellInstArray argument. It however accepts a micrometer-unit DCellInstArray object which is translated to database units internally.

This variant has been introduced in version 0.25.

(4) Signature: Instance **replace** (const Instance instance, const DCellInstArray cell_inst_array, unsigned long property_id)

Description: Replaces a cell instance (array) with a different one and new properties, where the cell instance is given in micrometer units

Returns: An Instance object representing the new instance

This method is identical to the corresponding replace variant with a CellInstArray argument and a property ID. It however accepts a micrometer-unit DCellInstArray object which is translated to database units internally.

This variant has been introduced in version 0.25.

replace_prop_id

Signature: Instance **replace_prop_id** (const Instance instance, unsigned long property_id)

Description: Replaces (or install) the properties of a cell

Returns: An Instance object representing the new instance

This method has been introduced in version 0.16. It can only be used in editable mode. Changes the properties Id of the given instance or install a properties Id on that instance if it does not have one yet. The property Id must be obtained from the Layout object's property_id method which associates a property set with a property Id.

set_property

Signature: void **set_property** (variant key, variant value)

Description: Sets the user property with the given key to the given value

This method is a convenience method that sets the property with the given key to the given value. If no property with that key exists, it will create one. Using that method is more convenient than creating a new property set with a new ID and assigning that properties ID. This method may change the properties ID. Note: GDS only supports integer keys. OASIS supports numeric and string keys. This method has been introduced in version 0.23.

shapes

(1) Signature: Shapes **shapes** (unsigned int layer_index)

Description: Returns the shapes list of the given layer

index: The layer index of the shapes list to retrieve

Returns: A reference to the shapes list

This method gives access to the shapes list on a certain layer. If the layer does not exist yet, it is created.

(2) Signature: *[const]* const Shapes ptr **shapes** (unsigned int layer_index)

Description: Returns the shapes list of the given layer (const version)

index: The layer index of the shapes list to retrieve

Returns: A reference to the shapes list

This method gives access to the shapes list on a certain layer. This is the const version - only const (reading) methods can be called on the returned object.

This variant has been introduced in version 0.26.4.

swap

Signature: void **swap** (unsigned int layer_index1, unsigned int layer_index2)

Description: Swaps the layers given

This method swaps two layers inside this cell.

transform

(1) Signature: Instance **transform** (const Instance instance, const Trans trans)

Description: Transforms the instance with the given transformation

Returns: A reference (an Instance object) to the new instance

This method has been introduced in version 0.16. The original instance may be deleted and re-inserted by this method. Therefore, a new reference is returned. It is permitted in editable mode only.

(2) Signature: Instance **transform** (const Instance instance, const ICplxTrans trans)

Description: Transforms the instance with the given complex integer transformation

Returns: A reference (an Instance object) to the new instance

This method has been introduced in version 0.23. The original instance may be deleted and re-inserted by this method. Therefore, a new reference is returned. It is permitted in editable mode only.

(3) Signature: Instance **transform** (const Instance instance, const DTrans trans)

Description: Transforms the instance with the transformation given in micrometer units

Returns: A reference (an Instance object) to the new instance

This method is identical to the corresponding transform method with a Trans argument. For this variant however, the transformation is given in micrometer units and is translated to database units internally.

This variant has been introduced in version 0.25.

(4) Signature: Instance **transform** (const Instance instance, const DCplxTrans trans)

Description: Transforms the instance with the given complex floating-point transformation given in micrometer units

Returns: A reference (an Instance object) to the new instance

This method is identical to the corresponding transform method with a ICplxTrans argument. For this variant however, the transformation is given in micrometer units and is translated to database units internally.

This variant has been introduced in version 0.25.

(5) Signature: void **transform** (const Trans trans)

Description: Transforms the cell by the given integer transformation

This method transforms all instances and all shapes by the given transformation. There is a variant called transform_into which applies the transformation to instances in a way such that it can be applied recursively to the child cells.

This method has been introduced in version 0.26.7.

(6) Signature: void **transform** (const ICplxTrans trans)

Description: Transforms the cell by the given complex integer transformation

This method transforms all instances and all shapes by the given transformation. There is a variant called transform_into which applies the transformation to instances in a way such that it can be applied recursively to the child cells. The difference is important in the presence of magnifications: "transform" will leave magnified instances while "transform_into" will not do so but expect the magnification to be applied inside the called cells too.

This method has been introduced in version 0.26.7.

(7) Signature: void **transform** (const DTrans trans)

Description: Transforms the cell by the given, micrometer-unit transformation

This method transforms all instances and all shapes by the given transformation. There is a variant called transform_into which applies the transformation to instances in a way such that it can be applied recursively to the child cells.

This method has been introduced in version 0.26.7.

(8) Signature: void **transform** (const DCplxTrans trans)

Description: Transforms the cell by the given, micrometer-unit transformation

This method transforms all instances and all shapes by the given transformation. There is a variant called transform_into which applies the transformation to instances in a way such that it can be applied recursively to the child cells. The difference is important in the presence of magnifications: "transform" will leave magnified instances while "transform_into" will not do so but expect the magnification to be applied inside the called cells too.

This method has been introduced in version 0.26.7.

transform_into

(1) Signature: Instance **transform_into** (const Instance instance, const Trans trans)

Description: Transforms the instance into a new coordinate system with the given transformation

Returns: A reference (an Instance object) to the new instance

In contrast to the transform method, this method allows propagation of the transformation into child cells. More precisely: it applies just a part of the given transformation to the instance, such that when transforming the cell instantiated and its shapes with the same transformation, the result will reflect the desired transformation. Mathematically spoken, the transformation of the instance (A) is transformed with the given transformation T using "A' = T * A * Tinv" where Tinv is the inverse of T. In effect, the transformation T commutes with the new instance transformation A' and can be applied to child cells as well. This method is therefore useful to transform a hierarchy of cells.

This method has been introduced in version 0.23. The original instance may be deleted and re-inserted by this method. Therefore, a new reference is returned. It is permitted in editable mode only.

(2) Signature: Instance **transform_into** (const Instance instance, const ICplxTrans trans)

Description: Transforms the instance into a new coordinate system with the given complex integer transformation

Returns: A reference (an Instance object) to the new instance

See the comments for the simple-transformation version for a description of this method. This method has been introduced in version 0.23. The original instance may be deleted and re-inserted by this method. Therefore, a new reference is returned. It is permitted in editable mode only.

(3) Signature: void **transform_into** (const Trans trans)

Description: Transforms the cell into a new coordinate system with the given transformation

This method transforms all instances and all shapes. The instances are transformed in a way that allows propagation of the transformation into child cells. For this, it applies just a part of the given transformation to the instance such that when transforming the shapes of the cell instantiated, the result will reflect the desired transformation. Mathematically spoken, the transformation of the instance (A) is transformed with the given transformation T using "A' = T * A * Tinv" where Tinv is the inverse of T. In effect, the transformation T commutes with the new instance transformation A' and can be applied to child cells as well. This method is therefore useful to transform a hierarchy of cells.

It has been introduced in version 0.23.

(4) Signature: void **transform_into** (const ICplxTrans trans)

Description: Transforms the cell into a new coordinate system with the given complex integer transformation

See the comments for the simple-transformation version for a description of this method. This method has been introduced in version 0.23.

(5) Signature: Instance **transform_into** (const Instance instance, const DTrans trans)

Description: Transforms the instance into a new coordinate system with the given transformation where the transformation is in micrometer units

Returns: A reference (an Instance object) to the new instance

This method is identical to the corresponding transform_into method with a Trans argument. For this variant however, the transformation is given in micrometer units and is translated to database units internally.

This variant has been introduced in version 0.25.

(6) Signature: Instance **transform_into** (const Instance instance, const DCplxTrans trans)

Description: Transforms the instance into a new coordinate system with the given complex transformation where the transformation is in micrometer units

Returns: A reference (an Instance object) to the new instance

This method is identical to the corresponding transform_into method with a ICplxTrans argument. For this variant however, the transformation is given in micrometer units and is translated to database units internally.

This variant has been introduced in version 0.25.

(7) Signature: void **transform_into** (const DTrans trans)

Description: Transforms the cell into a new coordinate system with the given transformation where the transformation is in micrometer units

This method is identical to the corresponding transform_into method with a Trans argument. For this variant however, the transformation is given in micrometer units and is translated to database units internally.

This variant has been introduced in version 0.25.

(8) Signature: void **transform_into** (const DCplxTrans trans)

Description: Transforms the cell into a new coordinate system with the given complex integer transformation where the transformation is in micrometer units

This method is identical to the corresponding transform_into method with a ICplxTrans argument. For this variant however, the transformation is given in micrometer units and is translated to database units internally.

This variant has been introduced in version 0.25.

write

(1) Signature: *[const]* void **write** (string file_name)

Description: Writes the cell to a layout file

The format of the file will be determined from the file name. Only the cell and its subtree below will be saved.

This method has been introduced in version 0.23.

(2) Signature: *[const]* void **write** (string file_name, const SaveLayoutOptions options)

Description: Writes the cell to a layout file

The format of the file will be determined from the file name. Only the cell and its subtree below will be saved. In contrast to the other 'write' method, this version allows one to specify save options, i.e. scaling etc.

This method has been introduced in version 0.23.

4.20. API reference - Class Instance

Notation used in Ruby API documentation

Module: db

Description: An instance proxy

An instance proxy is basically a pointer to an instance of different kinds, similar to Shape, the shape proxy. Instance objects can be duplicated without creating copies of the instances itself: the copy will still point to the same instance than the original.

When the Instance object is modified, the actual instance behind it is modified. The Instance object acts as a simplified interface for single and array instances with or without properties.

See The Database API for more details about the database objects.

Public constructors

new Instance ptr	**new**		Creates a new object of this class

Public methods

[const]	bool	**!=**	(const Instance b)	Tests for inequality of two Instance objects
[const]	bool	**<**	(const Instance b)	Provides an order criterion for two Instance objects
[const]	bool	**==**	(const Instance b)	Tests for equality of two Instance objects
[const]	variant	**[]**	(variant key)	Gets the user property with the given key or, if available, the PCell parameter with the name given by the key
	void	**[]=**	(variant key, variant value)	Sets the user property with the given key or, if available, the PCell parameter with the name given by the key
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	Vector	**a**		Returns the displacement vector for the 'a' axis
	void	**a=**	(const Vector a)	Sets the displacement vector for the 'a' axis

	void	**a=**	(const DVector a)	Sets the displacement vector for the 'a' axis in micrometer units
	void	**assign**	(const Instance other)	Assigns another object to self
[const]	Vector	**b**		Returns the displacement vector for the 'b' axis
	void	**b=**	(const Vector b)	Sets the displacement vector for the 'b' axis
	void	**b=**	(const DVector b)	Sets the displacement vector for the 'b' axis in micrometer units
[const]	Box	**bbox**		Gets the bounding box of the instance
[const]	Box	**bbox**	(unsigned int layer_index)	Gets the bounding box of the instance for a given layer
	Cell ptr	**cell**		Gets the Cell object of the cell this instance refers to
[const]	const Cell ptr	**cell**		Gets the Cell object of the cell this instance refers to
	void	**cell=**	(const Cell ptr cell)	Sets the Cell object this instance refers to
[const]	unsigned int	**cell_index**		Get the index of the cell this instance refers to
	void	**cell_index=**	(unsigned int cell_index)	Sets the index of the cell this instance refers to
[const]	CellInstArray	**cell_inst**		Gets the basic CellInstArray object associated with this instance reference.
	void	**cell_inst=**	(const CellInstArray inst)	Changes the CellInstArray object to the given one.
	void	**cell_inst=**	(const DCellInstArray inst)	Returns the basic cell instance array object by giving a micrometer unit object.
	void	**change_pcell_param**	(string name, variant value)	Changes a single parameter of a PCell instance to the given value
	void	**change_pcell_parameters**	(variant[] params)	Changes the parameters of a PCell instance to the list of parameters
	void	**change_pcell_param**	(map<string,variant> dict)	Changes the parameters of a PCell instance to the dictionary of parameters
	void	**convert_to_static**		Converts a PCell instance to a static cell
[const]	ICplxTrans	**cplx_trans**		Gets the complex transformation of the instance or the first instance in the array
	void	**cplx_trans=**	(const ICplxTrans t)	Sets the complex transformation of the instance or the first instance in the array

	void	**cplx_trans=**	(const DCplxTrans t)	Sets the complex transformation of the instance or the first instance in the array (in micrometer units)
[const]	DVector	**da**		Returns the displacement vector for the 'a' axis in micrometer units
	void	**da=**	(const DVector a)	Sets the displacement vector for the 'a' axis in micrometer units
[const]	DVector	**db**		Returns the displacement vector for the 'b' axis in micrometer units
	void	**db=**	(const DVector b)	Sets the displacement vector for the 'b' axis in micrometer units
[const]	DBox	**dbbox**		Gets the bounding box of the instance in micron units
[const]	DBox	**dbbox**	(unsigned int layer_index)	Gets the bounding box of the instance in micron units
	DCellInstArray	**dcell_inst**		Returns the micrometer unit version of the basic cell instance array object.
	void	**dcell_inst=**	(const DCellInstArray inst)	Returns the basic cell instance array object by giving a micrometer unit object.
[const]	DCplxTrans	**dcplx_trans**		Gets the complex transformation of the instance or the first instance in the array (in micrometer units)
	void	**dcplx_trans=**	(const DCplxTrans t)	Sets the complex transformation of the instance or the first instance in the array (in micrometer units)
	void	**delete**		Deletes this instance
	void	**delete_property**	(variant key)	Deletes the user property with the given key
[const]	DTrans	**dtrans**		Gets the transformation of the instance or the first instance in the array (in micrometer units)
	void	**dtrans=**	(const DTrans t)	Sets the transformation of the instance or the first instance in the array (in micrometer units)
[const]	new Instance ptr	**dup**		Creates a copy of self
	void	**explode**		Explodes the instance array
	void	**flatten**		Flattens the instance
	void	**flatten**	(int levels)	Flattens the instance
[const]	bool	**has_prop_id?**		Returns true, if the instance has properties
[const]	bool	**is_complex?**		Tests, if the array is a complex array
[const]	bool	**is_null?**		Checks, if the instance is a valid one

[const]	bool	**is_pcell?**		Returns a value indicating whether the instance is a PCell instance
[const]	bool	**is_regular_array?**		Tests, if this instance is a regular array
[const]	bool	**is_valid?**		Tests if the Instance object is still pointing to a valid instance
	Layout ptr	**layout**		Gets the layout this instance is contained in
[const]	const Layout ptr	**layout**		Gets the layout this instance is contained in
[const]	unsigned long	**na**		Returns the number of instances in the 'a' axis
	void	**na=**	(unsigned long na)	Sets the number of instances in the 'a' axis
[const]	unsigned long	**nb**		Returns the number of instances in the 'b' axis
	void	**nb=**	(unsigned long nb)	Sets the number of instances in the 'b' axis
	Cell ptr	**parent_cell**		Gets the cell this instance is contained in
[const]	const Cell ptr	**parent_cell**		Gets the cell this instance is contained in
	void	**parent_cell=**	(Cell ptr new_parent)	Moves the instance to a different cell
[const]	const PCellDeclaration ptr	**pcell_declaration**		Returns the PCell declaration object
[const]	variant	**pcell_parameter**	(string name)	Gets a PCell parameter by the name of the parameter
[const]	variant[]	**pcell_parameters**		Gets the parameters of a PCell instance as a list of values
[const]	map<string,variant>	**pcell_parameters_by_name**		Gets the parameters of a PCell instance as a dictionary of values vs. names
[const]	unsigned long	**prop_id**		Gets the properties ID associated with the instance
	void	**prop_id=**	(unsigned long id)	Sets the properties ID associated with the instance
[const]	variant	**property**	(variant key)	Gets the user property with the given key
	void	**set_property**	(variant key, variant value)	Sets the user property with the given key to the given value
[const]	unsigned long	**size**		Gets the number of single instances in the instance array
[const]	string	**to_s**		Creates a string showing the contents of the reference

[const]	string	**to_s**	(bool with_cellname)	Creates a string showing the contents of the reference
[const]	Trans	**trans**		Gets the transformation of the instance or the first instance in the array
	void	**trans=**	(const Trans t)	Sets the transformation of the instance or the first instance in the array
	void	**trans=**	(const DTrans t)	Sets the transformation of the instance or the first instance in the array (in micrometer units)
	void	**transform**	(const Trans t)	Transforms the instance array with the given transformation
	void	**transform**	(const ICplxTrans t)	Transforms the instance array with the given complex transformation
	void	**transform**	(const DTrans t)	Transforms the instance array with the given transformation (given in micrometer units)
	void	**transform**	(const DCplxTrans t)	Transforms the instance array with the given complex transformation (given in micrometer units)
	void	**transform_into**	(const Trans t)	Transforms the instance array with the given transformation
	void	**transform_into**	(const ICplxTrans t)	Transforms the instance array with the given transformation
	void	**transform_into**	(const DTrans t)	Transforms the instance array with the given transformation (given in micrometer units)
	void	**transform_into**	(const DCplxTrans t)	Transforms the instance array with the given complex transformation (given in micrometer units)

Deprecated methods (protected, public, static, non-static and constructors)

[const]	Box	**bbox_per_layer**	(unsigned int layer_index)	Use of this method is deprecated. Use bbox instead
	void	**create**		Use of this method is deprecated. Use _create instead
[const]	DBox	**dbbox_per_layer**	(unsigned int layer_index)	Use of this method is deprecated. Use dbbox instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=	**Signature**: *[const]* bool **!=** (const Instance b) **Description**: Tests for inequality of two Instance objects Warning: this operator returns true if both objects refer to the same instance, not just identical ones.
<	**Signature**: *[const]* bool **<** (const Instance b) **Description**: Provides an order criterion for two Instance objects Warning: this operator is just provided to establish any order, not a particular one.
==	**Signature**: *[const]* bool **==** (const Instance b) **Description**: Tests for equality of two Instance objects See the hint on the < operator.
[]	**Signature**: *[const]* variant **[]** (variant key) **Description**: Gets the user property with the given key or, if available, the PCell parameter with the name given by the key Getting the PCell parameter has priority over the user property. This method has been introduced in version 0.25.
[]=	**Signature**: void **[]=** (variant key, variant value) **Description**: Sets the user property with the given key or, if available, the PCell parameter with the name given by the key Setting the PCell parameter has priority over the user property. This method has been introduced in version 0.25.
_create	**Signature**: void **_create** **Description**: Ensures the C++ object is created Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
_destroy	**Signature**: void **_destroy** **Description**: Explicitly destroys the object Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
_destroyed?	**Signature**: *[const]* bool **_destroyed?** **Description**: Returns a value indicating whether the object was already destroyed This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
_is_const_object?	**Signature**: *[const]* bool **_is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

a

Signature: *[const]* Vector **a**

Description: Returns the displacement vector for the 'a' axis

Starting with version 0.25 the displacement is of vector type.

Python specific notes:
The object exposes a readable attribute 'a'. This is the getter.

a=

(1) Signature: void **a=** (const Vector a)

Description: Sets the displacement vector for the 'a' axis

If the instance was not an array instance before it is made one.

This method has been introduced in version 0.23. Starting with version 0.25 the displacement is of vector type.

Python specific notes:
The object exposes a writable attribute 'a'. This is the setter.

(2) Signature: void **a=** (const DVector a)

Description: Sets the displacement vector for the 'a' axis in micrometer units

Like a= with an integer displacement, this method will set the displacement vector but it accepts a vector in micrometer units that is of DVector type. The vector will be translated to database units internally.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a writable attribute 'a'. This is the setter.
The object exposes a writable attribute 'da'. This is the setter.

assign

Signature: void **assign** (const Instance other)

Description: Assigns another object to self

b

Signature: *[const]* Vector **b**

Description: Returns the displacement vector for the 'b' axis

Starting with version 0.25 the displacement is of vector type.

Python specific notes:
The object exposes a readable attribute 'b'. This is the getter.

b=

(1) Signature: void **b=** (const Vector b)

Description: Sets the displacement vector for the 'b' axis

If the instance was not an array instance before it is made one.

This method has been introduced in version 0.23. Starting with version 0.25 the displacement is of vector type.

Python specific notes:
The object exposes a writable attribute 'b'. This is the setter.

(2) Signature: void **b=** (const DVector b)

Description: Sets the displacement vector for the 'b' axis in micrometer units

Like b= with an integer displacement, this method will set the displacement vector but it accepts a vector in micrometer units that is of DVector type. The vector will be translated to database units internally.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a writable attribute 'b'. This is the setter.
The object exposes a writable attribute 'db'. This is the setter.

bbox

(1) Signature: *[const]* Box **bbox**

Description: Gets the bounding box of the instance

The bounding box incorporates all instances that the array represents. It gives the overall extension of the child cell as seen in the calling cell (or all array members if the instance forms an array). This method has been introduced in version 0.23.

(2) Signature: *[const]* Box **bbox** (unsigned int layer_index)

Description: Gets the bounding box of the instance for a given layer

layer_index:	The index of the layer the bounding box will be computed for.

The bounding box incorporates all instances that the array represents. It gives the overall extension of the child cell as seen in the calling cell (or all array members if the instance forms an array) for the given layer. If the layer is empty in this cell and all its children', an empty bounding box will be returned. This method has been introduced in version 0.25. 'bbox' is the preferred synonym for it since version 0.28.

bbox_per_layer

Signature: *[const]* Box **bbox_per_layer** (unsigned int layer_index)

Description: Gets the bounding box of the instance for a given layer

layer_index:	The index of the layer the bounding box will be computed for.

Use of this method is deprecated. Use bbox instead

The bounding box incorporates all instances that the array represents. It gives the overall extension of the child cell as seen in the calling cell (or all array members if the instance forms an array) for the given layer. If the layer is empty in this cell and all its children', an empty bounding box will be returned. This method has been introduced in version 0.25. 'bbox' is the preferred synonym for it since version 0.28.

cell

(1) Signature: Cell ptr **cell**

Description: Gets the Cell object of the cell this instance refers to

Please note that before version 0.23 this method returned the cell the instance is contained in. For consistency, this method has been renamed parent_cell.

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a readable attribute 'cell'. This is the getter.

(2) Signature: *[const]* const Cell ptr **cell**

Description: Gets the Cell object of the cell this instance refers to

This is the const version of the cell method. It will return a const Cell object and itself can be called on a const Instance object.

This variant has been introduced in version 0.25.

Python specific notes:
This method is available as 'cell_' in Python to distiguish it from the property with the same name.

cell=

Signature: void **cell=** (const Cell ptr cell)

Description: Sets the Cell object this instance refers to

Setting the cell object to nil is equivalent to deleting the instance.

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a writable attribute 'cell'. This is the setter.

cell_index

Signature: *[const]* unsigned int **cell_index**

Description: Get the index of the cell this instance refers to

Python specific notes:
The object exposes a readable attribute 'cell_index'. This is the getter.

cell_index=

Signature: void **cell_index=** (unsigned int cell_index)

Description: Sets the index of the cell this instance refers to

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a writable attribute 'cell_index'. This is the setter.

cell_inst

Signature: *[const]* CellInstArray **cell_inst**

Description: Gets the basic CellInstArray object associated with this instance reference.

Python specific notes:
The object exposes a readable attribute 'cell_inst'. This is the getter.

cell_inst=

(1) Signature: void **cell_inst=** (const CellInstArray inst)

Description: Changes the CellInstArray object to the given one.

This method replaces the instance by the given CellInstArray object.

This method has been introduced in version 0.22

Python specific notes:
The object exposes a writable attribute 'cell_inst'. This is the setter.

(2) Signature: void **cell_inst=** (const DCellInstArray inst)

Description: Returns the basic cell instance array object by giving a micrometer unit object.

This method replaces the instance by the given CellInstArray object and it internally transformed into database units.

This method has been introduced in version 0.25

Python specific notes:
The object exposes a writable attribute 'cell_inst'. This is the setter.
The object exposes a writable attribute 'dcell_inst'. This is the setter.

change_pcell_parameter

Signature: void **change_pcell_parameter** (string name, variant value)

Description: Changes a single parameter of a PCell instance to the given value

This method changes a parameter of a PCell instance to the given value. The name identifies the PCell parameter and must correspond to one parameter listed in the PCell declaration.

This method has been introduced in version 0.24.

change_pcell_parameters

(1) Signature: void **change_pcell_parameters** (variant[] params)

Description: Changes the parameters of a PCell instance to the list of parameters

This method changes the parameters of a PCell instance to the given list of parameters. The list must correspond to the parameters listed in the pcell declaration. A more convenient method is provided with the same name which accepts a dictionary of names and values . This method has been introduced in version 0.24.

(2) Signature: void **change_pcell_parameters** (map<string,variant> dict)

Description: Changes the parameters of a PCell instance to the dictionary of parameters

This method changes the parameters of a PCell instance to the given values. The values are specifies as a dictionary of names (keys) vs. values. Unknown names are ignored and only the parameters listed in the dictionary are changed.

This method has been introduced in version 0.24.

convert_to_static

Signature: void **convert_to_static**

Description: Converts a PCell instance to a static cell

If the instance is a PCell instance, this method will convert the cell into a static cell and remove the PCell variant if required. A new cell will be created containing the PCell content but being a static cell. If the instance is not a PCell instance, this method won't do anything.

This method has been introduced in version 0.24.

cplx_trans

Signature: *[const]* ICplxTrans **cplx_trans**

Description: Gets the complex transformation of the instance or the first instance in the array

This method is always valid compared to trans, since simple transformations can be expressed as complex transformations as well.

Python specific notes:
The object exposes a readable attribute 'cplx_trans'. This is the getter.

cplx_trans=

(1) Signature: void **cplx_trans=** (const ICplxTrans t)

Description: Sets the complex transformation of the instance or the first instance in the array

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a writable attribute 'cplx_trans'. This is the setter.

(2) Signature: void **cplx_trans=** (const DCplxTrans t)

Description: Sets the complex transformation of the instance or the first instance in the array (in micrometer units)

This method sets the transformation the same way as cplx_trans=, but the displacement of this transformation is given in micrometer units. It is internally translated into database units.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a writable attribute 'cplx_trans'. This is the setter.
The object exposes a writable attribute 'dcplx_trans'. This is the setter.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

da

Signature: *[const]* DVector **da**

Description: Returns the displacement vector for the 'a' axis in micrometer units

Like a, this method returns the displacement, but it will be translated to database units internally.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a readable attribute 'da'. This is the getter.

da=

Signature: void **da=** (const DVector a)

Description: Sets the displacement vector for the 'a' axis in micrometer units

Like a= with an integer displacement, this method will set the displacement vector but it accepts a vector in micrometer units that is of DVector type. The vector will be translated to database units internally.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a writable attribute 'a'. This is the setter.
The object exposes a writable attribute 'da'. This is the setter.

db

Signature: *[const]* DVector **db**

Description: Returns the displacement vector for the 'b' axis in micrometer units

Like b, this method returns the displacement, but it will be translated to database units internally.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a readable attribute 'db'. This is the getter.

db=

Signature: void **db=** (const DVector b)

Description: Sets the displacement vector for the 'b' axis in micrometer units

Like b= with an integer displacement, this method will set the displacement vector but it accepts a vector in micrometer units that is of DVector type. The vector will be translated to database units internally.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a writable attribute 'b'. This is the setter.
The object exposes a writable attribute 'db'. This is the setter.

dbbox

(1) Signature: *[const]* DBox **dbbox**

Description: Gets the bounding box of the instance in micron units

Gets the bounding box (see bbox) of the instance, but will compute the micrometer unit box by multiplying bbox with the database unit.

This method has been introduced in version 0.25.

(2) Signature: *[const]* DBox **dbbox** (unsigned int layer_index)

Description: Gets the bounding box of the instance in micron units

layer_index:	The index of the layer the bounding box will be computed for.

Gets the bounding box (see bbox) of the instance, but will compute the micrometer unit box by multiplying bbox with the database unit.

This method has been introduced in version 0.25. 'dbbox' is the preferred synonym for it since version 0.28.

dbbox_per_layer

Signature: *[const]* DBox **dbbox_per_layer** (unsigned int layer_index)

Description: Gets the bounding box of the instance in micron units

layer_index:	The index of the layer the bounding box will be computed for.

Use of this method is deprecated. Use dbbox instead

Gets the bounding box (see bbox) of the instance, but will compute the micrometer unit box by multiplying bbox with the database unit.

This method has been introduced in version 0.25. 'dbbox' is the preferred synonym for it since version 0.28.

dcell_inst

Signature: DCellInstArray **dcell_inst**

Description: Returns the micrometer unit version of the basic cell instance array object.

This method has been introduced in version 0.25

Python specific notes:
The object exposes a readable attribute 'dcell_inst'. This is the getter.

dcell_inst=

Signature: void **dcell_inst=** (const DCellInstArray inst)

Description: Returns the basic cell instance array object by giving a micrometer unit object.

This method replaces the instance by the given CellInstArray object and it internally transformed into database units.

This method has been introduced in version 0.25

Python specific notes:
The object exposes a writable attribute 'cell_inst'. This is the setter.
The object exposes a writable attribute 'dcell_inst'. This is the setter.

dcplx_trans

Signature: *[const]* DCplxTrans **dcplx_trans**

Description: Gets the complex transformation of the instance or the first instance in the array (in micrometer units)

This method returns the same transformation as cplx_trans, but the displacement of this transformation is given in micrometer units. It is internally translated from database units into micrometers.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a readable attribute 'dcplx_trans'. This is the getter.

dcplx_trans=

Signature: void **dcplx_trans=** (const DCplxTrans t)

Description: Sets the complex transformation of the instance or the first instance in the array (in micrometer units)

This method sets the transformation the same way as cplx_trans=, but the displacement of this transformation is given in micrometer units. It is internally translated into database units.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a writable attribute 'cplx_trans'. This is the setter.
The object exposes a writable attribute 'dcplx_trans'. This is the setter.

delete

Signature: void **delete**

Description: Deletes this instance

After this method was called, the instance object is pointing to nothing.

This method has been introduced in version 0.23.

delete_property

Signature: void **delete_property** (variant key)

Description: Deletes the user property with the given key

This method is a convenience method that deletes the property with the given key. It does nothing if no property with that key exists. Using that method is more convenient than creating a new property set with a new ID and assigning that properties ID. This method may change the properties ID. Calling this method may invalidate any iterators. It should not be called inside a loop iterating over instances.

This method has been introduced in version 0.22.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dtrans

Signature: *[const]* DTrans **dtrans**

Description: Gets the transformation of the instance or the first instance in the array (in micrometer units)

This method returns the same transformation as cplx_trans, but the displacement of this transformation is given in micrometer units. It is internally translated from database units into micrometers.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a readable attribute 'dtrans'. This is the getter.

dtrans=

Signature: void **dtrans=** (const DTrans t)

Description: Sets the transformation of the instance or the first instance in the array (in micrometer units)

This method sets the transformation the same way as cplx_trans=, but the displacement of this transformation is given in micrometer units. It is internally translated into database units.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a writable attribute 'trans'. This is the setter.
The object exposes a writable attribute 'dtrans'. This is the setter.

dup

Signature: *[const]* new Instance ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

explode

Signature: void **explode**

Description: Explodes the instance array

This method does nothing if the instance was not an array before. The instance object will point to the first instance of the array afterwards.

This method has been introduced in version 0.23.

flatten

(1) Signature: void **flatten**

Description: Flattens the instance

This method will convert the instance to a number of shapes which are equivalent to the content of the cell. The instance itself will be removed. There is another variant of this method which allows specification of the number of hierarchy levels to flatten.

This method has been introduced in version 0.24.

(2) Signature: void **flatten** (int levels)

Description: Flattens the instance

This method will convert the instance to a number of shapes which are equivalent to the content of the cell. The instance itself will be removed. This version of the method allows specification of the number of hierarchy levels to remove. Specifying 1 for 'levels' will remove the instance and replace it by the contents of the cell. Specifying a negative value or zero for the number of levels will flatten the instance completely.

This method has been introduced in version 0.24.

has_prop_id?

Signature: *[const]* bool **has_prop_id?**

Description: Returns true, if the instance has properties

is_complex?

Signature: *[const]* bool **is_complex?**

Description: Tests, if the array is a complex array

Returns true if the array represents complex instances (that is, with magnification and arbitrary rotation angles).

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_null?

Signature: *[const]* bool **is_null?**

Description: Checks, if the instance is a valid one

is_pcell?

Signature: *[const]* bool **is_pcell?**

Description: Returns a value indicating whether the instance is a PCell instance

This method has been introduced in version 0.24.

is_regular_array?

Signature: *[const]* bool **is_regular_array?**

Description: Tests, if this instance is a regular array

is_valid?

Signature: *[const]* bool **is_valid?**

Description: Tests if the Instance object is still pointing to a valid instance

If the instance represented by the given reference has been deleted, this method returns false. If however, another instance has been inserted already that occupies the original instances position, this method will return true again.

This method has been introduced in version 0.23 and is a shortcut for "inst.cell.is_valid?(inst)".

layout

(1) Signature: Layout ptr **layout**

Description: Gets the layout this instance is contained in

This method has been introduced in version 0.22.

(2) Signature: *[const]* const Layout ptr **layout**

Description: Gets the layout this instance is contained in

This const version of the method has been introduced in version 0.25.

na

Signature: *[const]* unsigned long **na**

Description: Returns the number of instances in the 'a' axis

Python specific notes:
The object exposes a readable attribute 'na'. This is the getter.

na=

Signature: void **na=** (unsigned long na)

Description: Sets the number of instances in the 'a' axis

If the instance was not an array instance before it is made one.

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a writable attribute 'na'. This is the setter.

nb

Signature: *[const]* unsigned long **nb**

Description: Returns the number of instances in the 'b' axis

Python specific notes:
The object exposes a readable attribute 'nb'. This is the getter.

nb=

Signature: void **nb=** (unsigned long nb)

Description: Sets the number of instances in the 'b' axis

If the instance was not an array instance before it is made one.

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a writable attribute 'nb'. This is the setter.

new

Signature: *[static]* new Instance ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

parent_cell

(1) Signature: Cell ptr **parent_cell**

Description: Gets the cell this instance is contained in

Returns nil if the instance does not live inside a cell. This method was named "cell" previously which lead to confusion with cell_index. It was renamed to "parent_cell" in version 0.23.

Python specific notes:
The object exposes a readable attribute 'parent_cell'. This is the getter.

(2) Signature: *[const]* const Cell ptr **parent_cell**

Description: Gets the cell this instance is contained in

Returns nil if the instance does not live inside a cell.

This const version of the parent_cell method has been introduced in version 0.25.

Python specific notes:
This method is available as 'parent_cell_' in Python to distiguish it from the property with the same name.

parent_cell=

Signature: void **parent_cell=** (Cell ptr new_parent)

Description: Moves the instance to a different cell

Both the current and the target cell must live in the same layout.

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a writable attribute 'parent_cell'. This is the setter.

pcell_declaration

Signature: *[const]* const PCellDeclaration ptr **pcell_declaration**

Description: Returns the PCell declaration object

If the instance is a PCell instance, this method returns the PCell declaration object for that PCell. If not, this method will return nil. This method has been introduced in version 0.24.

pcell_parameter

Signature: *[const]* variant **pcell_parameter** (string name)

Description: Gets a PCell parameter by the name of the parameter

Returns: The parameter value or nil if the instance is not a PCell or does not have a parameter with given name

This method has been introduced in version 0.25.

pcell_parameters

Signature: *[const]* variant[] **pcell_parameters**

Description: Gets the parameters of a PCell instance as a list of values

Returns: A list of values

If the instance is a PCell instance, this method will return an array of values where each value corresponds to one parameter. The order of the values is the order the parameters are declared in the PCell declaration. If the instance is not a PCell instance, this list returned will be empty.

This method has been introduced in version 0.24.

pcell_parameters_by_name

Signature: *[const]* map<string,variant> **pcell_parameters_by_name**

Description: Gets the parameters of a PCell instance as a dictionary of values vs. names

Returns: A dictionary of values by parameter name

If the instance is a PCell instance, this method will return a map of values vs. parameter names. The names are the ones defined in the PCell declaration.If the instance is not a PCell instance, the dictionary returned will be empty.

This method has been introduced in version 0.24.

prop_id

Signature: *[const]* unsigned long **prop_id**

Description: Gets the properties ID associated with the instance

Python specific notes:
The object exposes a readable attribute 'prop_id'. This is the getter.

prop_id=

Signature: void **prop_id=** (unsigned long id)

Description: Sets the properties ID associated with the instance

This method is provided, if a properties ID has been derived already. Usually it's more convenient to use delete_property, set_property or property.

This method has been introduced in version 0.22.

Python specific notes:
The object exposes a writable attribute 'prop_id'. This is the setter.

property

Signature: *[const]* variant **property** (variant key)

Description: Gets the user property with the given key

This method is a convenience method that gets the property with the given key. If no property with that key exists, it will return nil. Using that method is more convenient than using the layout object and the properties ID to retrieve the property value. This method has been introduced in version 0.22.

set_property

Signature: void **set_property** (variant key, variant value)

Description: Sets the user property with the given key to the given value

This method is a convenience method that sets the property with the given key to the given value. If no property with that key exists, it will create one. Using that method is more convenient than creating a new property set with a new ID and assigning that properties ID. This method may change the properties ID. Note: GDS only supports integer keys. OASIS supports numeric and string keys. Calling this method may invalidate any iterators. It should not be called inside a loop iterating over instances.

This method has been introduced in version 0.22.

size

Signature: *[const]* unsigned long **size**

Description: Gets the number of single instances in the instance array

If the instance represents a single instance, the count is 1. Otherwise it is na*nb.

Python specific notes:
This method is also available as 'len(object)'.

to_s

(1) Signature: *[const]* string **to_s**

Description: Creates a string showing the contents of the reference

This method has been introduced with version 0.16.

Python specific notes:
This method is also available as 'str(object)'.

(2) Signature: *[const]* string **to_s** (bool with_cellname)

Description: Creates a string showing the contents of the reference

Passing true to with_cellname makes the string contain the cellname instead of the cell index

This method has been introduced with version 0.23.

trans

Signature: *[const]* Trans **trans**

Description: Gets the transformation of the instance or the first instance in the array

The transformation returned is only valid if the array does not represent a complex transformation array

Python specific notes:
The object exposes a readable attribute 'trans'. This is the getter.

trans=

(1) Signature: void **trans=** (const Trans t)

Description: Sets the transformation of the instance or the first instance in the array

This method has been introduced in version 0.23.

Python specific notes:
The object exposes a writable attribute 'trans'. This is the setter.

(2) Signature: void **trans=** (const DTrans t)

Description: Sets the transformation of the instance or the first instance in the array (in micrometer units)

This method sets the transformation the same way as cplx_trans=, but the displacement of this transformation is given in micrometer units. It is internally translated into database units.

This method has been introduced in version 0.25.

Python specific notes:
The object exposes a writable attribute 'trans'. This is the setter.
The object exposes a writable attribute 'dtrans'. This is the setter.

transform

(1) Signature: void **transform** (const Trans t)

Description: Transforms the instance array with the given transformation

See Cell#transform for a description of this method.

This method has been introduced in version 0.23.

(2) Signature: void **transform** (const ICplxTrans t)

Description: Transforms the instance array with the given complex transformation

See Cell#transform for a description of this method.

This method has been introduced in version 0.23.

(3) Signature: void **transform** (const DTrans t)

Description: Transforms the instance array with the given transformation (given in micrometer units)

Transforms the instance like transform does, but with a transformation given in micrometer units. The displacement of this transformation is given in micrometers and is internally translated to database units.

This method has been introduced in version 0.25.

(4) Signature: void **transform** (const DCplxTrans t)

Description: Transforms the instance array with the given complex transformation (given in micrometer units)

Transforms the instance like transform does, but with a transformation given in micrometer units. The displacement of this transformation is given in micrometers and is internally translated to database units.

This method has been introduced in version 0.25.

transform_into

(1) Signature: void **transform_into** (const Trans t)

Description: Transforms the instance array with the given transformation

See Cell#transform_into for a description of this method.

This method has been introduced in version 0.23.

(2) Signature: void **transform_into** (const ICplxTrans t)

Description: Transforms the instance array with the given transformation

See Cell#transform_into for a description of this method.

This method has been introduced in version 0.23.

(3) Signature: void **transform_into** (const DTrans t)

Description: Transforms the instance array with the given transformation (given in micrometer units)

Transforms the instance like transform_into does, but with a transformation given in micrometer units. The displacement of this transformation is given in micrometers and is internally translated to database units.

This method has been introduced in version 0.25.

(4) Signature: void **transform_into** (const DCplxTrans t)

Description: Transforms the instance array with the given complex transformation (given in micrometer units)

Transforms the instance like transform_into does, but with a transformation given in micrometer units. The displacement of this transformation is given in micrometers and is internally translated to database units.

This method has been introduced in version 0.25.

4.21. API reference - Class ParentInstArray

Notation used in Ruby API documentation

Module: db

Description: A parent instance

A parent instance is basically an inverse instance: instead of pointing to the child cell, it is pointing to the parent cell and the transformation is representing the shift of the parent cell relative to the child cell. For memory performance, a parent instance is not stored as a instance but rather as a reference to a child instance and a reference to the cell which is the parent. The parent instance itself is computed on the fly. It is representative for a set of instances belonging to the same cell index. The special parent instance iterator takes care of producing the right sequence (Cell#each_parent_inst).

See The Database API for more details about the database objects.

Public constructors

new ParentInstArray ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const ParentIns other)	Assigns another object to self
[const]	Instance	**child_inst**		Retrieve the child instance associated with this parent instance
[const]	DCellInstArray	**dinst**		Compute the inverse instance by which the parent is seen from the child in micrometer units
[const]	new ParentInstArray ptr	**dup**		Creates a copy of self
[const]	CellInstArray	**inst**		Compute the inverse instance by which the parent is seen from the child
[const]	unsigned int	**parent_cell_index**		Gets the index of the parent cell

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method

will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const ParentInstArray other)

Description: Assigns another object to self

child_inst

Signature: *[const]* Instance **child_inst**

Description: Retrieve the child instance associated with this parent instance

Starting with version 0.15, this method returns an Instance object rather than a CellInstArray reference.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dinst

Signature: *[const]* DCellInstArray **dinst**

Description: Compute the inverse instance by which the parent is seen from the child in micrometer units

This convenience method has been introduced in version 0.28.

dup

Signature: *[const]* new ParentInstArray ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

inst

Signature: *[const]* CellInstArray **inst**

Description: Compute the inverse instance by which the parent is seen from the child

is_const_object?	**Signature**: *[const]* bool **is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference Use of this method is deprecated. Use _is_const_object? instead This method returns true, if self is a const reference. In that case, only const methods may be called on self.
new	**Signature**: *[static]* new ParentInstArray ptr **new** **Description**: Creates a new object of this class **Python specific notes:** This method is the default initializer of the object.
parent_cell_index	**Signature**: *[const]* unsigned int **parent_cell_index** **Description**: Gets the index of the parent cell

4.22. API reference - Class CellInstArray

Notation used in Ruby API documentation

Module: db

Description: A single or array cell instance

This object represents either single or array cell instances. A cell instance array is a regular array, described by two displacement vectors (a, b) and the instance count along that axes (na, nb).

In addition, this object represents either instances with simple transformations or instances with complex transformations. The latter includes magnified instances and instances rotated by an arbitrary angle.

The cell which is instantiated is given by a cell index. The cell index can be converted to a cell pointer by using Layout#cell. The cell index of a cell can be obtained using Cell#cell_index.

See The Database API for more details about the database objects.

Public constructors

new CellInstArray ptr	**new**		Creates en empty cell instance with size 0
new CellInstArray ptr	**new**	(unsigned int cell_index, const Trans trans)	Creates a single cell instance
new CellInstArray ptr	**new**	(const Cell ptr cell, const Trans trans)	Creates a single cell instance
new CellInstArray ptr	**new**	(unsigned int cell_index, const Vector disp)	Creates a single cell instance
new CellInstArray ptr	**new**	(const Cell ptr cell, const Vector disp)	Creates a single cell instance
new CellInstArray ptr	**new**	(unsigned int cell_index, const ICplxTrans trans)	Creates a single cell instance with a complex transformation
new CellInstArray ptr	**new**	(const Cell ptr cell, const ICplxTrans trans)	Creates a single cell instance with a complex transformation
new CellInstArray ptr	**new**	(unsigned int cell_index, const Trans trans, const Vector a, const Vector b, unsigned long na, unsigned long nb)	Creates a single cell instance
new CellInstArray ptr	**new**	(const Cell ptr cell, const Trans trans, const Vector a, const Vector b, unsigned long na, unsigned long nb)	Creates a single cell instance
new CellInstArray ptr	**new**	(unsigned int cell_index, const Vector disp, const Vector a, const Vector b, unsigned long na, unsigned long nb)	Creates a single cell instance

new CellInstArray ptr	new	(const Cell ptr cell, const Vector disp, const Vector a, const Vector b, unsigned long na, unsigned long nb)	Creates a single cell instance
new CellInstArray ptr	new	(unsigned int cell_index, const ICplxTrans trans, const Vector a, const Vector b, unsigned long na, unsigned long nb)	Creates a single cell instance with a complex transformation
new CellInstArray ptr	new	(const Cell ptr cell, const ICplxTrans trans, const Vector a, const Vector b, unsigned long na, unsigned long nb)	Creates a single cell instance with a complex transformation

Public methods

[const]	bool	!=	(const CellInstArray other)	Compares two arrays for inequality
[const]	bool	<	(const CellInstArray other)	Compares two arrays for 'less'
[const]	bool	==	(const CellInstArray other)	Compares two arrays for equality
	void	_create		Ensures the C++ object is created
	void	_destroy		Explicitly destroys the object
[const]	bool	_destroyed?		Returns a value indicating whether the object was already destroyed
[const]	bool	_is_const_object?		Returns a value indicating whether the reference is a const reference
	void	_manage		Marks the object as managed by the script side.
	void	_unmanage		Marks the object as no longer owned by the script side.
[const]	Vector	a		Gets the displacement vector for the 'a' axis
	void	a=	(const Vector vector)	Sets the displacement vector for the 'a' axis
	void	assign	(const CellInstArray other)	Assigns another object to self

[const]	Vector	**b**		Gets the displacement vector for the 'b' axis
	void	**b=**	(const Vector vector)	Sets the displacement vector for the 'b' axis
[const]	Box	**bbox**	(const Layout layout, unsigned int layer_index)	Gets the bounding box of the array with respect to one layer
[const]	Box	**bbox**	(const Layout layout)	Gets the bounding box of the array
	void	**cell=**	(Cell ptr cell)	Sets the cell this instance refers to
[const]	unsigned int	**cell_index**		Gets the cell index of the cell instantiated
	void	**cell_index=**	(unsigned int index)	Sets the index of the cell this instance refers to
[const]	ICplxTrans	**cplx_trans**		Gets the complex transformation of the first instance in the array
	void	**cplx_trans=**	(const ICplxTrans trans)	Sets the complex transformation of the instance or the first instance in the array
[const]	new CellInstArray ptr	**dup**		Creates a copy of self
[const,iter]	ICplxTrans	**each_cplx_trans**		Gets the complex transformations represented by this instance
[const,iter]	Trans	**each_trans**		Gets the simple transformations represented by this instance
[const]	unsigned long	**hash**		Computes a hash value
	void	**invert**		Inverts the array reference
[const]	bool	**is_complex?**		Gets a value indicating whether the array is a complex array
[const]	bool	**is_regular_array?**		Gets a value indicating whether this instance is a regular array
[const]	unsigned long	**na**		Gets the number of instances in the 'a' axis
	void	**na=**	(unsigned long n)	Sets the number of instances in the 'a' axis
[const]	unsigned long	**nb**		Gets the number of instances in the 'b' axis
	void	**nb=**	(unsigned long n)	Sets the number of instances in the 'b' axis
[const]	unsigned long	**size**		Gets the number of single instances in the array
[const]	string	**to_s**		Converts the array to a string

[const]	Trans	**trans**		Gets the transformation of the first instance in the array
	void	**trans=**	(const Trans t)	Sets the transformation of the instance or the first instance in the array
	void	**transform**	(const Trans trans)	Transforms the cell instance with the given transformation
	void	**transform**	(const ICplxTrans trans)	Transforms the cell instance with the given complex transformation
[const]	CellInstArray	**transformed**	(const Trans trans)	Gets the transformed cell instance
[const]	CellInstArray	**transformed**	(const ICplxTrans trans)	Gets the transformed cell instance (complex transformation)

Deprecated methods (protected, public, static, non-static and constructors)

[const]	Box	**bbox_per_layer**	(const Layout layout, unsigned int layer_index)	Use of this method is deprecated. Use bbox instead
	void	**create**		Use of this method is deprecated. Use _create instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=	**Signature**: *[const]* bool **!=** (const CellInstArray other) **Description**: Compares two arrays for inequality
<	**Signature**: *[const]* bool **<** (const CellInstArray other) **Description**: Compares two arrays for 'less' The comparison provides an arbitrary sorting criterion and not specific sorting order. It is guaranteed that if an array a is less than b, b is not less than a. In addition, it a is not less than b and b is not less than a, then a is equal to b.
==	**Signature**: *[const]* bool **==** (const CellInstArray other) **Description**: Compares two arrays for equality

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

a

Signature: *[const]* Vector **a**

Description: Gets the displacement vector for the 'a' axis

Starting with version 0.25 the displacement is of vector type.

Python specific notes:
The object exposes a readable attribute 'a'. This is the getter.

a=

Signature: void **a=** (const Vector vector)

Description: Sets the displacement vector for the 'a' axis

If the instance was not regular before this property is set, it will be initialized to a regular instance.

This method was introduced in version 0.22. Starting with version 0.25 the displacement is of vector type.

Python specific notes:
The object exposes a writable attribute 'a'. This is the setter.

assign

Signature: void **assign** (const CellInstArray other)

Description: Assigns another object to self

b

Signature: *[const]* Vector **b**

Description: Gets the displacement vector for the 'b' axis

Starting with version 0.25 the displacement is of vector type.

Python specific notes:
The object exposes a readable attribute 'b'. This is the getter.

b=

Signature: void **b=** (const Vector vector)

Description: Sets the displacement vector for the 'b' axis

If the instance was not regular before this property is set, it will be initialized to a regular instance.

This method was introduced in version 0.22. Starting with version 0.25 the displacement is of vector type.

Python specific notes:
The object exposes a writable attribute 'b'. This is the setter.

bbox

(1) Signature: *[const]* Box **bbox** (const Layout layout, unsigned int layer_index)

Description: Gets the bounding box of the array with respect to one layer

The bounding box incorporates all instances that the array represents. It needs the layout object to access the actual cell from the cell index.

'bbox' is the preferred synonym since version 0.28.

(2) Signature: *[const]* Box **bbox** (const Layout layout)

Description: Gets the bounding box of the array

The bounding box incorporates all instances that the array represents. It needs the layout object to access the actual cell from the cell index.

bbox_per_layer

Signature: *[const]* Box **bbox_per_layer** (const Layout layout, unsigned int layer_index)

Description: Gets the bounding box of the array with respect to one layer

Use of this method is deprecated. Use bbox instead

The bounding box incorporates all instances that the array represents. It needs the layout object to access the actual cell from the cell index.

'bbox' is the preferred synonym since version 0.28.

cell=

Signature: void **cell=** (Cell ptr cell)

Description: Sets the cell this instance refers to

This is a convenience method and equivalent to 'cell_index = cell.cell_index()'. There is no getter for the cell pointer because the CellInstArray object only knows about cell indexes.

This convenience method has been introduced in version 0.28.

Python specific notes:
The object exposes a writable attribute 'cell'. This is the setter.

cell_index

Signature: *[const]* unsigned int **cell_index**

Description: Gets the cell index of the cell instantiated

Use Layout#cell to get the Cell object from the cell index.

Python specific notes:
The object exposes a readable attribute 'cell_index'. This is the getter.

cell_index=

Signature: void **cell_index=** (unsigned int index)

Description: Sets the index of the cell this instance refers to

Python specific notes:
The object exposes a writable attribute 'cell_index'. This is the setter.

cplx_trans

Signature: *[const]* ICplxTrans **cplx_trans**

Description: Gets the complex transformation of the first instance in the array

This method is always applicable, compared to trans, since simple transformations can be expressed as complex transformations as well.

Python specific notes:
The object exposes a readable attribute 'cplx_trans'. This is the getter.

cplx_trans=

Signature: void **cplx_trans=** (const ICplxTrans trans)

Description: Sets the complex transformation of the instance or the first instance in the array

This method was introduced in version 0.22.

Python specific notes:
The object exposes a writable attribute 'cplx_trans'. This is the setter.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new CellInstArray ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

each_cplx_trans

Signature: *[const,iter]* ICplxTrans **each_cplx_trans**

Description: Gets the complex transformations represented by this instance

For a single instance, this iterator will deliver the single, complex transformation. For array instances, the iterator will deliver each complex transformation of the expanded array. This iterator is a generalization of each_trans for general complex transformations.

This method has been introduced in version 0.25.

each_trans

Signature: *[const,iter]* Trans **each_trans**

Description: Gets the simple transformations represented by this instance

For a single instance, this iterator will deliver the single, simple transformation. For array instances, the iterator will deliver each simple transformation of the expanded array.

This iterator will only deliver valid transformations if the instance array is not of complex type (see is_complex?). A more general iterator that delivers the complex transformations is each_cplx_trans.

This method has been introduced in version 0.25.

hash

Signature: *[const]* unsigned long **hash**

Description: Computes a hash value

Returns a hash value for the given cell instance. This method enables cell instances as hash keys.

This method has been introduced in version 0.25.

Python specific notes:
This method is also available as 'hash(object)'.

invert

Signature: void **invert**

Description: Inverts the array reference

The inverted array reference describes in which transformations the parent cell is seen from the current cell.

is_complex?

Signature: *[const]* bool **is_complex?**

Description: Gets a value indicating whether the array is a complex array

Returns true if the array represents complex instances (that is, with magnification and arbitrary rotation angles).

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_regular_array?

Signature: *[const]* bool **is_regular_array?**

Description: Gets a value indicating whether this instance is a regular array

na

Signature: *[const]* unsigned long **na**

Description: Gets the number of instances in the 'a' axis

Python specific notes:
The object exposes a readable attribute 'na'. This is the getter.

na=

Signature: void **na=** (unsigned long n)

Description: Sets the number of instances in the 'a' axis

If the instance was not regular before this property is set to a value larger than zero, it will be initialized to a regular instance. To make an instance a single instance, set na or nb to 0.

This method was introduced in version 0.22.

Python specific notes:
The object exposes a writable attribute 'na'. This is the setter.

nb

Signature: *[const]* unsigned long **nb**

Description: Gets the number of instances in the 'b' axis

Python specific notes:
The object exposes a readable attribute 'nb'. This is the getter.

nb=

Signature: void **nb=** (unsigned long n)

Description: Sets the number of instances in the 'b' axis

If the instance was not regular before this property is set to a value larger than zero, it will be initialized to a regular instance. To make an instance a single instance, set na or nb to 0.

This method was introduced in version 0.22.

Python specific notes:
The object exposes a writable attribute 'nb'. This is the setter.

new

(1) Signature: *[static]* new CellInstArray ptr **new**

Description: Creates en empty cell instance with size 0

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new CellInstArray ptr **new** (unsigned int cell_index, const Trans trans)

Description: Creates a single cell instance

cell_index:	The cell to instantiate
trans:	The transformation by which to instantiate the cell

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new CellInstArray ptr **new** (const Cell ptr cell, const Trans trans)

Description: Creates a single cell instance

cell: The cell to instantiate

trans: The transformation by which to instantiate the cell

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(4) Signature: *[static]* new CellInstArray ptr **new** (unsigned int cell_index, const Vector disp)

Description: Creates a single cell instance

cell_index: The cell to instantiate

disp: The displacement

This convenience initializer has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(5) Signature: *[static]* new CellInstArray ptr **new** (const Cell ptr cell, const Vector disp)

Description: Creates a single cell instance

cell: The cell to instantiate

disp: The displacement

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(6) Signature: *[static]* new CellInstArray ptr **new** (unsigned int cell_index, const ICplxTrans trans)

Description: Creates a single cell instance with a complex transformation

cell_index: The cell to instantiate

trans: The complex transformation by which to instantiate the cell

Python specific notes:
This method is the default initializer of the object.

(7) Signature: *[static]* new CellInstArray ptr **new** (const Cell ptr cell, const ICplxTrans trans)

Description: Creates a single cell instance with a complex transformation

cell: The cell to instantiate

trans: The complex transformation by which to instantiate the cell

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(8) Signature: *[static]* new CellInstArray ptr **new** (unsigned int cell_index, const Trans trans, const Vector a, const Vector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance

cell_index: The cell to instantiate

trans: The transformation by which to instantiate the cell

a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

Starting with version 0.25 the displacements are of vector type.

Python specific notes:
This method is the default initializer of the object.

(9) Signature: *[static]* new CellInstArray ptr **new** (const Cell ptr cell, const Trans trans, const Vector a, const Vector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance

cell:	The cell to instantiate
trans:	The transformation by which to instantiate the cell
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(10) Signature: *[static]* new CellInstArray ptr **new** (unsigned int cell_index, const Vector disp, const Vector a, const Vector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance

cell_index:	The cell to instantiate
disp:	The basic displacement of the first instance
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

This convenience initializer has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(11) Signature: *[static]* new CellInstArray ptr **new** (const Cell ptr cell, const Vector disp, const Vector a, const Vector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance

cell:	The cell to instantiate
disp:	The basic displacement of the first instance
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(12) Signature: *[static]* new CellInstArray ptr **new** (unsigned int cell_index, const ICplxTrans trans, const Vector a, const Vector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance with a complex transformation

cell_index:	The cell to instantiate
trans:	The complex transformation by which to instantiate the cell
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

Starting with version 0.25 the displacements are of vector type.

Python specific notes:
This method is the default initializer of the object.

(13) Signature: *[static]* new CellInstArray ptr **new** (const Cell ptr cell, const ICplxTrans trans, const Vector a, const Vector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance with a complex transformation

cell:	The cell to instantiate
trans:	The complex transformation by which to instantiate the cell
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

size

Signature: *[const]* unsigned long **size**

Description: Gets the number of single instances in the array

If the instance represents a single instance, the count is 1. Otherwise it is na*nb. Starting with version 0.27, there may be iterated instances for which the size is larger than 1, but is_regular_array? will return false. In this case, use each_trans or each_cplx_trans to retrieve the individual placements of the iterated instance.

Python specific notes:
This method is also available as 'len(object)'.

to_s

Signature: *[const]* string **to_s**

Description: Converts the array to a string

This method was introduced in version 0.22.

Python specific notes:
This method is also available as 'str(object)'.

trans

Signature: *[const]* Trans **trans**

Description: Gets the transformation of the first instance in the array

The transformation returned is only valid if the array does not represent a complex transformation array

Python specific notes:
The object exposes a readable attribute 'trans'. This is the getter.

trans=

Signature: void **trans=** (const Trans t)

Description: Sets the transformation of the instance or the first instance in the array

This method was introduced in version 0.22.

Python specific notes:
The object exposes a writable attribute 'trans'. This is the setter.

transform

(1) Signature: void **transform** (const Trans trans)

Description: Transforms the cell instance with the given transformation

This method has been introduced in version 0.20.

(2) Signature: void **transform** (const ICplxTrans trans)

Description: Transforms the cell instance with the given complex transformation

This method has been introduced in version 0.20.

transformed

(1) Signature: *[const]* CellInstArray **transformed** (const Trans trans)

Description: Gets the transformed cell instance

This method has been introduced in version 0.20.

(2) Signature: *[const]* CellInstArray **transformed** (const ICplxTrans trans)

Description: Gets the transformed cell instance (complex transformation)

This method has been introduced in version 0.20.

4.23. API reference - Class DCellInstArray

Notation used in Ruby API documentation

Module: db

Description: A single or array cell instance in micrometer units

This object is identical to CellInstArray, except that it holds coordinates in micron units instead of database units.

This class has been introduced in version 0.25.

Public constructors

new DCellInstArray ptr	**new**		Creates en empty cell instance with size 0
new DCellInstArray ptr	**new**	(unsigned int cell_index, const DTrans trans)	Creates a single cell instance
new DCellInstArray ptr	**new**	(const Cell ptr cell, const DTrans trans)	Creates a single cell instance
new DCellInstArray ptr	**new**	(unsigned int cell_index, const DVector disp)	Creates a single cell instance
new DCellInstArray ptr	**new**	(const Cell ptr cell, const DVector disp)	Creates a single cell instance
new DCellInstArray ptr	**new**	(unsigned int cell_index, const DCplxTrans trans)	Creates a single cell instance with a complex transformation
new DCellInstArray ptr	**new**	(const Cell ptr cell, const DCplxTrans trans)	Creates a single cell instance with a complex transformation
new DCellInstArray ptr	**new**	(unsigned int cell_index, const DTrans trans, const DVector a, const DVector b, unsigned long na, unsigned long nb)	Creates a single cell instance
new DCellInstArray ptr	**new**	(const Cell ptr cell, const DTrans trans, const DVector a, const DVector b, unsigned long na, unsigned long nb)	Creates a single cell instance
new DCellInstArray ptr	**new**	(unsigned int cell_index, const DVector disp, const DVector a, const DVector b, unsigned long na, unsigned long nb)	Creates a single cell instance
new DCellInstArray ptr	**new**	(const Cell ptr cell, const DVector disp, const DVector a, const DVector b, unsigned long na,	Creates a single cell instance

		unsigned long nb)	
new DCellInstArray ptr	new	(unsigned int cell_index, const DCplxTrans trans, const DVector a, const DVector b, unsigned long na, unsigned long nb)	Creates a single cell instance with a complex transformation
new DCellInstArray ptr	new	(const Cell ptr cell, const DCplxTrans trans, const DVector a, const DVector b, unsigned long na, unsigned long nb)	Creates a single cell instance with a complex transformation

Public methods

[const]	bool	!=	(const DCellInstArray other)	Compares two arrays for inequality
[const]	bool	<	(const DCellInstArray other)	Compares two arrays for 'less'
[const]	bool	==	(const DCellInstArray other)	Compares two arrays for equality
	void	_create		Ensures the C++ object is created
	void	_destroy		Explicitly destroys the object
[const]	bool	_destroyed?		Returns a value indicating whether the object was already destroyed
[const]	bool	_is_const_object?		Returns a value indicating whether the reference is a const reference
	void	_manage		Marks the object as managed by the script side.
	void	_unmanage		Marks the object as no longer owned by the script side.
[const]	DVector	a		Gets the displacement vector for the 'a' axis
	void	a=	(const DVector vector)	Sets the displacement vector for the 'a' axis
	void	assign	(const DCellInstArray other)	Assigns another object to self
[const]	DVector	b		Gets the displacement vector for the 'b' axis
	void	b=	(const DVector vector)	Sets the displacement vector for the 'b' axis

[const]	DBox	**bbox**	(const Layout layout, unsigned int layer_index)	Gets the bounding box of the array with respect to one layer
[const]	DBox	**bbox**	(const Layout layout)	Gets the bounding box of the array
	void	**cell=**	(Cell ptr cell)	Sets the cell this instance refers to
[const]	unsigned int	**cell_index**		Gets the cell index of the cell instantiated
	void	**cell_index=**	(unsigned int index)	Sets the index of the cell this instance refers to
[const]	DCplxTrans	**cplx_trans**		Gets the complex transformation of the first instance in the array
	void	**cplx_trans=**	(const DCplxTrans trans)	Sets the complex transformation of the instance or the first instance in the array
[const]	new DCellInstArray ptr	**dup**		Creates a copy of self
[const,iter]	DCplxTrans	**each_cplx_trans**		Gets the complex transformations represented by this instance
[const,iter]	DTrans	**each_trans**		Gets the simple transformations represented by this instance
[const]	unsigned long	**hash**		Computes a hash value
	void	**invert**		Inverts the array reference
[const]	bool	**is_complex?**		Gets a value indicating whether the array is a complex array
[const]	bool	**is_regular_array?**		Gets a value indicating whether this instance is a regular array
[const]	unsigned long	**na**		Gets the number of instances in the 'a' axis
	void	**na=**	(unsigned long n)	Sets the number of instances in the 'a' axis
[const]	unsigned long	**nb**		Gets the number of instances in the 'b' axis
	void	**nb=**	(unsigned long n)	Sets the number of instances in the 'b' axis
[const]	unsigned long	**size**		Gets the number of single instances in the array
[const]	string	**to_s**		Converts the array to a string
[const]	DTrans	**trans**		Gets the transformation of the first instance in the array

	void	**trans=**	(const DTrans t)	Sets the transformation of the instance or the first instance in the array
	void	**transform**	(const DTrans trans)	Transforms the cell instance with the given transformation
	void	**transform**	(const DCplxTrans trans)	Transforms the cell instance with the given complex transformation
[const]	DCellInstArray	**transformed**	(const DTrans trans)	Gets the transformed cell instance
[const]	DCellInstArray	**transformed**	(const DCplxTrans trans)	Gets the transformed cell instance (complex transformation)

Deprecated methods (protected, public, static, non-static and constructors)

[const]	DBox	**bbox_per_layer**	(const Layout layout, unsigned int layer_index)	Use of this method is deprecated. Use bbox instead
	void	**create**		Use of this method is deprecated. Use _create instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=

Signature: *[const]* bool **!=** (const DCellInstArray other)

Description: Compares two arrays for inequality

<

Signature: *[const]* bool **<** (const DCellInstArray other)

Description: Compares two arrays for 'less'

The comparison provides an arbitrary sorting criterion and not specific sorting order. It is guaranteed that if an array a is less than b, b is not less than a. In addition, it a is not less than b and b is not less than a, then a is equal to b.

==

Signature: *[const]* bool **==** (const DCellInstArray other)

Description: Compares two arrays for equality

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

a

Signature: *[const]* DVector **a**

Description: Gets the displacement vector for the 'a' axis

Python specific notes:
The object exposes a readable attribute 'a'. This is the getter.

a=

Signature: void **a=** (const DVector vector)

Description: Sets the displacement vector for the 'a' axis

If the instance was not regular before this property is set, it will be initialized to a regular instance.

Python specific notes:
The object exposes a writable attribute 'a'. This is the setter.

assign

Signature: void **assign** (const DCellInstArray other)

Description: Assigns another object to self

b

Signature: *[const]* DVector **b**

Description: Gets the displacement vector for the 'b' axis

Python specific notes:
The object exposes a readable attribute 'b'. This is the getter.

b=

Signature: void **b=** (const DVector vector)

Description: Sets the displacement vector for the 'b' axis

If the instance was not regular before this property is set, it will be initialized to a regular instance.

Python specific notes:
The object exposes a writable attribute 'b'. This is the setter.

bbox

(1) Signature: *[const]* DBox **bbox** (const Layout layout, unsigned int layer_index)

Description: Gets the bounding box of the array with respect to one layer

The bounding box incorporates all instances that the array represents. It needs the layout object to access the actual cell from the cell index.

'bbox' is the preferred synonym since version 0.28.

(2) Signature: *[const]* DBox **bbox** (const Layout layout)

Description: Gets the bounding box of the array

The bounding box incorporates all instances that the array represents. It needs the layout object to access the actual cell from the cell index.

bbox_per_layer

Signature: *[const]* DBox **bbox_per_layer** (const Layout layout, unsigned int layer_index)

Description: Gets the bounding box of the array with respect to one layer

Use of this method is deprecated. Use bbox instead

The bounding box incorporates all instances that the array represents. It needs the layout object to access the actual cell from the cell index.

'bbox' is the preferred synonym since version 0.28.

cell=

Signature: void **cell=** (Cell ptr cell)

Description: Sets the cell this instance refers to

This is a convenience method and equivalent to 'cell_index = cell.cell_index()'. There is no getter for the cell pointer because the CellInstArray object only knows about cell indexes.

This convenience method has been introduced in version 0.28.

Python specific notes:
The object exposes a writable attribute 'cell'. This is the setter.

cell_index

Signature: *[const]* unsigned int **cell_index**

Description: Gets the cell index of the cell instantiated

Use Layout#cell to get the Cell object from the cell index.

Python specific notes:
The object exposes a readable attribute 'cell_index'. This is the getter.

cell_index=

Signature: void **cell_index=** (unsigned int index)

Description: Sets the index of the cell this instance refers to

Python specific notes:
The object exposes a writable attribute 'cell_index'. This is the setter.

cplx_trans

Signature: *[const]* DCplxTrans **cplx_trans**

Description: Gets the complex transformation of the first instance in the array

This method is always applicable, compared to trans, since simple transformations can be expressed as complex transformations as well.

Python specific notes:
The object exposes a readable attribute 'cplx_trans'. This is the getter.

cplx_trans=

Signature: void **cplx_trans=** (const DCplxTrans trans)

Description: Sets the complex transformation of the instance or the first instance in the array

Python specific notes:
The object exposes a writable attribute 'cplx_trans'. This is the setter.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new DCellInstArray ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

each_cplx_trans

Signature: *[const,iter]* DCplxTrans **each_cplx_trans**

Description: Gets the complex transformations represented by this instance

For a single instance, this iterator will deliver the single, complex transformation. For array instances, the iterator will deliver each complex transformation of the expanded array. This iterator is a generalization of each_trans for general complex transformations.

each_trans

Signature: *[const,iter]* DTrans **each_trans**

Description: Gets the simple transformations represented by this instance

For a single instance, this iterator will deliver the single, simple transformation. For array instances, the iterator will deliver each simple transformation of the expanded array.

This iterator will only deliver valid transformations if the instance array is not of complex type (see is_complex?). A more general iterator that delivers the complex transformations is each_cplx_trans.

hash

Signature: *[const]* unsigned long **hash**

Description: Computes a hash value

Returns a hash value for the given cell instance. This method enables cell instances as hash keys.

This method has been introduced in version 0.25.

Python specific notes:
This method is also available as 'hash(object)'.

invert

Signature: void **invert**

Description: Inverts the array reference

The inverted array reference describes in which transformations the parent cell is seen from the current cell.

is_complex?

Signature: *[const]* bool **is_complex?**

Description: Gets a value indicating whether the array is a complex array

Returns true if the array represents complex instances (that is, with magnification and arbitrary rotation angles).

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_regular_array?

Signature: *[const]* bool **is_regular_array?**

Description: Gets a value indicating whether this instance is a regular array

na

Signature: *[const]* unsigned long **na**

Description: Gets the number of instances in the 'a' axis

Python specific notes:
The object exposes a readable attribute 'na'. This is the getter.

na=

Signature: void **na=** (unsigned long n)

Description: Sets the number of instances in the 'a' axis

If the instance was not regular before this property is set to a value larger than zero, it will be initialized to a regular instance. To make an instance a single instance, set na or nb to 0.

Python specific notes:
The object exposes a writable attribute 'na'. This is the setter.

nb

Signature: *[const]* unsigned long **nb**

Description: Gets the number of instances in the 'b' axis

Python specific notes:
The object exposes a readable attribute 'nb'. This is the getter.

nb=

Signature: void **nb=** (unsigned long n)

Description: Sets the number of instances in the 'b' axis

If the instance was not regular before this property is set to a value larger than zero, it will be initialized to a regular instance. To make an instance a single instance, set na or nb to 0.

Python specific notes:
The object exposes a writable attribute 'nb'. This is the setter.

new

(1) Signature: *[static]* new DCellInstArray ptr **new**

Description: Creates en empty cell instance with size 0

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new DCellInstArray ptr **new** (unsigned int cell_index, const DTrans trans)

Description: Creates a single cell instance

cell_index:	The cell to instantiate
trans:	The transformation by which to instantiate the cell

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new DCellInstArray ptr **new** (const Cell ptr cell, const DTrans trans)

Description: Creates a single cell instance

cell:	The cell to instantiate
trans:	The transformation by which to instantiate the cell

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(4) Signature: *[static]* new DCellInstArray ptr **new** (unsigned int cell_index, const DVector disp)

Description: Creates a single cell instance

cell_index:	The cell to instantiate
disp:	The displacement

This convenience initializer has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(5) Signature: *[static]* new DCellInstArray ptr **new** (const Cell ptr cell, const DVector disp)

Description: Creates a single cell instance

cell:	The cell to instantiate
disp:	The displacement

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(6) Signature: *[static]* new DCellInstArray ptr **new** (unsigned int cell_index, const DCplxTrans trans)

Description: Creates a single cell instance with a complex transformation

cell_index:	The cell to instantiate
trans:	The complex transformation by which to instantiate the cell

Python specific notes:
This method is the default initializer of the object.

(7) Signature: *[static]* new DCellInstArray ptr **new** (const Cell ptr cell, const DCplxTrans trans)

Description: Creates a single cell instance with a complex transformation

cell:	The cell to instantiate
trans:	The complex transformation by which to instantiate the cell

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(8) Signature: *[static]* new DCellInstArray ptr **new** (unsigned int cell_index, const DTrans trans, const DVector a, const DVector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance

cell_index:	The cell to instantiate
trans:	The transformation by which to instantiate the cell
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

Python specific notes:
This method is the default initializer of the object.

(9) Signature: *[static]* new DCellInstArray ptr **new** (const Cell ptr cell, const DTrans trans, const DVector a, const DVector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance

cell:	The cell to instantiate

trans:	The transformation by which to instantiate the cell
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(10) Signature: *[static]* new DCellInstArray ptr **new** (unsigned int cell_index, const DVector disp, const DVector a, const DVector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance

cell_index:	The cell to instantiate
disp:	The basic displacement of the first instance
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

This convenience initializer has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(11) Signature: *[static]* new DCellInstArray ptr **new** (const Cell ptr cell, const DVector disp, const DVector a, const DVector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance

cell:	The cell to instantiate
disp:	The basic displacement of the first instance
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

(12) Signature: *[static]* new DCellInstArray ptr **new** (unsigned int cell_index, const DCplxTrans trans, const DVector a, const DVector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance with a complex transformation

cell_index:	The cell to instantiate
trans:	The complex transformation by which to instantiate the cell
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis

nb:	The number of placements in the 'b' axis

Python specific notes:
This method is the default initializer of the object.

(13) Signature: *[static]* new DCellInstArray ptr **new** (const Cell ptr cell, const DCplxTrans trans, const DVector a, const DVector b, unsigned long na, unsigned long nb)

Description: Creates a single cell instance with a complex transformation

cell:	The cell to instantiate
trans:	The complex transformation by which to instantiate the cell
a:	The displacement vector of the array in the 'a' axis
b:	The displacement vector of the array in the 'b' axis
na:	The number of placements in the 'a' axis
nb:	The number of placements in the 'b' axis

This convenience variant takes a Cell pointer and is equivalent to using 'cell.cell_index()'. It has been introduced in version 0.28.

Python specific notes:
This method is the default initializer of the object.

size

Signature: *[const]* unsigned long **size**

Description: Gets the number of single instances in the array

If the instance represents a single instance, the count is 1. Otherwise it is na*nb. Starting with version 0.27, there may be iterated instances for which the size is larger than 1, but is_regular_array? will return false. In this case, use each_trans or each_cplx_trans to retrieve the individual placements of the iterated instance.

Python specific notes:
This method is also available as 'len(object)'.

to_s

Signature: *[const]* string **to_s**

Description: Converts the array to a string

Python specific notes:
This method is also available as 'str(object)'.

trans

Signature: *[const]* DTrans **trans**

Description: Gets the transformation of the first instance in the array

The transformation returned is only valid if the array does not represent a complex transformation array

Python specific notes:
The object exposes a readable attribute 'trans'. This is the getter.

trans=

Signature: void **trans=** (const DTrans t)

Description: Sets the transformation of the instance or the first instance in the array

Python specific notes:
The object exposes a writable attribute 'trans'. This is the setter.

transform

(1) Signature: void **transform** (const DTrans trans)

Description: Transforms the cell instance with the given transformation

	(2) Signature: void **transform** (const DCplxTrans trans) **Description**: Transforms the cell instance with the given complex transformation
transformed	**(1) Signature**: *[const]* DCellInstArray **transformed** (const DTrans trans) **Description**: Gets the transformed cell instance **(2) Signature**: *[const]* DCellInstArray **transformed** (const DCplxTrans trans) **Description**: Gets the transformed cell instance (complex transformation)

4.24. API reference - Class CellMapping

Notation used in Ruby API documentation

Module: db

Description: A cell mapping (source to target layout)

A cell mapping is an association of cells in two layouts forming pairs of cells, i.e. one cell corresponds to another cell in the other layout. The CellMapping object describes the mapping of cells of a source layout B to a target layout A. The cell mapping object is basically a table associating a cell in layout B with a cell in layout A.

The cell mapping is of particular interest for providing the cell mapping recipe in Cell#copy_tree_shapes or Cell#move_tree_shapes.

The mapping object is used to create and hold that table. There are three basic modes in which a table can be generated:

- Top-level identity (for_single_cell and for_single_cell_full)
- Top-level identify for multiple cells (for_multi_cells_full and for_multi_cells_full)
- Geometrical identity (from_geometry and from_geometry_full)
- Name identity (from_names and from_names_full)

'full' refers to the way cells are treated which are not mentioned. In the 'full' versions, cells for which no mapping is established explicitly - specifically all child cells in top-level identity modes - are created in the target layout and instantiated according to their source layout hierarchy. Then, these new cells become targets of the respective source cells. In the plain version (without 'full' cells), no additional cells are created. For the case of Layout#copy_tree_shapes cells not explicitly mapped are flattened. Hence for example, for_single_cell will flatten all children of the source cell during Layout#copy_tree_shapes or Layout#move_tree_shapes.

Top-level identity means that only one cell (the top cell) is regarded identical. All child cells are not considered identical. In full mode (see below), this will create a new, identical cell tree below the top cell in layout A.

Geometrical identity is defined by the exact identity of the set of expanded instances in each starting cell. Therefore, when a cell is mapped to another cell, shapes can be transferred from one cell to another while effectively rendering the same flat geometry (in the context of the given starting cells). Location identity is basically the safest way to map cells from one hierarchy into another, because it preserves the flat shape geometry. However in some cases the algorithm may find multiple mapping candidates. In that case it will make a guess about what mapping to choose.

Name identity means that cells are identified by their names - for a source cell in layer B, a target cell with the same name is looked up in the target layout A and a mapping is created if a cell with the same name is found. However, name identity does not mean that the cells are actually equivalent because they may be placed differently. Hence, cell mapping by name is not a good choice when it is important to preserve the shape geometry of a layer.

A cell might not be mapped to another cell which basically means that there is no corresponding cell. In this case, flattening to the next mapped cell is an option to transfer geometries despite the missing mapping. You can enforce a mapping by using the mapping generator methods in 'full' mode, i.e. from_names_full or from_geometry_full. These versions will create new cells and their corresponding instances in the target layout if no suitable target cell is found.

This is a simple example for a cell mapping preserving the hierarchy of the source cell and creating a hierarchy copy in the top cell of the target layout ('hierarchical merge'):

```
cell_names = [ "A", "B", "C" ]

source = RBA::Layout::new
source.read("input.gds")

target = RBA::Layout::new
target_top = target.create_cell("IMPORTED")

cm = RBA::CellMapping::new
# Copies the source layout hierarchy into the target top cell:
cm.for_single_cell_full(target_top, source.top_cell)
target.copy_tree_shapes(source, cm)
```

Without 'full', the effect is move-with-flattening (note we're using 'move' in this example):

```
cell_names = [ "A", "B", "C" ]

source = RBA::Layout::new
source.read("input.gds")

target = RBA::Layout::new
target_top = target.create_cell("IMPORTED")

cm = RBA::CellMapping::new
# Flattens the source layout hierarchy into the target top cell:
cm.for_single_cell(target_top, source.top_cell)
target.move_tree_shapes(source, cm)
```

This is another example for using CellMapping in multiple top cell identity mode. It extracts cells 'A', 'B' and 'C' from one layout and copies them to another. It will also copy all shapes and all child cells. Child cells which are shared between the three initial cells will be shared in the target layout too.

```
cell_names = [ "A", "B", "C" ]

source = RBA::Layout::new
source.read("input.gds")

target = RBA::Layout::new

source_cells = cell_names.collect { |n| source.cell_by_name(n) }
target_cells = cell_names.collect { |n| target.create_cell(n) }

cm = RBA::CellMapping::new
cm.for_multi_cells_full(target_cells, source_cells)
target.copy_tree_shapes(source, cm)
```

Public constructors

new CellMapping ptr	**new**		Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const CellMapping other)	Assigns another object to self

[const]	unsigned int	**cell_mapping**	(unsigned int cell_index_b)	Determines cell mapping of a layout_b cell to the corresponding layout_a cell.
	void	**clear**		Clears the mapping.
[const]	new CellMapping ptr	**dup**		Creates a copy of self
	void	**for_multi_cells**	(const Layout layout_a, unsigned int[] cell_indexes_a, const Layout layout_b, unsigned int[] cell_indexes_b)	Initializes the cell mapping for top-level identity
	void	**for_multi_cells**	(Cell ptr[] cell_a, const Cell ptr[] cell_b)	Initializes the cell mapping for top-level identity
	unsigned int[]	**for_multi_cells_full**	(Layout layout_a, unsigned int[] cell_indexes_a, const Layout layout_b, unsigned int[] cell_indexes_b)	Initializes the cell mapping for top-level identity in full mapping mode
	unsigned int[]	**for_multi_cells_full**	(Cell ptr[] cell_a, const Cell ptr[] cell_b)	Initializes the cell mapping for top-level identity in full mapping mode
	void	**for_single_cell**	(const Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)	Initializes the cell mapping for top-level identity
	void	**for_single_cell**	(Cell cell_a, const Cell cell_b)	Initializes the cell mapping for top-level identity
	unsigned int[]	**for_single_cell_full**	(Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)	Initializes the cell mapping for top-level identity in full mapping mode
	unsigned int[]	**for_single_cell_full**	(Cell cell_a, const Cell cell_b)	Initializes the cell mapping for top-level identity in full mapping mode
	void	**from_geometry**	(const Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)	Initializes the cell mapping using the geometrical identity
	void	**from_geometry**	(Cell cell_a, const Cell cell_b)	Initializes the cell mapping using the geometrical identity
	unsigned int[]	**from_geometry_full**	(Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)	Initializes the cell mapping using the geometrical identity in full mapping mode
	unsigned int[]	**from_geometry_full**	(Cell cell_a, const Cell cell_b)	Initializes the cell mapping using the geometrical identity in full mapping mode
	void	**from_names**	(const Layout layout_a, unsigned int cell_index_a, const Layout layout_b,	Initializes the cell mapping using the name identity

			unsigned int cell_index_b)	
	void	**from_names**	(Cell cell_a, const Cell cell_b)	Initializes the cell mapping using the name identity
	unsigned int[]	**from_names_full**	(Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)	Initializes the cell mapping using the name identity in full mapping mode
	unsigned int[]	**from_names_full**	(Cell cell_a, const Cell cell_b)	Initializes the cell mapping using the name identity in full mapping mode
[const]	bool	**has_mapping?**	(unsigned int cell_index_b)	Returns as value indicating whether a cell of layout_b has a mapping to a layout_a cell.
	void	**map**	(unsigned int cell_index_b, unsigned int cell_index_a)	Explicitly specifies a mapping.
[const]	map<unsigned int,unsigned int>	**table**		Returns the mapping table.

Public static methods and constants

unsigned int	**DropCell**	A constant indicating the request to drop a cell

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

DropCell

Signature: *[static]* unsigned int **DropCell**

Description: A constant indicating the request to drop a cell

If used as a pseudo-target for the cell mapping, this index indicates that the cell shall be dropped rather than created on the target side or skipped by flattening. Instead, all shapes of this cell are discarded and its children are not translated unless explicitly requested or if required are children for other cells.

This constant has been introduced in version 0.25.

Python specific notes:
The object exposes a readable attribute 'DropCell'. This is the getter.

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const CellMapping other)

Description: Assigns another object to self

cell_mapping

Signature: *[const]* unsigned int **cell_mapping** (unsigned int cell_index_b)

Description: Determines cell mapping of a layout_b cell to the corresponding layout_a cell.

cell_index_b:	The index of the cell in layout_b whose mapping is requested.
Returns:	The cell index in layout_a.

Note that the returned index can be DropCell to indicate the cell shall be dropped.

clear

Signature: void **clear**

Description: Clears the mapping.

This method has been introduced in version 0.23.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new CellMapping ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

for_multi_cells

(1) Signature: void **for_multi_cells** (const Layout layout_a, unsigned int[] cell_indexes_a, const Layout layout_b, unsigned int[] cell_indexes_b)

Description: Initializes the cell mapping for top-level identity

layout_a:	The target layout.
cell_indexes_a:	A list of cell indexes for the target cells.
layout_b:	The source layout.
cell_indexes_b:	A list of cell indexes for the source cells (same number of indexes than cell_indexes_a).

The cell mapping is created for cells from cell_indexes_b to cell from cell_indexes_a in the respective layouts. This method clears the mapping and creates one for each cell pair from cell_indexes_b vs. cell_indexes_a. If used for Layout#copy_tree_shapes or Layout#move_tree_shapes, this cell mapping will essentially flatten the source cells in the target layout.

This method is equivalent to clear, followed by map(cell_index_a, cell_index_b) for each cell pair.

This method has been introduced in version 0.27.

(2) Signature: void **for_multi_cells** (Cell ptr[] cell_a, const Cell ptr[] cell_b)

Description: Initializes the cell mapping for top-level identity

cell_a: A list of target cells.

cell_b: A list of source cells.

Returns: A list of indexes of cells created.

This is a convenience version which uses cell references instead of layout/cell index combinations. It has been introduced in version 0.28.

for_multi_cells_full

(1) Signature: unsigned int[] **for_multi_cells_full** (Layout layout_a, unsigned int[] cell_indexes_a, const Layout layout_b, unsigned int[] cell_indexes_b)

Description: Initializes the cell mapping for top-level identity in full mapping mode

layout_a: The target layout.

cell_indexes_a: A list of cell indexes for the target cells.

layout_b: The source layout.

cell_indexes_b: A list of cell indexes for the source cells (same number of indexes than cell_indexes_a).

The cell mapping is created for cells from cell_indexes_b to cell from cell_indexes_a in the respective layouts. This method clears the mapping and creates one for each cell pair from cell_indexes_b vs. cell_indexes_a. In addition and in contrast to for_multi_cells, this method completes the mapping by adding all the child cells of all cells in cell_indexes_b to layout_a and creating the proper instances.

This method has been introduced in version 0.27.

(2) Signature: unsigned int[] **for_multi_cells_full** (Cell ptr[] cell_a, const Cell ptr[] cell_b)

Description: Initializes the cell mapping for top-level identity in full mapping mode

cell_a: A list of target cells.

cell_b: A list of source cells.

Returns: A list of indexes of cells created.

This is a convenience version which uses cell references instead of layout/cell index combinations. It has been introduced in version 0.28.

for_single_cell

(1) Signature: void **for_single_cell** (const Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)

Description: Initializes the cell mapping for top-level identity

layout_a: The target layout.

cell_index_a: The index of the target cell.

layout_b: The source layout.

cell_index_b: The index of the source cell.

The cell mapping is created for cell_b to cell_a in the respective layouts. This method clears the mapping and creates one for the single cell pair. If used for Cell#copy_tree or Cell#move_tree, this cell mapping will essentially flatten the cell.

This method is equivalent to clear, followed by map(cell_index_a, cell_index_b).

This method has been introduced in version 0.23.

(2) Signature: void **for_single_cell** (Cell cell_a, const Cell cell_b)

Description: Initializes the cell mapping for top-level identity

cell_a: The target cell.

cell_b: The source cell.

Returns: A list of indexes of cells created.

This is a convenience version which uses cell references instead of layout/cell index combinations. It has been introduced in version 0.28.

for_single_cell_full

(1) Signature: unsigned int[] **for_single_cell_full** (Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)

Description: Initializes the cell mapping for top-level identity in full mapping mode

layout_a: The target layout.

cell_index_a: The index of the target cell.

layout_b: The source layout.

cell_index_b: The index of the source cell.

The cell mapping is created for cell_b to cell_a in the respective layouts. This method clears the mapping and creates one for the single cell pair. In addition and in contrast to for_single_cell, this method completes the mapping by adding all the child cells of cell_b to layout_a and creating the proper instances.

This method has been introduced in version 0.23.

(2) Signature: unsigned int[] **for_single_cell_full** (Cell cell_a, const Cell cell_b)

Description: Initializes the cell mapping for top-level identity in full mapping mode

cell_a: The target cell.

cell_b: The source cell.

Returns: A list of indexes of cells created.

This is a convenience version which uses cell references instead of layout/cell index combinations. It has been introduced in version 0.28.

from_geometry

(1) Signature: void **from_geometry** (const Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)

Description: Initializes the cell mapping using the geometrical identity

layout_a: The target layout.

cell_index_a: The index of the target starting cell.

layout_b: The source layout.

cell_index_b: The index of the source starting cell.

The cell mapping is created for cells below cell_a and cell_b in the respective layouts. This method employs geometrical identity to derive mappings for the child cells of the starting cell in layout A and B. If the geometrical identity is ambiguous, the algorithm will make an arbitrary choice.

This method has been introduced in version 0.23.

(2) Signature: void **from_geometry** (Cell cell_a, const Cell cell_b)

Description: Initializes the cell mapping using the geometrical identity

cell_a: The target cell.

cell_b: The source cell.

Returns: A list of indexes of cells created.

This is a convenience version which uses cell references instead of layout/cell index combinations. It has been introduced in version 0.28.

from_geometry_full

(1) Signature: unsigned int[] **from_geometry_full** (Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)

Description: Initializes the cell mapping using the geometrical identity in full mapping mode

layout_a:	The target layout.
cell_index_a:	The index of the target starting cell.
layout_b:	The source layout.
cell_index_b:	The index of the source starting cell.
Returns:	A list of indexes of cells created.

The cell mapping is created for cells below cell_a and cell_b in the respective layouts. This method employs geometrical identity to derive mappings for the child cells of the starting cell in layout A and B. If the geometrical identity is ambiguous, the algorithm will make an arbitrary choice.

Full mapping means that cells which are not found in the target layout A are created there plus their corresponding instances are created as well. The returned list will contain the indexes of all cells created for that reason.

This method has been introduced in version 0.23.

(2) Signature: unsigned int[] **from_geometry_full** (Cell cell_a, const Cell cell_b)

Description: Initializes the cell mapping using the geometrical identity in full mapping mode

cell_a:	The target cell.
cell_b:	The source cell.
Returns:	A list of indexes of cells created.

This is a convenience version which uses cell references instead of layout/cell index combinations. It has been introduced in version 0.28.

from_names

(1) Signature: void **from_names** (const Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)

Description: Initializes the cell mapping using the name identity

layout_a:	The target layout.
cell_index_a:	The index of the target starting cell.
layout_b:	The source layout.
cell_index_b:	The index of the source starting cell.

The cell mapping is created for cells below cell_a and cell_b in the respective layouts. This method employs name identity to derive mappings for the child cells of the starting cell in layout A and B.

This method has been introduced in version 0.23.

(2) Signature: void **from_names** (Cell cell_a, const Cell cell_b)

Description: Initializes the cell mapping using the name identity

cell_a:	The target cell.
cell_b:	The source cell.
Returns:	A list of indexes of cells created.

This is a convenience version which uses cell references instead of layout/cell index combinations. It has been introduced in version 0.28.

from_names_full

(1) Signature: unsigned int[] **from_names_full** (Layout layout_a, unsigned int cell_index_a, const Layout layout_b, unsigned int cell_index_b)

Description: Initializes the cell mapping using the name identity in full mapping mode

layout_a:	The target layout.
cell_index_a:	The index of the target starting cell.
layout_b:	The source layout.
cell_index_b:	The index of the source starting cell.
Returns:	A list of indexes of cells created.

The cell mapping is created for cells below cell_a and cell_b in the respective layouts. This method employs name identity to derive mappings for the child cells of the starting cell in layout A and B.

Full mapping means that cells which are not found in the target layout A are created there plus their corresponding instances are created as well. The returned list will contain the indexes of all cells created for that reason.

This method has been introduced in version 0.23.

(2) Signature: unsigned int[] **from_names_full** (Cell cell_a, const Cell cell_b)

Description: Initializes the cell mapping using the name identity in full mapping mode

cell_a:	The target cell.
cell_b:	The source cell.
Returns:	A list of indexes of cells created.

This is a convenience version which uses cell references instead of layout/cell index combinations. It has been introduced in version 0.28.

has_mapping?

Signature: *[const]* bool **has_mapping?** (unsigned int cell_index_b)

Description: Returns as value indicating whether a cell of layout_b has a mapping to a layout_a cell.

cell_index_b:	The index of the cell in layout_b whose mapping is requested.
Returns:	true, if the cell has a mapping

Note that if the cell is supposed to be dropped (see DropCell), the respective source cell will also be regarded "mapped", so has_mapping? will return true in this case.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

map

Signature: void **map** (unsigned int cell_index_b, unsigned int cell_index_a)

Description: Explicitly specifies a mapping.

cell_index_b:	The index of the cell in layout B (the "source")
cell_index_a:	The index of the cell in layout A (the "target") - this index can be DropCell

Beside using the mapping generator algorithms provided through from_names and from_geometry, it is possible to explicitly specify cell mappings using this method.

This method has been introduced in version 0.23.

new

Signature: *[static]* new CellMapping ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

table

Signature: *[const]* map<unsigned int,unsigned int> **table**

Description: Returns the mapping table.

The mapping table is a dictionary where the keys are source layout cell indexes and the values are the target layout cell indexes. Note that the target cell index can be DropCell to indicate that a cell is supposed to be dropped.

This method has been introduced in version 0.25.

4.25. API reference - Class CompoundRegionOperationNode

Notation used in Ruby API documentation

Module: db

Description: A base class for compound DRC operations

Sub-classes: LogicalOp, GeometricalOp, ResultType, ParameterType, RatioParameterType

This class is not intended to be used directly but rather provide a factory for various incarnations of compound operation nodes. Compound operations are a way to specify complex DRC operations put together by building a tree of operations. This operation tree then is executed with Region#complex_op and will act on individual clusters of shapes and their interacting neighbors.

A basic concept to the compound operations is the 'subject' (primary) and 'intruder' (secondary) input. The 'subject' is the Region, 'complex_op' with the operation tree is executed on. 'intruders' are regions inserted into the equation through secondary input nodes created with new_secondary_node. The algorithm will execute the operation tree for every subject shape considering intruder shapes from the secondary inputs. The algorithm will only act on subject shapes primarily. As a consequence, 'lonely' intruder shapes without a subject shape are not considered at all. Only subject shapes trigger evaluation of the operation tree.

The search distance for intruder shapes is determined by the operation and computed from the operation's requirements.

This class has been introduced in version 0.27. The API is considered internal and will change without notice.

Public constructors

new CompoundRegionOperationNode ptr	**new**		Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	string	**description**		Gets the description for this node
	void	**description=**	(string d)	Sets the description for this node
[const]	int	**distance**		Gets the distance value for this node
	void	**distance=**	(int d)	Sets the distance value for this nodeUsually it's not required to provide a distance because the nodes compute a distance based on their operation. If necessary you can supply a distance. The processor will use this distance or the computed one, whichever is larger.
[const]	CompoundRegionOpe	**result_type**		Gets the result type of this node

Public static methods and constants

new CompoundRegionOperat ptr	new_area_filter	(CompoundRegionOperationNode ptr input, bool inverse = false, long amin = 0, long amax = max)	Creates a node filtering the input by area.
new CompoundRegionOperationNode ptr	new_area_sum_filter	(CompoundRegionOperationNode ptr input, bool inverse = false, long amin = 0, long amax = max)	Creates a node filtering the input by area sum.
new CompoundRegionOperat ptr	new_bbox_filter	(CompoundRegionOperationNode ptr input, CompoundRegionOperationNode::Parame parameter, bool inverse = false, unsigned int pmin = 0, unsigned int pmax = max)	Creates a node filtering the input by bounding box parameters.
new CompoundRegionOperationNode ptr	new_case	(CompoundRegionOperationNode ptr[] inputs)	Creates a 'switch ladder' (case statement) compound operation node.
new CompoundRegionOperat ptr	new_centers	(CompoundRegionOperationNode ptr input, unsigned int length, double fraction)	Creates a node delivering a part at the center of each input edge.
new CompoundRegionOperationNode ptr	new_convex_decomposition	(CompoundRegionOperationNode ptr input, PreferredOrientation mode)	Creates a node providing a composition into convex pieces.
new CompoundRegionOperat ptr	new_corners_as_d	(CompoundRegionOperationNode ptr input, double angle_min, bool include_angle_min, double angle_max, bool include_angle_max)	Creates a node turning corners into dots (single-point edges).
new CompoundRegionOperationNode ptr	new_corners_as_edge_pairs	(CompoundRegionOperationNode ptr input, double angle_min, bool include_angle_min, double angle_max, bool include_angle_max)	Creates a node turning corners into edge pairs containing the two edges adjacent to the corner.
new CompoundRegionOperat ptr	new_corners_as_r	(CompoundRegionOperationNode ptr input, double angle_min, bool include_angle_min, double angle_max, bool include_angle_max, int dim)	Creates a node turning corners into rectangles.

new CompoundRegionOperationNode ptr	new_count_filter	(CompoundRegionOperationNode ptr inputs, bool invert = false, unsigned long min_count = 0, unsigned long max_count = 18446744073709551615)	Creates a node selecting results but their shape count.
new CompoundRegionOperat ptr	new_edge_length_	(CompoundRegionOperationNode ptr input, bool inverse = false, unsigned int lmin = 0, unsigned int lmax = max)	Creates a node filtering edges by their length.
new CompoundRegionOperationNode ptr	new_edge_length_sum_filter	(CompoundRegionOperationNode ptr input, bool inverse = false, unsigned int lmin = 0, unsigned int lmax = max)	Creates a node filtering edges by their length sum (over the local set).
new CompoundRegionOperat ptr	new_edge_orientat	(CompoundRegionOperationNode ptr input, bool inverse, double amin, bool include_amin, double amax, bool include_amax)	Creates a node filtering edges by their orientation.
new CompoundRegionOperationNode ptr	new_edge_pair_to_first_edges	(CompoundRegionOperationNode ptr input)	Creates a node delivering the first edge of each edges pair.
new CompoundRegionOperat ptr	new_edge_pair_to_	(CompoundRegionOperationNode ptr input)	Creates a node delivering the second edge of each edges pair.
new CompoundRegionOperationNode ptr	new_edges	(CompoundRegionOperationNode ptr input, EdgeMode mode = All)	Creates a node converting polygons into its edges.
new CompoundRegionOperat ptr	new_empty	(CompoundRegionOperationNode::Result type)	Creates a node delivering an empty result of the given type
new CompoundRegionOperationNode ptr	new_enclosed_check	(CompoundRegionOperationNode ptr other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)	Creates a node providing an enclosed (secondary enclosing primary) check.

new CompoundRegionOperat ptr	new_enclosing	(CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false, unsigned long min_count = 1, unsigned long max_count = unlimited)	Creates a node representing an inside selection operation between the inputs.
new CompoundRegionOperationNode ptr	new_enclosing_check	(CompoundRegionOperationNode ptr other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)	Creates a node providing an inside (enclosure) check.
new CompoundRegionOperat ptr	new_end_segment	(CompoundRegionOperationNode ptr input, unsigned int length, double fraction)	Creates a node delivering a part at the end of each input edge.
new CompoundRegionOperationNode ptr	new_extended	(CompoundRegionOperationNode ptr input, int ext_b, int ext_e, int ext_o, int ext_i)	Creates a node delivering a polygonized version of the edges with the four extension parameters.
new CompoundRegionOperat ptr	new_extended_in	(CompoundRegionOperationNode ptr input, int e)	Creates a node delivering a polygonized, inside-extended version of the edges.
new CompoundRegionOperationNode ptr	new_extended_out	(CompoundRegionOperationNode ptr input, int e)	Creates a node delivering a polygonized, inside-extended version of the edges.
new CompoundRegionOperat ptr	new_extents	(CompoundRegionOperationNode ptr input, int e = 0)	Creates a node returning the extents of the objects.
new CompoundRegionOperationNode ptr	new_foreign		Creates a node object representing the primary input without the current polygon
new CompoundRegionOperat ptr	new_geometrical_b	(CompoundRegionOperationNode::Geome op, CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b)	Creates a node representing a geometrical boolean operation between the inputs.
new CompoundRegionOperationNode ptr	new_hole_count_filter	(CompoundRegionOperationNode ptr input, bool inverse = false,	Creates a node filtering the input by number of holes per polygon.

		unsigned long hmin = 0, unsigned long hmax = max)	
new CompoundRegionOperat ptr	new_holes	(CompoundRegionOperationNode ptr input)	Creates a node extracting the holes from polygons.
new CompoundRegionOperationNode ptr	new_hulls	(CompoundRegionOperationNode ptr input)	Creates a node extracting the hulls from polygons.
new CompoundRegionOperat ptr	new_inside	(CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false)	Creates a node representing an inside selection operation between the inputs.
new CompoundRegionOperationNode ptr	new_interacting	(CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false, unsigned long min_count = 1, unsigned long max_count = unlimited)	Creates a node representing an interacting selection operation between the inputs.
new CompoundRegionOperat ptr	new_isolated_chec	(int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)	Creates a node providing a isolated polygons (space between different polygons) check.
new CompoundRegionOperationNode ptr	new_join	(CompoundRegionOperationNode ptr[] inputs)	Creates a node that joins the inputs.
new CompoundRegionOperat ptr	new_logical_boole	(CompoundRegionOperationNode::Logical op, bool invert, CompoundRegionOperationNode ptr[] inputs)	Creates a node representing a logical boolean operation between the inputs.
new CompoundRegionOperationNode ptr	new_merged	(CompoundRegionOperationNode ptr input, bool min_coherence = false, unsigned int min_wc = 0)	Creates a node providing merged input polygons.
new CompoundRegionOperat ptr	new_minkowski_su	(CompoundRegionOperationNode ptr input, const Edge e)	Creates a node providing a Minkowski sum with an edge.
new CompoundRegionOperationNode ptr	new_minkowski_sum	(CompoundRegionOperationNode ptr input, const Polygon p)	Creates a node providing a Minkowski sum with a polygon.

new CompoundRegionOperat ptr	new_minkowski_su	(CompoundRegionOperationNode ptr input, const Box p)	Creates a node providing a Minkowski sum with a box.
new CompoundRegionOperationNode ptr	new_minkowski_sum	(CompoundRegionOperationNode ptr input, Point[] p)	Creates a node providing a Minkowski sum with a point sequence forming a contour.
new CompoundRegionOperat ptr	new_notch_check	(int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)	Creates a node providing a intra-polygon space check.
new CompoundRegionOperationNode ptr	new_outside	(CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false)	Creates a node representing an outside selection operation between the inputs.
new CompoundRegionOperat ptr	new_overlap_chec	(CompoundRegionOperationNode ptr other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)	Creates a node providing an overlap check.
new CompoundRegionOperationNode ptr	new_overlapping	(CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false, unsigned long min_count = 1, unsigned long max_count = unlimited)	Creates a node representing an overlapping selection operation between the inputs.
new CompoundRegionOperat ptr	new_perimeter_filt	(CompoundRegionOperationNode ptr input, bool inverse = false, unsigned long pmin = 0, unsigned long pmax = max)	Creates a node filtering the input by perimeter.
new CompoundRegionOperationNode ptr	new_perimeter_sum_filter	(CompoundRegionOperationNode ptr input, bool inverse = false, unsigned long amin = 0, unsigned long amax = max)	Creates a node filtering the input by area sum.

new CompoundRegionOperat ptr	new_polygon_brea	(CompoundRegionOperationNode ptr input, unsigned long max_vertex_count, double max_area_ratio)	Creates a node providing a composition into parts with less than the given number of points and a smaller area ratio.
new CompoundRegionOperationNode ptr	new_polygons	(CompoundRegionOperationNode ptr input, int e = 0)	Creates a node converting the input to polygons.
new CompoundRegionOperat ptr	new_primary		Creates a node object representing the primary input
new CompoundRegionOperationNode ptr	new_ratio_filter	(CompoundRegionOperationNode ptr input, CompoundRegionOperationNode::RatioParameterType parameter, bool inverse = false, double pmin = 0, bool pmin_included = true, double pmax = max, bool pmax_included = true)	Creates a node filtering the input by ratio parameters.
new CompoundRegionOperat ptr	new_rectangle_filt	(CompoundRegionOperationNode ptr input, bool is_square = false, bool inverse = false)	Creates a node filtering the input for rectangular or square shapes.
new CompoundRegionOperationNode ptr	new_rectilinear_filter	(CompoundRegionOperationNode ptr input, bool inverse = false)	Creates a node filtering the input for rectilinear shapes (or non-rectilinear ones with 'inverse' set to 'true').
new CompoundRegionOperat ptr	new_relative_exter	(CompoundRegionOperationNode ptr input, double fx1, double fy1, double fx2, double fy2, int dx, int dy)	Creates a node returning markers at specified locations of the extent (e.g. at the center).
new CompoundRegionOperationNode ptr	new_relative_extents_as_edges	(CompoundRegionOperationNode ptr input, double fx1, double fy1, double fx2, double fy2)	Creates a node returning edges at specified locations of the extent (e.g. at the center).
new CompoundRegionOperat ptr	new_rounded_corr	(CompoundRegionOperationNode ptr input, double rinner, double router, unsigned int n)	Creates a node generating rounded corners.
new CompoundRegionOperationNode ptr	new_secondary	(Region ptr region)	Creates a node object representing the secondary input from the given region

new CompoundRegionOperat ptr	new_separation_cl	(CompoundRegionOperationNode ptr other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)	Creates a node providing a separation check.
new CompoundRegionOperationNode ptr	new_sized	(CompoundRegionOperationNode ptr input, int dx, int dy, unsigned int mode)	Creates a node providing sizing.
new CompoundRegionOperat ptr	new_smoothed	(CompoundRegionOperationNode ptr input, int d, bool keep_hv = false)	Creates a node smoothing the polygons.
new CompoundRegionOperationNode ptr	new_space_check	(int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)	Creates a node providing a space check.
new CompoundRegionOperat ptr	new_start_segmen	(CompoundRegionOperationNode ptr input, unsigned int length, double fraction)	Creates a node delivering a part at the beginning of each input edge.
new CompoundRegionOperationNode ptr	new_strange_polygon_filter	(CompoundRegionOperationNode ptr input)	Creates a node extracting strange polygons.
new CompoundRegionOperat ptr	new_trapezoid_dec	(CompoundRegionOperationNode ptr input, TrapezoidDecompositionMode mode)	Creates a node providing a composition into trapezoids.

	new CompoundRegionOperationNode ptr	**new_width_check**	(int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)	Creates a node providing a width check.

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**		Use of this method is deprecated. Use _create instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead
[static]	new CompoundRegionOpera ptr	**new_minkowsky_sum**	(CompoundRegionOper ptr input, const Edge e)	Use of this method is deprecated. Use new_minkowski_sum instead
[static]	new CompoundRegionOperationNode ptr	**new_minkowsky_sum**	(CompoundRegionOperationNode ptr input, const Polygon p)	Use of this method is deprecated. Use new_minkowski_sum instead
[static]	new CompoundRegionOpera ptr	**new_minkowsky_sum**	(CompoundRegionOper ptr input, const Box p)	Use of this method is deprecated. Use new_minkowski_sum instead
[static]	new CompoundRegionOperationNode ptr	**new_minkowsky_sum**	(CompoundRegionOperationNode ptr input, Point[] p)	Use of this method is deprecated. Use new_minkowski_sum instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

description

Signature: *[const]* string **description**

Description: Gets the description for this node

Python specific notes:
The object exposes a readable attribute 'description'. This is the getter.

description=

Signature: void **description=** (string d)

Description: Sets the description for this node

Python specific notes:
The object exposes a writable attribute 'description'. This is the setter.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

distance

Signature: *[const]* int **distance**

Description: Gets the distance value for this node

Python specific notes:
The object exposes a readable attribute 'distance'. This is the getter.

distance=

Signature: void **distance=** (int d)

Description: Sets the distance value for this nodeUsually it's not required to provide a distance because the nodes compute a distance based on their operation. If necessary you can supply a distance. The processor will use this distance or the computed one, whichever is larger.

Python specific notes:
The object exposes a writable attribute 'distance'. This is the setter.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

new

Signature: *[static]* new CompoundRegionOperationNode ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

new_area_filter

Signature: *[static]* new CompoundRegionOperationNode ptr **new_area_filter** (CompoundRegionOperationNode ptr input, bool inverse = false, long amin = 0, long amax = max)

Description: Creates a node filtering the input by area.

This node renders the input if the area is between amin and amax (exclusively). If 'inverse' is set to true, the input shape is returned if the area is less than amin (exclusively) or larger than amax (inclusively).

new_area_sum_filter

Signature: *[static]* new CompoundRegionOperationNode ptr **new_area_sum_filter** (CompoundRegionOperationNode ptr input, bool inverse = false, long amin = 0, long amax = max)

	Description: Creates a node filtering the input by area sum. Like new_area_filter, but applies to the sum of all shapes in the current set.
new_bbox_filter	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_bbox_filter** (CompoundRegionOperationNode ptr input, CompoundRegionOperationNode::ParameterType parameter, bool inverse = false, unsigned int pmin = 0, unsigned int pmax = max) **Description**: Creates a node filtering the input by bounding box parameters. This node renders the input if the specified bounding box parameter of the input shape is between pmin and pmax (exclusively). If 'inverse' is set to true, the input shape is returned if the parameter is less than pmin (exclusively) or larger than pmax (inclusively).
new_case	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_case** (CompoundRegionOperationNode ptr[] inputs) **Description**: Creates a 'switch ladder' (case statement) compound operation node. The inputs are treated as a sequence of condition/result pairs: c1,r1,c2,r2 etc. If there is an odd number of inputs, the last element is taken as the default result. The implementation will evaluate c1 and if not empty, will render r1. Otherwise, c2 will be evaluated and r2 rendered if c2 isn't empty etc. If none of the conditions renders a non-empty set and a default result is present, the default will be returned. Otherwise, the result is empty.
new_centers	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_centers** (CompoundRegionOperationNode ptr input, unsigned int length, double fraction) **Description**: Creates a node delivering a part at the center of each input edge.
new_convex_decomposition	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_convex_decomposition** (CompoundRegionOperationNode ptr input, PreferredOrientation mode) **Description**: Creates a node providing a composition into convex pieces.
new_corners_as_dots	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_corners_as_dots** (CompoundRegionOperationNode ptr input, double angle_min, bool include_angle_min, double angle_max, bool include_angle_max) **Description**: Creates a node turning corners into dots (single-point edges).
new_corners_as_edge_pairs	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_corners_as_edge_pairs** (CompoundRegionOperationNode ptr input, double angle_min, bool include_angle_min, double angle_max, bool include_angle_max) **Description**: Creates a node turning corners into edge pairs containing the two edges adjacent to the corner. The first edge will be the incoming edge and the second one the outgoing edge. This feature has been introduced in version 0.27.1.
new_corners_as_rectangles	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_corners_as_rectangles** (CompoundRegionOperationNode ptr input, double angle_min, bool include_angle_min, double angle_max, bool include_angle_max, int dim) **Description**: Creates a node turning corners into rectangles.
new_count_filter	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_count_filter** (CompoundRegionOperationNode ptr inputs, bool invert = false, unsigned long min_count = 0, unsigned long max_count = 18446744073709551615)

	Description: Creates a node selecting results but their shape count.
new_edge_length_filter	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_edge_length_filter** (CompoundRegionOperationNode ptr input, bool inverse = false, unsigned int lmin = 0, unsigned int lmax = max) **Description**: Creates a node filtering edges by their length.
new_edge_length_sum_filter	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_edge_length_sum_filter** (CompoundRegionOperationNode ptr input, bool inverse = false, unsigned int lmin = 0, unsigned int lmax = max) **Description**: Creates a node filtering edges by their length sum (over the local set).
new_edge_orientation_filter	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_edge_orientation_filter** (CompoundRegionOperationNode ptr input, bool inverse, double amin, bool include_amin, double amax, bool include_amax) **Description**: Creates a node filtering edges by their orientation.
new_edge_pair_to_first_edges	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_edge_pair_to_first_edges** (CompoundRegionOperationNode ptr input) **Description**: Creates a node delivering the first edge of each edges pair.
new_edge_pair_to_second_edges	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_edge_pair_to_second_edges** (CompoundRegionOperationNode ptr input) **Description**: Creates a node delivering the second edge of each edges pair.
new_edges	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_edges** (CompoundRegionOperationNode ptr input, EdgeMode mode = All) **Description**: Creates a node converting polygons into its edges. The 'mode' argument allows selecting specific edges when generating edges from a polygon. See EdgeMode for the various options. By default, all edges are generated from polygons. The 'mode' argument has been added in version 0.29.
new_empty	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_empty** (CompoundRegionOperationNode::ResultType type) **Description**: Creates a node delivering an empty result of the given type
new_enclosed_check	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_enclosed_check** (CompoundRegionOperationNode ptr other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false) **Description**: Creates a node providing an enclosed (secondary enclosing primary) check. This method has been added in version 0.27.5. The zero_distance_mode argument has been inserted in version 0.29.
new_enclosing	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_enclosing** (CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false, unsigned long min_count = 1, unsigned long max_count = unlimited)

	Description: Creates a node representing an inside selection operation between the inputs.
new_enclosing_check	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_enclosing_check** (CompoundRegionOperationNode ptr other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false) **Description**: Creates a node providing an inside (enclosure) check. The zero_distance_mode argument has been inserted in version 0.29.
new_end_segments	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_end_segments** (CompoundRegionOperationNode ptr input, unsigned int length, double fraction) **Description**: Creates a node delivering a part at the end of each input edge.
new_extended	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_extended** (CompoundRegionOperationNode ptr input, int ext_b, int ext_e, int ext_o, int ext_i) **Description**: Creates a node delivering a polygonized version of the edges with the four extension parameters.
new_extended_in	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_extended_in** (CompoundRegionOperationNode ptr input, int e) **Description**: Creates a node delivering a polygonized, inside-extended version of the edges.
new_extended_out	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_extended_out** (CompoundRegionOperationNode ptr input, int e) **Description**: Creates a node delivering a polygonized, inside-extended version of the edges.
new_extents	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_extents** (CompoundRegionOperationNode ptr input, int e = 0) **Description**: Creates a node returning the extents of the objects. The 'e' parameter provides a generic enlargement which is applied to the boxes. This is helpful to cover dot-like edges or edge pairs in the input.
new_foreign	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_foreign** **Description**: Creates a node object representing the primary input without the current polygon
new_geometrical_boolean	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_geometrical_boolean** (CompoundRegionOperationNode::GeometricalOp op, CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b) **Description**: Creates a node representing a geometrical boolean operation between the inputs.
new_hole_count_filter	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_hole_count_filter** (CompoundRegionOperationNode ptr input, bool inverse = false, unsigned long hmin = 0, unsigned long hmax = max) **Description**: Creates a node filtering the input by number of holes per polygon.

	This node renders the input if the hole count is between hmin and hmax (exclusively). If 'inverse' is set to true, the input shape is returned if the hole count is less than hmin (exclusively) or larger than hmax (inclusively).
new_holes	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_holes** (CompoundRegionOperationNode ptr input) **Description**: Creates a node extracting the holes from polygons.
new_hulls	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_hulls** (CompoundRegionOperationNode ptr input) **Description**: Creates a node extracting the hulls from polygons.
new_inside	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_inside** (CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false) **Description**: Creates a node representing an inside selection operation between the inputs.
new_interacting	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_interacting** (CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false, unsigned long min_count = 1, unsigned long max_count = unlimited) **Description**: Creates a node representing an interacting selection operation between the inputs.
new_isolated_check	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_isolated_check** (int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false) **Description**: Creates a node providing a isolated polygons (space between different polygons) check. The zero_distance_mode argument has been inserted in version 0.29.
new_join	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_join** (CompoundRegionOperationNode ptr[] inputs) **Description**: Creates a node that joins the inputs.
new_logical_boolean	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_logical_boolean** (CompoundRegionOperationNode::LogicalOp op, bool invert, CompoundRegionOperationNode ptr[] inputs) **Description**: Creates a node representing a logical boolean operation between the inputs. A logical AND operation will evaluate the arguments and render the subject shape when all arguments are non-empty. The logical OR operation will evaluate the arguments and render the subject shape when one argument is non-empty. Setting 'inverse' to true will reverse the result and return the subject shape when one argument is empty in the AND case and when all arguments are empty in the OR case.
new_merged	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_merged** (CompoundRegionOperationNode ptr input, bool min_coherence = false, unsigned int min_wc = 0)

	Description: Creates a node providing merged input polygons.
new_minkowski_sum	**(1) Signature**: *[static]* new CompoundRegionOperationNode ptr **new_minkowski_sum** (CompoundRegionOperationNode ptr input, const Edge e) **Description**: Creates a node providing a Minkowski sum with an edge. **(2) Signature**: *[static]* new CompoundRegionOperationNode ptr **new_minkowski_sum** (CompoundRegionOperationNode ptr input, const Polygon p) **Description**: Creates a node providing a Minkowski sum with a polygon. **(3) Signature**: *[static]* new CompoundRegionOperationNode ptr **new_minkowski_sum** (CompoundRegionOperationNode ptr input, const Box p) **Description**: Creates a node providing a Minkowski sum with a box. **(4) Signature**: *[static]* new CompoundRegionOperationNode ptr **new_minkowski_sum** (CompoundRegionOperationNode ptr input, Point[] p) **Description**: Creates a node providing a Minkowski sum with a point sequence forming a contour.
new_minkowsky_sum	**(1) Signature**: *[static]* new CompoundRegionOperationNode ptr **new_minkowsky_sum** (CompoundRegionOperationNode ptr input, const Edge e) **Description**: Creates a node providing a Minkowski sum with an edge. Use of this method is deprecated. Use new_minkowski_sum instead **(2) Signature**: *[static]* new CompoundRegionOperationNode ptr **new_minkowsky_sum** (CompoundRegionOperationNode ptr input, const Polygon p) **Description**: Creates a node providing a Minkowski sum with a polygon. Use of this method is deprecated. Use new_minkowski_sum instead **(3) Signature**: *[static]* new CompoundRegionOperationNode ptr **new_minkowsky_sum** (CompoundRegionOperationNode ptr input, const Box p) **Description**: Creates a node providing a Minkowski sum with a box. Use of this method is deprecated. Use new_minkowski_sum instead **(4) Signature**: *[static]* new CompoundRegionOperationNode ptr **new_minkowsky_sum** (CompoundRegionOperationNode ptr input, Point[] p) **Description**: Creates a node providing a Minkowski sum with a point sequence forming a contour. Use of this method is deprecated. Use new_minkowski_sum instead
new_notch_check	**Signature**: *[static]* new CompoundRegionOperationNode ptr **new_notch_check** (int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false) **Description**: Creates a node providing a intra-polygon space check. The zero_distance_mode argument has been inserted in version 0.29.

new_outside

Signature: *[static]* new CompoundRegionOperationNode ptr **new_outside** (CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false)

Description: Creates a node representing an outside selection operation between the inputs.

new_overlap_check

Signature: *[static]* new CompoundRegionOperationNode ptr **new_overlap_check** (CompoundRegionOperationNode ptr other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)

Description: Creates a node providing an overlap check.

The zero_distance_mode argument has been inserted in version 0.29.

new_overlapping

Signature: *[static]* new CompoundRegionOperationNode ptr **new_overlapping** (CompoundRegionOperationNode ptr a, CompoundRegionOperationNode ptr b, bool inverse = false, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Creates a node representing an overlapping selection operation between the inputs.

new_perimeter_filter

Signature: *[static]* new CompoundRegionOperationNode ptr **new_perimeter_filter** (CompoundRegionOperationNode ptr input, bool inverse = false, unsigned long pmin = 0, unsigned long pmax = max)

Description: Creates a node filtering the input by perimeter.

This node renders the input if the perimeter is between pmin and pmax (exclusively). If 'inverse' is set to true, the input shape is returned if the perimeter is less than pmin (exclusively) or larger than pmax (inclusively).

new_perimeter_sum_filter

Signature: *[static]* new CompoundRegionOperationNode ptr **new_perimeter_sum_filter** (CompoundRegionOperationNode ptr input, bool inverse = false, unsigned long amin = 0, unsigned long amax = max)

Description: Creates a node filtering the input by area sum.

Like new_perimeter_filter, but applies to the sum of all shapes in the current set.

new_polygon_breaker

Signature: *[static]* new CompoundRegionOperationNode ptr **new_polygon_breaker** (CompoundRegionOperationNode ptr input, unsigned long max_vertex_count, double max_area_ratio)

Description: Creates a node providing a composition into parts with less than the given number of points and a smaller area ratio.

new_polygons

Signature: *[static]* new CompoundRegionOperationNode ptr **new_polygons** (CompoundRegionOperationNode ptr input, int e = 0)

Description: Creates a node converting the input to polygons.

e: The enlargement parameter when converting edges or edge pairs to polygons.

new_primary

Signature: *[static]* new CompoundRegionOperationNode ptr **new_primary**

Description: Creates a node object representing the primary input

new_ratio_filter

Signature: *[static]* new CompoundRegionOperationNode ptr **new_ratio_filter** (CompoundRegionOperationNode ptr input, CompoundRegionOperationNode::RatioParameterType parameter, bool inverse = false, double pmin = 0, bool pmin_included = true, double pmax = max, bool pmax_included = true)

Description: Creates a node filtering the input by ratio parameters.

This node renders the input if the specified ratio parameter of the input shape is between pmin and pmax. If 'pmin_included' is true, the range will include pmin. Same for 'pmax_included' and pmax. If 'inverse' is set to true, the input shape is returned if the parameter is not within the specified range.

new_rectangle_filter

Signature: *[static]* new CompoundRegionOperationNode ptr **new_rectangle_filter** (CompoundRegionOperationNode ptr input, bool is_square = false, bool inverse = false)

Description: Creates a node filtering the input for rectangular or square shapes.

If 'is_square' is true, only squares will be selected. If 'inverse' is true, the non-rectangle/non-square shapes are returned.

new_rectilinear_filter

Signature: *[static]* new CompoundRegionOperationNode ptr **new_rectilinear_filter** (CompoundRegionOperationNode ptr input, bool inverse = false)

Description: Creates a node filtering the input for rectilinear shapes (or non-rectilinear ones with 'inverse' set to 'true').

new_relative_extents

Signature: *[static]* new CompoundRegionOperationNode ptr **new_relative_extents** (CompoundRegionOperationNode ptr input, double fx1, double fy1, double fx2, double fy2, int dx, int dy)

Description: Creates a node returning markers at specified locations of the extent (e.g. at the center).

new_relative_extents_as_edge

Signature: *[static]* new CompoundRegionOperationNode ptr **new_relative_extents_as_edges** (CompoundRegionOperationNode ptr input, double fx1, double fy1, double fx2, double fy2)

Description: Creates a node returning edges at specified locations of the extent (e.g. at the center).

new_rounded_corners

Signature: *[static]* new CompoundRegionOperationNode ptr **new_rounded_corners** (CompoundRegionOperationNode ptr input, double rinner, double router, unsigned int n)

Description: Creates a node generating rounded corners.

rinner: The inner corner radius.@param router The outer corner radius.@param n The number if points per full circle.

new_secondary

Signature: *[static]* new CompoundRegionOperationNode ptr **new_secondary** (Region ptr region)

Description: Creates a node object representing the secondary input from the given region

new_separation_check

Signature: *[static]* new CompoundRegionOperationNode ptr **new_separation_check** (CompoundRegionOperationNode ptr other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)

Description: Creates a node providing a separation check.

The zero_distance_mode argument has been inserted in version 0.29.

new_sized

Signature: *[static]* new CompoundRegionOperationNode ptr **new_sized** (CompoundRegionOperationNode ptr input, int dx, int dy, unsigned int mode)

Description: Creates a node providing sizing.

new_smoothed

Signature: *[static]* new CompoundRegionOperationNode ptr **new_smoothed** (CompoundRegionOperationNode ptr input, int d, bool keep_hv = false)

Description: Creates a node smoothing the polygons.

d: The tolerance to be applied for the smoothing.

keep_hv: If true, horizontal and vertical edges are maintained.

new_space_check

Signature: *[static]* new CompoundRegionOperationNode ptr **new_space_check** (int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, Region::OppositeFilter opposite_filter = NoOppositeFilter, Region::RectFilter rect_filter = NoRectFilter, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)

Description: Creates a node providing a space check.

The zero_distance_mode argument has been inserted in version 0.29.

new_start_segments

Signature: *[static]* new CompoundRegionOperationNode ptr **new_start_segments** (CompoundRegionOperationNode ptr input, unsigned int length, double fraction)

Description: Creates a node delivering a part at the beginning of each input edge.

new_strange_polygons_filter

Signature: *[static]* new CompoundRegionOperationNode ptr **new_strange_polygons_filter** (CompoundRegionOperationNode ptr input)

Description: Creates a node extracting strange polygons.

'strange polygons' are ones which cannot be oriented - e.g. '8' shape polygons.

new_trapezoid_decomposition

Signature: *[static]* new CompoundRegionOperationNode ptr **new_trapezoid_decomposition** (CompoundRegionOperationNode ptr input, TrapezoidDecompositionMode mode)

Description: Creates a node providing a composition into trapezoids.

new_width_check

Signature: *[static]* new CompoundRegionOperationNode ptr **new_width_check** (int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max., bool shielded = true, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching, bool negative = false)

Description: Creates a node providing a width check.

The zero_distance_mode argument has been inserted in version 0.29.

result_type

Signature: *[const]* CompoundRegionOperationNode::ResultType **result_type**

Description: Gets the result type of this node

4.26. API reference - Class CompoundRegionOperationNode::LogicalOp

Notation used in Ruby API documentation

Module: db

Description: This class represents the CompoundRegionOperationNode::LogicalOp enum

This class is equivalent to the class CompoundRegionOperationNode::LogicalOp

This enum has been introduced in version 0.27.

Public constructors

new CompoundRegionOperationNode::LogicalOp ptr	**new**	(int i)	Creates an enum from an integer value
new CompoundRegionOperationNode::LogicalOp ptr	**new**	(string s)	Creates an enum from a string value

Public methods

[const]	bool	**!=**	(const CompoundRegionOperatic other)	Compares two enums for inequality
[const]	bool	**!=**	(int other)	Compares an enum with an integer for inequality
[const]	bool	**<**	(const CompoundRegionOperatic other)	Returns true if the first enum is less (in the enum symbol order) than the second
[const]	bool	**<**	(int other)	Returns true if the enum is less (in the enum symbol order) than the integer value
[const]	bool	**==**	(const CompoundRegionOperatic other)	Compares two enums
[const]	bool	**==**	(int other)	Compares an enum with an integer value
[const]	int	**hash**		Gets the hash value from the enum
[const]	string	**inspect**		Converts an enum to a visual string
[const]	int	**to_i**		Gets the integer value from the enum
[const]	string	**to_s**		Gets the symbolic string from an enum

Public static methods and constants

[static,const]	CompoundRegionOperationNode::Logical(	**LogAnd**	Indicates a logical '&&' (and).
[static,const]	CompoundRegionOperationNode::LogicalOp	**LogOr**	Indicates a logical '||' (or).

Detailed description

!=	**(1) Signature**: *[const]* bool **!=** (const CompoundRegionOperationNode::LogicalOp other) **Description**: Compares two enums for inequality **(2) Signature**: *[const]* bool **!=** (int other) **Description**: Compares an enum with an integer for inequality
<	**(1) Signature**: *[const]* bool **<** (const CompoundRegionOperationNode::LogicalOp other) **Description**: Returns true if the first enum is less (in the enum symbol order) than the second **(2) Signature**: *[const]* bool **<** (int other) **Description**: Returns true if the enum is less (in the enum symbol order) than the integer value
==	**(1) Signature**: *[const]* bool **==** (const CompoundRegionOperationNode::LogicalOp other) **Description**: Compares two enums **(2) Signature**: *[const]* bool **==** (int other) **Description**: Compares an enum with an integer value
LogAnd	**Signature**: *[static,const]* CompoundRegionOperationNode::LogicalOp **LogAnd** **Description**: Indicates a logical '&&' (and). **Python specific notes:** The object exposes a readable attribute 'LogAnd'. This is the getter.
LogOr	**Signature**: *[static,const]* CompoundRegionOperationNode::LogicalOp **LogOr** **Description**: Indicates a logical '||' (or). **Python specific notes:** The object exposes a readable attribute 'LogOr'. This is the getter.
hash	**Signature**: *[const]* int **hash** **Description**: Gets the hash value from the enum **Python specific notes:** This method is also available as 'hash(object)'.
inspect	**Signature**: *[const]* string **inspect** **Description**: Converts an enum to a visual string **Python specific notes:** This method is also available as 'repr(object)'.
new	**(1) Signature**: *[static]* new CompoundRegionOperationNode::LogicalOp ptr **new** (int i) **Description**: Creates an enum from an integer value **Python specific notes:** This method is the default initializer of the object.

(2) Signature: *[static]* new CompoundRegionOperationNode::LogicalOp ptr **new** (string s)

Description: Creates an enum from a string value

Python specific notes:
This method is the default initializer of the object.

to_i

Signature: *[const]* int **to_i**

Description: Gets the integer value from the enum

Python specific notes:
This method is also available as 'int(object)'.

to_s

Signature: *[const]* string **to_s**

Description: Gets the symbolic string from an enum

Python specific notes:
This method is also available as 'str(object)'.

4.27. API reference - Class CompoundRegionOperationNode::GeometricalOp

Notation used in Ruby API documentation

Module: db

Description: This class represents the CompoundRegionOperationNode::GeometricalOp enum

This class is equivalent to the class CompoundRegionOperationNode::GeometricalOp

This enum has been introduced in version 0.27.

Public constructors

new CompoundRegionOperationNode::GeometricalOp ptr	**new**	(int i)	Creates an enum from an integer value
new CompoundRegionOperationNode::GeometricalOp ptr	**new**	(string s)	Creates an enum from a string value

Public methods

[const]	bool	**!=**	(const CompoundRegionOperatic other)	Compares two enums for inequality
[const]	bool	**!=**	(int other)	Compares an enum with an integer for inequality
[const]	bool	**<**	(const CompoundRegionOperatic other)	Returns true if the first enum is less (in the enum symbol order) than the second
[const]	bool	**<**	(int other)	Returns true if the enum is less (in the enum symbol order) than the integer value
[const]	bool	**==**	(const CompoundRegionOperatic other)	Compares two enums
[const]	bool	**==**	(int other)	Compares an enum with an integer value
[const]	int	**hash**		Gets the hash value from the enum
[const]	string	**inspect**		Converts an enum to a visual string
[const]	int	**to_i**		Gets the integer value from the enum
[const]	string	**to_s**		Gets the symbolic string from an enum

Public static methods and constants

[static,const]	CompoundRegionOperationNode::Geometric	**And**	Indicates a geometrical '&' (and).
[static,const]	CompoundRegionOperationNode::GeometricalOp	**Not**	Indicates a geometrical '-' (not).

[static,const]	CompoundRegionOperationNode::Geometric **Or**	Indicates a geometrical '|' (or).
[static,const]	CompoundRegionOperationNode::GeometricalOp **Xor**	Indicates a geometrical '^' (xor).

Detailed description

!=	**(1) Signature**: *[const]* bool **!=** (const CompoundRegionOperationNode::GeometricalOp other) **Description**: Compares two enums for inequality **(2) Signature**: *[const]* bool **!=** (int other) **Description**: Compares an enum with an integer for inequality
<	**(1) Signature**: *[const]* bool **<** (const CompoundRegionOperationNode::GeometricalOp other) **Description**: Returns true if the first enum is less (in the enum symbol order) than the second **(2) Signature**: *[const]* bool **<** (int other) **Description**: Returns true if the enum is less (in the enum symbol order) than the integer value
==	**(1) Signature**: *[const]* bool **==** (const CompoundRegionOperationNode::GeometricalOp other) **Description**: Compares two enums **(2) Signature**: *[const]* bool **==** (int other) **Description**: Compares an enum with an integer value
And	**Signature**: *[static,const]* CompoundRegionOperationNode::GeometricalOp **And** **Description**: Indicates a geometrical '&' (and). **Python specific notes:** The object exposes a readable attribute 'And'. This is the getter.
Not	**Signature**: *[static,const]* CompoundRegionOperationNode::GeometricalOp **Not** **Description**: Indicates a geometrical '-' (not). **Python specific notes:** The object exposes a readable attribute 'Not'. This is the getter.
Or	**Signature**: *[static,const]* CompoundRegionOperationNode::GeometricalOp **Or** **Description**: Indicates a geometrical '|' (or). **Python specific notes:** The object exposes a readable attribute 'Or'. This is the getter.
Xor	**Signature**: *[static,const]* CompoundRegionOperationNode::GeometricalOp **Xor** **Description**: Indicates a geometrical '^' (xor). **Python specific notes:** The object exposes a readable attribute 'Xor'. This is the getter.

hash

Signature: *[const]* int **hash**

Description: Gets the hash value from the enum

Python specific notes:
This method is also available as 'hash(object)'.

inspect

Signature: *[const]* string **inspect**

Description: Converts an enum to a visual string

Python specific notes:
This method is also available as 'repr(object)'.

new

(1) Signature: *[static]* new CompoundRegionOperationNode::GeometricalOp ptr **new** (int i)

Description: Creates an enum from an integer value

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new CompoundRegionOperationNode::GeometricalOp ptr **new** (string s)

Description: Creates an enum from a string value

Python specific notes:
This method is the default initializer of the object.

to_i

Signature: *[const]* int **to_i**

Description: Gets the integer value from the enum

Python specific notes:
This method is also available as 'int(object)'.

to_s

Signature: *[const]* string **to_s**

Description: Gets the symbolic string from an enum

Python specific notes:
This method is also available as 'str(object)'.

4.28. API reference - Class CompoundRegionOperationNode::ResultType

Notation used in Ruby API documentation

Module: db

Description: This class represents the CompoundRegionOperationNode::ResultType enum

This class is equivalent to the class CompoundRegionOperationNode::ResultType

This enum has been introduced in version 0.27.

Public constructors

new CompoundRegionOperationNode::ResultType ptr	**new**	(int i)	Creates an enum from an integer value
new CompoundRegionOperationNode::ResultType ptr	**new**	(string s)	Creates an enum from a string value

Public methods

[const]	bool	**!=**	(const CompoundRegionOperatic other)	Compares two enums for inequality
[const]	bool	**!=**	(int other)	Compares an enum with an integer for inequality
[const]	bool	**<**	(const CompoundRegionOperatic other)	Returns true if the first enum is less (in the enum symbol order) than the second
[const]	bool	**<**	(int other)	Returns true if the enum is less (in the enum symbol order) than the integer value
[const]	bool	**==**	(const CompoundRegionOperatic other)	Compares two enums
[const]	bool	**==**	(int other)	Compares an enum with an integer value
[const]	int	**hash**		Gets the hash value from the enum
[const]	string	**inspect**		Converts an enum to a visual string
[const]	int	**to_i**		Gets the integer value from the enum
[const]	string	**to_s**		Gets the symbolic string from an enum

Public static methods and constants

[static,const]	CompoundRegionOperationNode::ResultT	**EdgePairs**	Indicates edge pair result type.
[static,const]	CompoundRegionOperationNode::ResultType	**Edges**	Indicates edge result type.

[static,const]	CompoundRegionOperationNode::ResultT	**Region**	Indicates polygon result type.

Detailed description

!=

(1) Signature: *[const]* bool **!=** (const CompoundRegionOperationNode::ResultType other)
Description: Compares two enums for inequality

(2) Signature: *[const]* bool **!=** (int other)
Description: Compares an enum with an integer for inequality

<

(1) Signature: *[const]* bool **<** (const CompoundRegionOperationNode::ResultType other)
Description: Returns true if the first enum is less (in the enum symbol order) than the second

(2) Signature: *[const]* bool **<** (int other)
Description: Returns true if the enum is less (in the enum symbol order) than the integer value

==

(1) Signature: *[const]* bool **==** (const CompoundRegionOperationNode::ResultType other)
Description: Compares two enums

(2) Signature: *[const]* bool **==** (int other)
Description: Compares an enum with an integer value

EdgePairs

Signature: *[static,const]* CompoundRegionOperationNode::ResultType **EdgePairs**
Description: Indicates edge pair result type.
Python specific notes:
The object exposes a readable attribute 'EdgePairs'. This is the getter.

Edges

Signature: *[static,const]* CompoundRegionOperationNode::ResultType **Edges**
Description: Indicates edge result type.
Python specific notes:
The object exposes a readable attribute 'Edges'. This is the getter.

Region

Signature: *[static,const]* CompoundRegionOperationNode::ResultType **Region**
Description: Indicates polygon result type.
Python specific notes:
The object exposes a readable attribute 'Region'. This is the getter.

hash

Signature: *[const]* int **hash**
Description: Gets the hash value from the enum
Python specific notes:
This method is also available as 'hash(object)'.

inspect

Signature: *[const]* string **inspect**
Description: Converts an enum to a visual string
Python specific notes:

This method is also available as 'repr(object)'.

new

(1) Signature: *[static]* new CompoundRegionOperationNode::ResultType ptr **new** (int i)

Description: Creates an enum from an integer value

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new CompoundRegionOperationNode::ResultType ptr **new** (string s)

Description: Creates an enum from a string value

Python specific notes:
This method is the default initializer of the object.

to_i

Signature: *[const]* int **to_i**

Description: Gets the integer value from the enum

Python specific notes:
This method is also available as 'int(object)'.

to_s

Signature: *[const]* string **to_s**

Description: Gets the symbolic string from an enum

Python specific notes:
This method is also available as 'str(object)'.

4.29. API reference - Class CompoundRegionOperationNode::ParameterType

Notation used in Ruby API documentation

Module: db

Description: This class represents the parameter type enum used in \CompoundRegionOperationNode#new_bbox_filter

This class is equivalent to the class CompoundRegionOperationNode::ParameterType

This enum has been introduced in version 0.27.

Public constructors

new CompoundRegionOperationNode::ParameterType ptr	**new**	(int i)	Creates an enum from an integer value
new CompoundRegionOperationNode::ParameterType ptr	**new**	(string s)	Creates an enum from a string value

Public methods

[const]	bool	**!=**	(const CompoundRegionOperatic other)	Compares two enums for inequality
[const]	bool	**!=**	(int other)	Compares an enum with an integer for inequality
[const]	bool	**<**	(const CompoundRegionOperatic other)	Returns true if the first enum is less (in the enum symbol order) than the second
[const]	bool	**<**	(int other)	Returns true if the enum is less (in the enum symbol order) than the integer value
[const]	bool	**==**	(const CompoundRegionOperatic other)	Compares two enums
[const]	bool	**==**	(int other)	Compares an enum with an integer value
[const]	int	**hash**		Gets the hash value from the enum
[const]	string	**inspect**		Converts an enum to a visual string
[const]	int	**to_i**		Gets the integer value from the enum
[const]	string	**to_s**		Gets the symbolic string from an enum

Public static methods and constants

[static,const]	CompoundRegionOperationNode::Pa	**BoxAverageDim**	Measures the average of width and height of the bounding box

[static,const]	CompoundRegionOperationNode::Parameter	**BoxHeight**	Measures the height of the bounding box
[static,const]	CompoundRegionOperationNode::Pa	**BoxMaxDim**	Measures the maximum dimension of the bounding box
[static,const]	CompoundRegionOperationNode::Parameter	**BoxMinDim**	Measures the minimum dimension of the bounding box
[static,const]	CompoundRegionOperationNode::Pa	**BoxWidth**	Measures the width of the bounding box

Detailed description

!=	**(1) Signature**: *[const]* bool **!=** (const CompoundRegionOperationNode::ParameterType other) **Description**: Compares two enums for inequality **(2) Signature**: *[const]* bool **!=** (int other) **Description**: Compares an enum with an integer for inequality
<	**(1) Signature**: *[const]* bool **<** (const CompoundRegionOperationNode::ParameterType other) **Description**: Returns true if the first enum is less (in the enum symbol order) than the second **(2) Signature**: *[const]* bool **<** (int other) **Description**: Returns true if the enum is less (in the enum symbol order) than the integer value
==	**(1) Signature**: *[const]* bool **==** (const CompoundRegionOperationNode::ParameterType other) **Description**: Compares two enums **(2) Signature**: *[const]* bool **==** (int other) **Description**: Compares an enum with an integer value
BoxAverageDim	**Signature**: *[static,const]* CompoundRegionOperationNode::ParameterType **BoxAverageDim** **Description**: Measures the average of width and height of the bounding box **Python specific notes:** The object exposes a readable attribute 'BoxAverageDim'. This is the getter.
BoxHeight	**Signature**: *[static,const]* CompoundRegionOperationNode::ParameterType **BoxHeight** **Description**: Measures the height of the bounding box **Python specific notes:** The object exposes a readable attribute 'BoxHeight'. This is the getter.
BoxMaxDim	**Signature**: *[static,const]* CompoundRegionOperationNode::ParameterType **BoxMaxDim** **Description**: Measures the maximum dimension of the bounding box **Python specific notes:** The object exposes a readable attribute 'BoxMaxDim'. This is the getter.

BoxMinDim

Signature: *[static,const]* CompoundRegionOperationNode::ParameterType **BoxMinDim**

Description: Measures the minimum dimension of the bounding box

Python specific notes:
The object exposes a readable attribute 'BoxMinDim'. This is the getter.

BoxWidth

Signature: *[static,const]* CompoundRegionOperationNode::ParameterType **BoxWidth**

Description: Measures the width of the bounding box

Python specific notes:
The object exposes a readable attribute 'BoxWidth'. This is the getter.

hash

Signature: *[const]* int **hash**

Description: Gets the hash value from the enum

Python specific notes:
This method is also available as 'hash(object)'.

inspect

Signature: *[const]* string **inspect**

Description: Converts an enum to a visual string

Python specific notes:
This method is also available as 'repr(object)'.

new

(1) Signature: *[static]* new CompoundRegionOperationNode::ParameterType ptr **new** (int i)

Description: Creates an enum from an integer value

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new CompoundRegionOperationNode::ParameterType ptr **new** (string s)

Description: Creates an enum from a string value

Python specific notes:
This method is the default initializer of the object.

to_i

Signature: *[const]* int **to_i**

Description: Gets the integer value from the enum

Python specific notes:
This method is also available as 'int(object)'.

to_s

Signature: *[const]* string **to_s**

Description: Gets the symbolic string from an enum

Python specific notes:
This method is also available as 'str(object)'.

4.30. API reference - Class CompoundRegionOperationNode::RatioParameterType

Notation used in Ruby API documentation

Module: db

Description: This class represents the parameter type enum used in \CompoundRegionOperationNode#new_ratio_filter

This class is equivalent to the class CompoundRegionOperationNode::RatioParameterType

This enum has been introduced in version 0.27.

Public constructors

new CompoundRegionOperationNode::RatioParameter ptr	**new**	(int i)	Creates an enum from an integer value
new CompoundRegionOperationNode::RatioParameterType ptr	**new**	(string s)	Creates an enum from a string value

Public methods

[const]	bool	**!=**	(const CompoundRegionOperatic other)	Compares two enums for inequality
[const]	bool	**!=**	(int other)	Compares an enum with an integer for inequality
[const]	bool	**<**	(const CompoundRegionOperatic other)	Returns true if the first enum is less (in the enum symbol order) than the second
[const]	bool	**<**	(int other)	Returns true if the enum is less (in the enum symbol order) than the integer value
[const]	bool	**==**	(const CompoundRegionOperatic other)	Compares two enums
[const]	bool	**==**	(int other)	Compares an enum with an integer value
[const]	int	**hash**		Gets the hash value from the enum
[const]	string	**inspect**		Converts an enum to a visual string
[const]	int	**to_i**		Gets the integer value from the enum
[const]	string	**to_s**		Gets the symbolic string from an enum

Public static methods and constants

[static,const]	CompoundRegionOperationNode::Ra	**AreaRatio**	Measures the area ratio (bounding box area / polygon area)

[static,const]	CompoundRegionOperationNode::RatioParameterType **AspectRatio**	Measures the aspect ratio of the bounding box (larger / smaller dimension)
[static,const]	CompoundRegionOperationNode::RatioParameterType **RelativeHeight**	Measures the relative height (height / width)

Detailed description

!=

(1) Signature: *[const]* bool **!=** (const CompoundRegionOperationNode::RatioParameterType other)
Description: Compares two enums for inequality

(2) Signature: *[const]* bool **!=** (int other)
Description: Compares an enum with an integer for inequality

<

(1) Signature: *[const]* bool **<** (const CompoundRegionOperationNode::RatioParameterType other)
Description: Returns true if the first enum is less (in the enum symbol order) than the second

(2) Signature: *[const]* bool **<** (int other)
Description: Returns true if the enum is less (in the enum symbol order) than the integer value

==

(1) Signature: *[const]* bool **==** (const CompoundRegionOperationNode::RatioParameterType other)
Description: Compares two enums

(2) Signature: *[const]* bool **==** (int other)
Description: Compares an enum with an integer value

AreaRatio

Signature: *[static,const]* CompoundRegionOperationNode::RatioParameterType **AreaRatio**
Description: Measures the area ratio (bounding box area / polygon area)
Python specific notes:
The object exposes a readable attribute 'AreaRatio'. This is the getter.

AspectRatio

Signature: *[static,const]* CompoundRegionOperationNode::RatioParameterType **AspectRatio**
Description: Measures the aspect ratio of the bounding box (larger / smaller dimension)
Python specific notes:
The object exposes a readable attribute 'AspectRatio'. This is the getter.

RelativeHeight

Signature: *[static,const]* CompoundRegionOperationNode::RatioParameterType **RelativeHeight**
Description: Measures the relative height (height / width)
Python specific notes:
The object exposes a readable attribute 'RelativeHeight'. This is the getter.

hash

Signature: *[const]* int **hash**
Description: Gets the hash value from the enum
Python specific notes:
This method is also available as 'hash(object)'.

inspect	**Signature**: *[const]* string **inspect** **Description**: Converts an enum to a visual string **Python specific notes:** This method is also available as 'repr(object)'.
new	**(1) Signature**: *[static]* new CompoundRegionOperationNode::RatioParameterType ptr **new** (int i) **Description**: Creates an enum from an integer value **Python specific notes:** This method is the default initializer of the object. **(2) Signature**: *[static]* new CompoundRegionOperationNode::RatioParameterType ptr **new** (string s) **Description**: Creates an enum from a string value **Python specific notes:** This method is the default initializer of the object.
to_i	**Signature**: *[const]* int **to_i** **Description**: Gets the integer value from the enum **Python specific notes:** This method is also available as 'int(object)'.
to_s	**Signature**: *[const]* string **to_s** **Description**: Gets the symbolic string from an enum **Python specific notes:** This method is also available as 'str(object)'.

4.31. API reference - Class TrapezoidDecompositionMode

Notation used in Ruby API documentation

Module: db

Description: This class represents the TrapezoidDecompositionMode enum used within trapezoid decomposition

This enum has been introduced in version 0.27.

Public constructors

new TrapezoidDecompositionMode ptr	**new**	(int i)	Creates an enum from an integer value
new TrapezoidDecompositionMode ptr	**new**	(string s)	Creates an enum from a string value

Public methods

[const]	bool	**!=**	(const TrapezoidDecompo other)	Compares two enums for inequality
[const]	bool	**!=**	(int other)	Compares an enum with an integer for inequality
[const]	bool	**<**	(const TrapezoidDecompo other)	Returns true if the first enum is less (in the enum symbol order) than the second
[const]	bool	**<**	(int other)	Returns true if the enum is less (in the enum symbol order) than the integer value
[const]	bool	**==**	(const TrapezoidDecompo other)	Compares two enums
[const]	bool	**==**	(int other)	Compares an enum with an integer value
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const TrapezoidDecompo other)	Assigns another object to self

[const]	new TrapezoidDecompositionMode ptr	**dup**	Creates a copy of self
[const]	int	**hash**	Gets the hash value from the enum
[const]	string	**inspect**	Converts an enum to a visual string
[const]	int	**to_i**	Gets the integer value from the enum
[const]	string	**to_s**	Gets the symbolic string from an enum

Public static methods and constants

[static,const]	TrapezoidDecompositionMode	**TD_htrapezoids**	Indicates horizontal trapezoid decomposition.
[static,const]	TrapezoidDecompositionMode	**TD_simple**	Indicates unspecific decomposition.
[static,const]	TrapezoidDecompositionMode	**TD_vtrapezoids**	Indicates vertical trapezoid decomposition.

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=	**(1) Signature**: *[const]* bool **!=** (const TrapezoidDecompositionMode other) **Description**: Compares two enums for inequality **(2) Signature**: *[const]* bool **!=** (int other) **Description**: Compares an enum with an integer for inequality
<	**(1) Signature**: *[const]* bool **<** (const TrapezoidDecompositionMode other) **Description**: Returns true if the first enum is less (in the enum symbol order) than the second **(2) Signature**: *[const]* bool **<** (int other) **Description**: Returns true if the enum is less (in the enum symbol order) than the integer value
==	**(1) Signature**: *[const]* bool **==** (const TrapezoidDecompositionMode other) **Description**: Compares two enums

(2) Signature: *[const]* bool **==** (int other)

Description: Compares an enum with an integer value

TD_htrapezoids

Signature: *[static,const]* TrapezoidDecompositionMode **TD_htrapezoids**

Description: Indicates horizontal trapezoid decomposition.

Python specific notes:
The object exposes a readable attribute 'TD_htrapezoids'. This is the getter.

TD_simple

Signature: *[static,const]* TrapezoidDecompositionMode **TD_simple**

Description: Indicates unspecific decomposition.

Python specific notes:
The object exposes a readable attribute 'TD_simple'. This is the getter.

TD_vtrapezoids

Signature: *[static,const]* TrapezoidDecompositionMode **TD_vtrapezoids**

Description: Indicates vertical trapezoid decomposition.

Python specific notes:
The object exposes a readable attribute 'TD_vtrapezoids'. This is the getter.

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const TrapezoidDecompositionMode other)

Description: Assigns another object to self

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new TrapezoidDecompositionMode ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

hash

Signature: *[const]* int **hash**

Description: Gets the hash value from the enum

Python specific notes:
This method is also available as 'hash(object)'.

inspect

Signature: *[const]* string **inspect**

Description: Converts an enum to a visual string

Python specific notes:

	This method is also available as 'repr(object)'.
is_const_object?	**Signature**: *[const]* bool **is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference Use of this method is deprecated. Use _is_const_object? instead This method returns true, if self is a const reference. In that case, only const methods may be called on self.
new	**(1) Signature**: *[static]* new TrapezoidDecompositionMode ptr **new** (int i) **Description**: Creates an enum from an integer value **Python specific notes:** This method is the default initializer of the object. **(2) Signature**: *[static]* new TrapezoidDecompositionMode ptr **new** (string s) **Description**: Creates an enum from a string value **Python specific notes:** This method is the default initializer of the object.
to_i	**Signature**: *[const]* int **to_i** **Description**: Gets the integer value from the enum **Python specific notes:** This method is also available as 'int(object)'.
to_s	**Signature**: *[const]* string **to_s** **Description**: Gets the symbolic string from an enum **Python specific notes:** This method is also available as 'str(object)'.

4.32. API reference - Class PreferredOrientation

Notation used in Ruby API documentation

Module: db

Description: This class represents the PreferredOrientation enum used within polygon decomposition

This enum has been introduced in version 0.27.

Public constructors

new PreferredOrientation ptr	**new**	(int i)	Creates an enum from an integer value
new PreferredOrientation ptr	**new**	(string s)	Creates an enum from a string value

Public methods

[const]	bool	**!=**	(const PreferredOrientati other)	Compares two enums for inequality
[const]	bool	**!=**	(int other)	Compares an enum with an integer for inequality
[const]	bool	**<**	(const PreferredOrientati other)	Returns true if the first enum is less (in the enum symbol order) than the second
[const]	bool	**<**	(int other)	Returns true if the enum is less (in the enum symbol order) than the integer value
[const]	bool	**==**	(const PreferredOrientati other)	Compares two enums
[const]	bool	**==**	(int other)	Compares an enum with an integer value
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const PreferredOrientati other)	Assigns another object to self

[const]	new PreferredOrientation ptr	**dup**	Creates a copy of self
[const]	int	**hash**	Gets the hash value from the enum
[const]	string	**inspect**	Converts an enum to a visual string
[const]	int	**to_i**	Gets the integer value from the enum
[const]	string	**to_s**	Gets the symbolic string from an enum

Public static methods and constants

[static,const]	PreferredOrientation	**PO_any**	Indicates any orientation.
[static,const]	PreferredOrientation	**PO_horizontal**	Indicates horizontal orientation.
[static,const]	PreferredOrientation	**PO_htrapezoids**	Indicates horizontal trapezoid decomposition.
[static,const]	PreferredOrientation	**PO_vertical**	Indicates vertical orientation.
[static,const]	PreferredOrientation	**PO_vtrapezoids**	Indicates vertical trapezoid decomposition.

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=	**(1) Signature**: *[const]* bool **!=** (const PreferredOrientation other) **Description**: Compares two enums for inequality **(2) Signature**: *[const]* bool **!=** (int other) **Description**: Compares an enum with an integer for inequality
<	**(1) Signature**: *[const]* bool **<** (const PreferredOrientation other) **Description**: Returns true if the first enum is less (in the enum symbol order) than the second **(2) Signature**: *[const]* bool **<** (int other) **Description**: Returns true if the enum is less (in the enum symbol order) than the integer value

==	**(1) Signature**: *[const]* bool **==** (const PreferredOrientation other) **Description**: Compares two enums **(2) Signature**: *[const]* bool **==** (int other) **Description**: Compares an enum with an integer value
PO_any	**Signature**: *[static,const]* PreferredOrientation **PO_any** **Description**: Indicates any orientation. **Python specific notes:** The object exposes a readable attribute 'PO_any'. This is the getter.
PO_horizontal	**Signature**: *[static,const]* PreferredOrientation **PO_horizontal** **Description**: Indicates horizontal orientation. **Python specific notes:** The object exposes a readable attribute 'PO_horizontal'. This is the getter.
PO_htrapezoids	**Signature**: *[static,const]* PreferredOrientation **PO_htrapezoids** **Description**: Indicates horizontal trapezoid decomposition. **Python specific notes:** The object exposes a readable attribute 'PO_htrapezoids'. This is the getter.
PO_vertical	**Signature**: *[static,const]* PreferredOrientation **PO_vertical** **Description**: Indicates vertical orientation. **Python specific notes:** The object exposes a readable attribute 'PO_vertical'. This is the getter.
PO_vtrapezoids	**Signature**: *[static,const]* PreferredOrientation **PO_vtrapezoids** **Description**: Indicates vertical trapezoid decomposition. **Python specific notes:** The object exposes a readable attribute 'PO_vtrapezoids'. This is the getter.
_create	**Signature**: void **_create** **Description**: Ensures the C++ object is created Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
_destroy	**Signature**: void **_destroy** **Description**: Explicitly destroys the object Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
_destroyed?	**Signature**: *[const]* bool **_destroyed?** **Description**: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const PreferredOrientation other)

Description: Assigns another object to self

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new PreferredOrientation ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

hash

Signature: *[const]* int **hash**

Description: Gets the hash value from the enum

Python specific notes:
This method is also available as 'hash(object)'.

inspect

Signature: *[const]* string **inspect**

Description: Converts an enum to a visual string

Python specific notes:
This method is also available as 'repr(object)'.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

new

(1) Signature: *[static]* new PreferredOrientation ptr **new** (int i)

Description: Creates an enum from an integer value

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new PreferredOrientation ptr **new** (string s)

Description: Creates an enum from a string value

Python specific notes:
This method is the default initializer of the object.

to_i

Signature: *[const]* int **to_i**

Description: Gets the integer value from the enum

Python specific notes:
This method is also available as 'int(object)'.

to_s

Signature: *[const]* string **to_s**

Description: Gets the symbolic string from an enum

Python specific notes:
This method is also available as 'str(object)'.

4.33. API reference - Class Edge

Notation used in Ruby API documentation

Module: db

Description: An edge class

An edge is a connection between points, usually participating in a larger context such as a polygon. An edge has a defined direction (from p1 to p2). Edges play a role in the database as parts of polygons and to describe a line through both points. Although supported, edges are rarely used as individual database objects.

See The Database API for more details about the database objects like the Edge class.

Public constructors

new Edge ptr	**new**	(const DEdge dedge)	Creates an integer coordinate edge from a floating-point coordinate edge
new Edge ptr	**new**		Default constructor: creates a degenerated edge 0,0 to 0,0
new Edge ptr	**new**	(int x1, int y1, int x2, int y2)	Constructor with two coordinates given as single values
new Edge ptr	**new**	(const Point p1, const Point p2)	Constructor with two points

Public methods

[const]	bool	**!=**	(const Edge e)	Inequality test
[const]	Edge	*****	(double scale_factor)	Scale edge
[const]	bool	**<**	(const Edge e)	Less operator
[const]	bool	**==**	(const Edge e)	Equality test
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const Edge other)	Assigns another object to self

[const]	Box	**bbox**		Return the bounding box of the edge.
[const]	variant	**clipped**	(const Box box)	Returns the edge clipped at the given box
[const]	variant	**clipped_line**	(const Box box)	Returns the line through the edge clipped at the given box
[const]	bool	**coincident?**	(const Edge e)	Coincidence check.
[const]	bool	**contains?**	(const Point p)	Tests whether a point is on an edge.
[const]	bool	**contains_excl?**	(const Point p)	Tests whether a point is on an edge excluding the endpoints.
[const]	bool	**crossed_by?**	(const Edge e)	Checks, if the line given by self is crossed by the edge e
[const]	Point	**crossing_point**	(const Edge e)	Returns the crossing point on two edges.
[const]	variant	**cut_point**	(const Edge e)	Returns the intersection point of the lines through the two edges.
[const]	Vector	**d**		Gets the edge extension as a vector.
[const]	int	**distance**	(const Point p)	Gets the distance of the point from the line through the edge.
[const]	unsigned int	**distance_abs**	(const Point p)	Absolute distance between the edge and a point.
[const]	new Edge ptr	**dup**		Creates a copy of self
[const]	int	**dx**		The horizontal extend of the edge.
[const]	unsigned int	**dx_abs**		The absolute value of the horizontal extend of the edge.
[const]	int	**dy**		The vertical extend of the edge.
[const]	unsigned int	**dy_abs**		The absolute value of the vertical extend of the edge.
	Edge	**enlarge**	(const Vector p)	Enlarges the edge.
[const]	Edge	**enlarged**	(const Vector p)	Returns the enlarged edge (does not modify self)
	unsigned int	**euclidian_distance**	(const Point p)	Gets the distance of the point from the the edge.
	Edge	**extend**	(int d)	Extends the edge (modifies self)
[const]	Edge	**extended**	(int d)	Returns the extended edge (does not modify self)
[const]	unsigned long	**hash**		Computes a hash value
[const]	variant	**intersection_point**	(const Edge e)	Returns the intersection point of two edges.

[const]	bool	**intersects?**	(const Edge e)	Intersection test.
[const]	bool	**is_degenerate?**		Test for degenerated edge
[const]	bool	**is_parallel?**	(const Edge e)	Test for being parallel
[const]	unsigned int	**length**		The length of the edge
	Edge	**move**	(const Vector p)	Moves the edge.
	Edge	**move**	(int dx, int dy)	Moves the edge.
[const]	Edge	**moved**	(const Vector p)	Returns the moved edge (does not modify self)
[const]	Edge	**moved**	(int dx, int dy)	Returns the moved edge (does not modify self)
[const]	unsigned int	**ortho_length**		The orthogonal length of the edge ("manhattan-length")
[const]	Point	**p1**		The first point.
	void	**p1=**	(const Point point)	Sets the first point.
[const]	Point	**p2**		The second point.
	void	**p2=**	(const Point point)	Sets the second point.
	Edge	**shift**	(int d)	Shifts the edge (modifies self)
[const]	Edge	**shifted**	(int d)	Returns the shifted edge (does not modify self)
[const]	int	**side_of**	(const Point p)	Indicates at which side the point is located relative to the edge.
[const]	long	**sq_length**		The square of the length of the edge
	Edge	**swap_points**		Swap the points of the edge
[const]	Edge	**swapped_points**		Returns an edge in which both points are swapped
[const]	DEdge	**to_dtype**	(double dbu = 1)	Converts the edge to a floating-point coordinate edge
[const]	string	**to_s**	(double dbu = 0)	Returns a string representing the edge
[const]	Edge	**transformed**	(const ICplxTrans t)	Transform the edge.
[const]	Edge	**transformed**	(const Trans t)	Transform the edge.
[const]	DEdge	**transformed**	(const CplxTrans t)	Transform the edge.

[const]	int	**x1**		Shortcut for p1.x
	void	**x1=**	(int coord)	Sets p1.x
[const]	int	**x2**		Shortcut for p2.x
	void	**x2=**	(int coord)	Sets p2.x
[const]	int	**y1**		Shortcut for p1.y
	void	**y1=**	(int coord)	Sets p1.y
[const]	int	**y2**		Shortcut for p2.y
	void	**y2=**	(int coord)	Sets p2.y

Public static methods and constants

new Edge ptr	**from_s**	(string s)	Creates an object from a string

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**		Use of this method is deprecated. Use _create instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[static]	new Edge ptr	**from_dedge**	(const DEdge dedge)	Use of this method is deprecated. Use new instead
[const]	bool	**intersect?**	(const Edge e)	Use of this method is deprecated. Use intersects? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead
[static]	new Edge ptr	**new_pp**	(const Point p1, const Point p2)	Use of this method is deprecated. Use new instead
[static]	new Edge ptr	**new_xyxy**	(int x1, int y1, int x2, int y2)	Use of this method is deprecated. Use new instead
[const]	DEdge	**transformed_cplx**	(const CplxTrans t)	Use of this method is deprecated. Use transformed instead

Detailed description

!=

Signature: *[const]* bool **!=** (const Edge e)

Description: Inequality test

e: The object to compare against

*****

Signature: *[const]* Edge ***** (double scale_factor)

Description: Scale edge

scale_factor: The scaling factor

Returns: The scaled edge

The * operator scales self with the given factor.

This method has been introduced in version 0.22.

Python specific notes:
This method also implements '__rmul__'.

<

Signature: *[const]* bool **<** (const Edge e)

Description: Less operator

e: The object to compare against

Returns: True, if the edge is 'less' as the other edge with respect to first and second point

==

Signature: *[const]* bool **==** (const Edge e)

Description: Equality test

e: The object to compare against

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const Edge other)

Description: Assigns another object to self

bbox

Signature: *[const]* Box **bbox**

Description: Return the bounding box of the edge.

clipped

Signature: *[const]* variant **clipped** (const Box box)

Description: Returns the edge clipped at the given box

box:	The clip box.
Returns:	The clipped edge or nil if the edge does not intersect with the box.

This method has been introduced in version 0.26.2.

clipped_line

Signature: *[const]* variant **clipped_line** (const Box box)

Description: Returns the line through the edge clipped at the given box

box:	The clip box.
Returns:	The part of the line through the box or nil if the line does not intersect with the box.

In contrast to clipped, this method will consider the edge extended infinitely (a "line"). The returned edge will be the part of this line going through the box.

This method has been introduced in version 0.26.2.

coincident?

Signature: *[const]* bool **coincident?** (const Edge e)

Description: Coincidence check.

e:	the edge to test with
Returns:	True if the edges are coincident.

Checks whether a edge is coincident with another edge. Coincidence is defined by being parallel and that at least one point of one edge is on the other edge.

contains?

Signature: *[const]* bool **contains?** (const Point p)

Description: Tests whether a point is on an edge.

p: The point to test with the edge.

Returns: True if the point is on the edge.

A point is on a edge if it is on (or at least closer than a grid point to) the edge.

contains_excl?

Signature: *[const]* bool **contains_excl?** (const Point p)

Description: Tests whether a point is on an edge excluding the endpoints.

p: The point to test with the edge.

Returns: True if the point is on the edge but not equal p1 or p2.

A point is on a edge if it is on (or at least closer than a grid point to) the edge.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

crossed_by?

Signature: *[const]* bool **crossed_by?** (const Edge e)

Description: Checks, if the line given by self is crossed by the edge e

e: The edge representing the line that the edge must be crossing.

self if considered an infinite line. This predicate renders true if the edge e is cut by this line. In other words: this method returns true if e.p1 is in one semispace of self while e.p2 is in the other or one of them is exactly on self.

crossing_point

Signature: *[const]* Point **crossing_point** (const Edge e)

Description: Returns the crossing point on two edges.

e: The edge representing the line that self must be crossing.

Returns: The point where self crosses the line given by "e".

This method delivers the point where the given line (self) crosses the edge given by the argument "e". self is considered infinitely long and is required to cut through the edge "e". If self does not cut this line, the result is undefined. See crossed_by? for a description of the crossing predicate.

This method has been introduced in version 0.19.

cut_point

Signature: *[const]* variant **cut_point** (const Edge e)

Description: Returns the intersection point of the lines through the two edges.

e: The edge to test.

Returns: The point where the lines intersect.

This method delivers the intersection point between the lines through the two edges. If the lines are parallel and do not intersect, the result will be nil. In contrast to intersection_point, this method will regard the edges as infinitely extended and intersection is not confined to the edge span.

This method has been introduced in version 0.27.1.

d

Signature: *[const]* Vector **d**

Description: Gets the edge extension as a vector.

This method is equivalent to p2 - p1. This method has been introduced in version 0.26.2.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

distance

Signature: *[const]* int **distance** (const Point p)

Description: Gets the distance of the point from the line through the edge.

p:	The point to test.
Returns:	The distance

Returns the distance between the edge and the point. The distance is signed which is negative if the point is to the "right" of the edge and positive if the point is to the "left". The distance is measured by projecting the point onto the line through the edge. If the edge is degenerated, the distance is not defined.

This method considers the edge to define an infinite line running through it. distance returns the distance of 'p' to this line. A similar method is euclidian_distance, but the latter regards the edge a finite set of points between the endpoints.

distance_abs

Signature: *[const]* unsigned int **distance_abs** (const Point p)

Description: Absolute distance between the edge and a point.

p:	The point to test.
Returns:	The distance

Returns the distance between the edge and the point.

dup

Signature: *[const]* new Edge ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

dx

Signature: *[const]* int **dx**

Description: The horizontal extend of the edge.

dx_abs

Signature: *[const]* unsigned int **dx_abs**

Description: The absolute value of the horizontal extend of the edge.

dy

Signature: *[const]* int **dy**

Description: The vertical extend of the edge.

dy_abs

Signature: *[const]* unsigned int **dy_abs**

Description: The absolute value of the vertical extend of the edge.

enlarge

Signature: Edge **enlarge** (const Vector p)

Description: Enlarges the edge.

p: The distance to move the edge points.

Returns: The enlarged edge.

Enlarges the edge by the given distance and returns the enlarged edge. The edge is overwritten. Enlargement means that the first point is shifted by -p, the second by p.

enlarged

Signature: *[const]* Edge **enlarged** (const Vector p)

Description: Returns the enlarged edge (does not modify self)

p: The distance to move the edge points.

Returns: The enlarged edge.

Enlarges the edge by the given offset and returns the enlarged edge. The edge is not modified. Enlargement means that the first point is shifted by -p, the second by p.

euclidian_distance

Signature: unsigned int **euclidian_distance** (const Point p)

Description: Gets the distance of the point from the the edge.

p: The point to test.

Returns: The distance

Returns the minimum distance of the point to any point on the edge. Unlike distance, the edge is considered a finite set of points between the endpoints. The result is also not signed like it is the case for distance.

This method has been introduced in version 0.28.14.

extend

Signature: Edge **extend** (int d)

Description: Extends the edge (modifies self)

d: The distance by which to shift the end points.

Returns: The extended edge (self).

Extends the edge by the given distance and returns the extended edge. The edge is not modified. Extending means that the first point is shifted by -d along the edge, the second by d. The length of the edge will increase by 2*d.

extended is a version that does not modify self but returns the extended edges.

This method has been introduced in version 0.23.

extended

Signature: *[const]* Edge **extended** (int d)

Description: Returns the extended edge (does not modify self)

d: The distance by which to shift the end points.

Returns: The extended edge.

Extends the edge by the given distance and returns the extended edge. The edge is not modified. Extending means that the first point is shifted by -d along the edge, the second by d. The length of the edge will increase by 2*d.

extend is a version that modifies self (in-place).

This method has been introduced in version 0.23.

from_dedge

Signature: *[static]* new Edge ptr **from_dedge** (const DEdge dedge)

Description: Creates an integer coordinate edge from a floating-point coordinate edge

Use of this method is deprecated. Use new instead

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_dedge'.

Python specific notes:
This method is the default initializer of the object.

from_s

Signature: *[static]* new Edge ptr **from_s** (string s)

Description: Creates an object from a string

Creates the object from a string representation (as returned by to_s)

This method has been added in version 0.23.

hash

Signature: *[const]* unsigned long **hash**

Description: Computes a hash value

Returns a hash value for the given edge. This method enables edges as hash keys.

This method has been introduced in version 0.25.

Python specific notes:
This method is also available as 'hash(object)'.

intersect?

Signature: *[const]* bool **intersect?** (const Edge e)

Description: Intersection test.

e: The edge to test.

Use of this method is deprecated. Use intersects? instead

Returns true if the edges intersect. Two edges intersect if they share at least one point. If the edges coincide, they also intersect. If one of the edges is degenerate (both points are identical), that point is required to sit exaclty on the other edge. If both edges are degenerate, their points are required to be identical.

The 'intersects' (with an 's') synonym has been introduced in version 0.28.12.

intersection_point

Signature: *[const]* variant **intersection_point** (const Edge e)

Description: Returns the intersection point of two edges.

e: The edge to test.

Returns: The point where the edges intersect.

This method delivers the intersection point. If the edges do not intersect, the result will be nil.

This method has been introduced in version 0.19. From version 0.26.2, this method will return nil in case of non-intersection.

intersects?

Signature: *[const]* bool **intersects?** (const Edge e)

Description: Intersection test.

e: The edge to test.

Returns true if the edges intersect. Two edges intersect if they share at least one point. If the edges coincide, they also intersect. If one of the edges is degenerate (both points are identical), that point is required to sit exaclty on the other edge. If both edges are degenerate, their points are required to be identical.

The 'intersects' (with an 's') synonym has been introduced in version 0.28.12.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_degenerate?

Signature: *[const]* bool **is_degenerate?**

Description: Test for degenerated edge

An edge is degenerate, if both end and start point are identical.

is_parallel?

Signature: *[const]* bool **is_parallel?** (const Edge e)

Description: Test for being parallel

e: The edge to test against

Returns: True if both edges are parallel

length

Signature: *[const]* unsigned int **length**

Description: The length of the edge

move

(1) Signature: Edge **move** (const Vector p)

Description: Moves the edge.

p: The distance to move the edge.

Returns: The moved edge.

Moves the edge by the given offset and returns the moved edge. The edge is overwritten.

(2) Signature: Edge **move** (int dx, int dy)

Description: Moves the edge.

dx: The x distance to move the edge.

dy: The y distance to move the edge.

Returns: The moved edge.

Moves the edge by the given offset and returns the moved edge. The edge is overwritten.

This version has been added in version 0.23.

moved

(1) Signature: *[const]* Edge **moved** (const Vector p)

Description: Returns the moved edge (does not modify self)

p: The distance to move the edge.

Returns: The moved edge.

Moves the edge by the given offset and returns the moved edge. The edge is not modified.

(2) Signature: *[const]* Edge **moved** (int dx, int dy)

Description: Returns the moved edge (does not modify self)

dx: The x distance to move the edge.

dy: The y distance to move the edge.

Returns: The moved edge.

Moves the edge by the given offset and returns the moved edge. The edge is not modified.

This version has been added in version 0.23.

new

(1) Signature: *[static]* new Edge ptr **new** (const DEdge dedge)

Description: Creates an integer coordinate edge from a floating-point coordinate edge

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_dedge'.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new Edge ptr **new**

Description: Default constructor: creates a degenerated edge 0,0 to 0,0

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new Edge ptr **new** (int x1, int y1, int x2, int y2)

Description: Constructor with two coordinates given as single values

Two points are given to create a new edge.

Python specific notes:
This method is the default initializer of the object.

(4) Signature: *[static]* new Edge ptr **new** (const Point p1, const Point p2)

Description: Constructor with two points

Two points are given to create a new edge.

Python specific notes:
This method is the default initializer of the object.

new_pp

Signature: *[static]* new Edge ptr **new_pp** (const Point p1, const Point p2)

Description: Constructor with two points

Use of this method is deprecated. Use new instead

Two points are given to create a new edge.

Python specific notes:
This method is the default initializer of the object.

new_xyxy

Signature: *[static]* new Edge ptr **new_xyxy** (int x1, int y1, int x2, int y2)

Description: Constructor with two coordinates given as single values

Use of this method is deprecated. Use new instead

Two points are given to create a new edge.

Python specific notes:
This method is the default initializer of the object.

ortho_length

Signature: *[const]* unsigned int **ortho_length**

Description: The orthogonal length of the edge ("manhattan-length")

Returns: The orthogonal length (abs(dx)+abs(dy))

p1

Signature: *[const]* Point **p1**

Description: The first point.

Python specific notes:
The object exposes a readable attribute 'p1'. This is the getter.

p1=

Signature: void **p1=** (const Point point)

Description: Sets the first point.

This method has been added in version 0.23.

Python specific notes:
The object exposes a writable attribute 'p1'. This is the setter.

p2

Signature: *[const]* Point **p2**

Description: The second point.

Python specific notes:
The object exposes a readable attribute 'p2'. This is the getter.

p2=

Signature: void **p2=** (const Point point)

Description: Sets the second point.

This method has been added in version 0.23.

Python specific notes:
The object exposes a writable attribute 'p2'. This is the setter.

shift

Signature: Edge **shift** (int d)

Description: Shifts the edge (modifies self)

d: The distance by which to shift the edge.

Returns: The shifted edge (self).

Shifts the edge by the given distance and returns the shifted edge. The edge is not modified. Shifting by a positive value will produce an edge which is shifted by d to the left. Shifting by a negative value will produce an edge which is shifted by d to the right.

shifted is a version that does not modify self but returns the extended edges.

This method has been introduced in version 0.23.

shifted

Signature: *[const]* Edge **shifted** (int d)

Description: Returns the shifted edge (does not modify self)

d: The distance by which to shift the edge.

Returns: The shifted edge.

Shifts the edge by the given distance and returns the shifted edge. The edge is not modified. Shifting by a positive value will produce an edge which is shifted by d to the left. Shifting by a negative value will produce an edge which is shifted by d to the right.

shift is a version that modifies self (in-place).

This method has been introduced in version 0.23.

side_of

Signature: *[const]* int **side_of** (const Point p)

Description: Indicates at which side the point is located relative to the edge.

p: The point to test.

Returns: The side value

Returns 1 if the point is "left" of the edge, 0 if on and -1 if the point is "right" of the edge.

sq_length

Signature: *[const]* long **sq_length**

Description: The square of the length of the edge

swap_points

Signature: Edge **swap_points**

Description: Swap the points of the edge

This version modifies self. A version that does not modify self is swapped_points. Swapping the points basically reverses the direction of the edge.

This method has been introduced in version 0.23.

swapped_points

Signature: *[const]* Edge **swapped_points**

Description: Returns an edge in which both points are swapped

Swapping the points basically reverses the direction of the edge.

This method has been introduced in version 0.23.

to_dtype

Signature: *[const]* DEdge **to_dtype** (double dbu = 1)

Description: Converts the edge to a floating-point coordinate edge

The database unit can be specified to translate the integer-coordinate edge into a floating-point coordinate edge in micron units. The database unit is basically a scaling factor.

This method has been introduced in version 0.25.

to_s

Signature: *[const]* string **to_s** (double dbu = 0)

Description: Returns a string representing the edge

If a DBU is given, the output units will be micrometers.

The DBU argument has been added in version 0.27.6.

Python specific notes:
This method is also available as 'str(object)'.

transformed

(1) Signature: *[const]* Edge **transformed** (const ICplxTrans t)

Description: Transform the edge.

t: The transformation to apply.

Returns: The transformed edge (in this case an integer coordinate edge).

Transforms the edge with the given complex transformation. Does not modify the edge but returns the transformed edge.

This method has been introduced in version 0.18.

(2) Signature: *[const]* Edge **transformed** (const Trans t)

Description: Transform the edge.

t: The transformation to apply.

Returns: The transformed edge.

Transforms the edge with the given transformation. Does not modify the edge but returns the transformed edge.

(3) Signature: *[const]* DEdge **transformed** (const CplxTrans t)

Description: Transform the edge.

t: The transformation to apply.

Returns: The transformed edge.

Transforms the edge with the given complex transformation. Does not modify the edge but returns the transformed edge.

transformed_cplx

Signature: *[const]* DEdge **transformed_cplx** (const CplxTrans t)

Description: Transform the edge.

t: The transformation to apply.

Returns: The transformed edge.

Use of this method is deprecated. Use transformed instead

Transforms the edge with the given complex transformation. Does not modify the edge but returns the transformed edge.

x1

Signature: *[const]* int **x1**

Description: Shortcut for p1.x

Python specific notes:
The object exposes a readable attribute 'x1'. This is the getter.

x1=

Signature: void **x1=** (int coord)

Description: Sets p1.x

This method has been added in version 0.23.

Python specific notes:
The object exposes a writable attribute 'x1'. This is the setter.

x2

Signature: *[const]* int **x2**

Description: Shortcut for p2.x

Python specific notes:

	The object exposes a readable attribute 'x2'. This is the getter.
x2=	**Signature**: void **x2=** (int coord) **Description**: Sets p2.x This method has been added in version 0.23. **Python specific notes:** The object exposes a writable attribute 'x2'. This is the setter.
y1	**Signature**: *[const]* int **y1** **Description**: Shortcut for p1.y **Python specific notes:** The object exposes a readable attribute 'y1'. This is the getter.
y1=	**Signature**: void **y1=** (int coord) **Description**: Sets p1.y This method has been added in version 0.23. **Python specific notes:** The object exposes a writable attribute 'y1'. This is the setter.
y2	**Signature**: *[const]* int **y2** **Description**: Shortcut for p2.y **Python specific notes:** The object exposes a readable attribute 'y2'. This is the getter.
y2=	**Signature**: void **y2=** (int coord) **Description**: Sets p2.y This method has been added in version 0.23. **Python specific notes:** The object exposes a writable attribute 'y2'. This is the setter.

4.34. API reference - Class DEdge

Notation used in Ruby API documentation

Module: db

Description: An edge class

An edge is a connection between points, usually participating in a larger context such as a polygon. An edge has a defined direction (from p1 to p2). Edges play a role in the database as parts of polygons and to describe a line through both points. The Edge object is also used inside the boolean processor (EdgeProcessor). Although supported, edges are rarely used as individual database objects.

See The Database API for more details about the database objects like the Edge class.

Public constructors

new DEdge ptr	**new**	(const Edge edge)	Creates a floating-point coordinate edge from an integer coordinate edge
new DEdge ptr	**new**		Default constructor: creates a degenerated edge 0,0 to 0,0
new DEdge ptr	**new**	(double x1, double y1, double x2, double y2)	Constructor with two coordinates given as single values
new DEdge ptr	**new**	(const DPoint p1, const DPoint p2)	Constructor with two points

Public methods

[const]	bool	**!=**	(const DEdge e)	Inequality test
[const]	DEdge	*****	(double scale_factor)	Scale edge
[const]	bool	**<**	(const DEdge e)	Less operator
[const]	bool	**==**	(const DEdge e)	Equality test
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const DEdge other)	Assigns another object to self

[const]	DBox	**bbox**		Return the bounding box of the edge.
[const]	variant	**clipped**	(const DBox box)	Returns the edge clipped at the given box
[const]	variant	**clipped_line**	(const DBox box)	Returns the line through the edge clipped at the given box
[const]	bool	**coincident?**	(const DEdge e)	Coincidence check.
[const]	bool	**contains?**	(const DPoint p)	Tests whether a point is on an edge.
[const]	bool	**contains_excl?**	(const DPoint p)	Tests whether a point is on an edge excluding the endpoints.
[const]	bool	**crossed_by?**	(const DEdge e)	Checks, if the line given by self is crossed by the edge e
[const]	DPoint	**crossing_point**	(const DEdge e)	Returns the crossing point on two edges.
[const]	variant	**cut_point**	(const DEdge e)	Returns the intersection point of the lines through the two edges.
[const]	DVector	**d**		Gets the edge extension as a vector.
[const]	double	**distance**	(const DPoint p)	Gets the distance of the point from the line through the edge.
[const]	double	**distance_abs**	(const DPoint p)	Absolute distance between the edge and a point.
[const]	new DEdge ptr	**dup**		Creates a copy of self
[const]	double	**dx**		The horizontal extend of the edge.
[const]	double	**dx_abs**		The absolute value of the horizontal extend of the edge.
[const]	double	**dy**		The vertical extend of the edge.
[const]	double	**dy_abs**		The absolute value of the vertical extend of the edge.
	DEdge	**enlarge**	(const DVector p)	Enlarges the edge.
[const]	DEdge	**enlarged**	(const DVector p)	Returns the enlarged edge (does not modify self)
	double	**euclidian_distance**	(const DPoint p)	Gets the distance of the point from the the edge.
	DEdge	**extend**	(double d)	Extends the edge (modifies self)
[const]	DEdge	**extended**	(double d)	Returns the extended edge (does not modify self)
[const]	unsigned long	**hash**		Computes a hash value

[const]	variant	**intersection_point**	(const DEdge e)	Returns the intersection point of two edges.
[const]	bool	**intersects?**	(const DEdge e)	Intersection test.
[const]	bool	**is_degenerate?**		Test for degenerated edge
[const]	bool	**is_parallel?**	(const DEdge e)	Test for being parallel
[const]	double	**length**		The length of the edge
	DEdge	**move**	(const DVector p)	Moves the edge.
	DEdge	**move**	(double dx, double dy)	Moves the edge.
[const]	DEdge	**moved**	(const DVector p)	Returns the moved edge (does not modify self)
[const]	DEdge	**moved**	(double dx, double dy)	Returns the moved edge (does not modify self)
[const]	double	**ortho_length**		The orthogonal length of the edge ("manhattan-length")
[const]	DPoint	**p1**		The first point.
	void	**p1=**	(const DPoint point)	Sets the first point.
[const]	DPoint	**p2**		The second point.
	void	**p2=**	(const DPoint point)	Sets the second point.
	DEdge	**shift**	(double d)	Shifts the edge (modifies self)
[const]	DEdge	**shifted**	(double d)	Returns the shifted edge (does not modify self)
[const]	int	**side_of**	(const DPoint p)	Indicates at which side the point is located relative to the edge.
[const]	double	**sq_length**		The square of the length of the edge
	DEdge	**swap_points**		Swap the points of the edge
[const]	DEdge	**swapped_points**		Returns an edge in which both points are swapped
[const]	Edge	**to_itype**	(double dbu = 1)	Converts the edge to an integer coordinate edge
[const]	string	**to_s**	(double dbu = 0)	Returns a string representing the edge
[const]	Edge	**transformed**	(const VCplxTrans t)	Transforms the edge with the given complex transformation
[const]	DEdge	**transformed**	(const DTrans t)	Transform the edge.

[const]	DEdge	**transformed**	(const DCplxTrans t)	Transform the edge.
[const]	double	**x1**		Shortcut for p1.x
	void	**x1=**	(double coord)	Sets p1.x
[const]	double	**x2**		Shortcut for p2.x
	void	**x2=**	(double coord)	Sets p2.x
[const]	double	**y1**		Shortcut for p1.y
	void	**y1=**	(double coord)	Sets p1.y
[const]	double	**y2**		Shortcut for p2.y
	void	**y2=**	(double coord)	Sets p2.y

Public static methods and constants

new DEdge ptr	**from_s**	(string s)	Creates an object from a string

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**		Use of this method is deprecated. Use _create instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[static]	new DEdge ptr	**from_iedge**	(const Edge edge)	Use of this method is deprecated. Use new instead
[const]	bool	**intersect?**	(const DEdge e)	Use of this method is deprecated. Use intersects? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead
[static]	new DEdge ptr	**new_pp**	(const DPoint p1, const DPoint p2)	Use of this method is deprecated. Use new instead
[static]	new DEdge ptr	**new_xyxy**	(double x1, double y1, double x2, double y2)	Use of this method is deprecated. Use new instead
[const]	DEdge	**transformed_cplx**	(const DCplxTrans t)	Use of this method is deprecated. Use transformed instead

Detailed description

!=

Signature: *[const]* bool **!=** (const DEdge e)

Description: Inequality test

e: The object to compare against

*****

Signature: *[const]* DEdge ***** (double scale_factor)

Description: Scale edge

scale_factor: The scaling factor

Returns: The scaled edge

The * operator scales self with the given factor.

This method has been introduced in version 0.22.

Python specific notes:
This method also implements '__rmul__'.

<

Signature: *[const]* bool **<** (const DEdge e)

Description: Less operator

e: The object to compare against

Returns: True, if the edge is 'less' as the other edge with respect to first and second point

==

Signature: *[const]* bool **==** (const DEdge e)

Description: Equality test

e: The object to compare against

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const DEdge other)

Description: Assigns another object to self

bbox

Signature: *[const]* DBox **bbox**

Description: Return the bounding box of the edge.

clipped

Signature: *[const]* variant **clipped** (const DBox box)

Description: Returns the edge clipped at the given box

box:	The clip box.
Returns:	The clipped edge or nil if the edge does not intersect with the box.

This method has been introduced in version 0.26.2.

clipped_line

Signature: *[const]* variant **clipped_line** (const DBox box)

Description: Returns the line through the edge clipped at the given box

box:	The clip box.
Returns:	The part of the line through the box or nil if the line does not intersect with the box.

In contrast to clipped, this method will consider the edge extended infinitely (a "line"). The returned edge will be the part of this line going through the box.

This method has been introduced in version 0.26.2.

coincident?

Signature: *[const]* bool **coincident?** (const DEdge e)

Description: Coincidence check.

e:	the edge to test with

Returns: True if the edges are coincident.

Checks whether a edge is coincident with another edge. Coincidence is defined by being parallel and that at least one point of one edge is on the other edge.

contains?

Signature: *[const]* bool **contains?** (const DPoint p)

Description: Tests whether a point is on an edge.

p: The point to test with the edge.

Returns: True if the point is on the edge.

A point is on a edge if it is on (or at least closer than a grid point to) the edge.

contains_excl?

Signature: *[const]* bool **contains_excl?** (const DPoint p)

Description: Tests whether a point is on an edge excluding the endpoints.

p: The point to test with the edge.

Returns: True if the point is on the edge but not equal p1 or p2.

A point is on a edge if it is on (or at least closer than a grid point to) the edge.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

crossed_by?

Signature: *[const]* bool **crossed_by?** (const DEdge e)

Description: Checks, if the line given by self is crossed by the edge e

e: The edge representing the line that the edge must be crossing.

self if considered an infinite line. This predicate renders true if the edge e is cut by this line. In other words: this method returns true if e.p1 is in one semispace of self while e.p2 is in the other or one of them is exactly on self.

crossing_point

Signature: *[const]* DPoint **crossing_point** (const DEdge e)

Description: Returns the crossing point on two edges.

e: The edge representing the line that self must be crossing.

Returns: The point where self crosses the line given by "e".

This method delivers the point where the given line (self) crosses the edge given by the argument "e". self is considered infinitely long and is required to cut through the edge "e". If self does not cut this line, the result is undefined. See crossed_by? for a description of the crossing predicate.

This method has been introduced in version 0.19.

cut_point

Signature: *[const]* variant **cut_point** (const DEdge e)

Description: Returns the intersection point of the lines through the two edges.

e: The edge to test.

Returns: The point where the lines intersect.

This method delivers the intersection point between the lines through the two edges. If the lines are parallel and do not intersect, the result will be nil. In contrast to intersection_point, this method will regard the edges as infinitely extended and intersection is not confined to the edge span.

This method has been introduced in version 0.27.1.

d

Signature: *[const]* DVector **d**

Description: Gets the edge extension as a vector.

This method is equivalent to p2 - p1. This method has been introduced in version 0.26.2.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

distance

Signature: *[const]* double **distance** (const DPoint p)

Description: Gets the distance of the point from the line through the edge.

p:	The point to test.
Returns:	The distance

Returns the distance between the edge and the point. The distance is signed which is negative if the point is to the "right" of the edge and positive if the point is to the "left". The distance is measured by projecting the point onto the line through the edge. If the edge is degenerated, the distance is not defined.

This method considers the edge to define an infinite line running through it. distance returns the distance of 'p' to this line. A similar method is euclidian_distance, but the latter regards the edge a finite set of points between the endpoints.

distance_abs

Signature: *[const]* double **distance_abs** (const DPoint p)

Description: Absolute distance between the edge and a point.

p:	The point to test.
Returns:	The distance

Returns the distance between the edge and the point.

dup

Signature: *[const]* new DEdge ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

dx

Signature: *[const]* double **dx**

Description: The horizontal extend of the edge.

dx_abs

Signature: *[const]* double **dx_abs**

Description: The absolute value of the horizontal extend of the edge.

dy

Signature: *[const]* double **dy**

Description: The vertical extend of the edge.

dy_abs

Signature: *[const]* double **dy_abs**

Description: The absolute value of the vertical extend of the edge.

enlarge

Signature: DEdge **enlarge** (const DVector p)

Description: Enlarges the edge.

p: The distance to move the edge points.

Returns: The enlarged edge.

Enlarges the edge by the given distance and returns the enlarged edge. The edge is overwritten. Enlargement means that the first point is shifted by -p, the second by p.

enlarged

Signature: *[const]* DEdge **enlarged** (const DVector p)

Description: Returns the enlarged edge (does not modify self)

p: The distance to move the edge points.

Returns: The enlarged edge.

Enlarges the edge by the given offset and returns the enlarged edge. The edge is not modified. Enlargement means that the first point is shifted by -p, the second by p.

euclidian_distance

Signature: double **euclidian_distance** (const DPoint p)

Description: Gets the distance of the point from the the edge.

p: The point to test.

Returns: The distance

Returns the minimum distance of the point to any point on the edge. Unlike distance, the edge is considered a finite set of points between the endpoints. The result is also not signed like it is the case for distance.

This method has been introduced in version 0.28.14.

extend

Signature: DEdge **extend** (double d)

Description: Extends the edge (modifies self)

d: The distance by which to shift the end points.

Returns: The extended edge (self).

Extends the edge by the given distance and returns the extended edge. The edge is not modified. Extending means that the first point is shifted by -d along the edge, the second by d. The length of the edge will increase by 2*d.

extended is a version that does not modify self but returns the extended edges.

This method has been introduced in version 0.23.

extended

Signature: *[const]* DEdge **extended** (double d)

Description: Returns the extended edge (does not modify self)

d: The distance by which to shift the end points.

Returns: The extended edge.

Extends the edge by the given distance and returns the extended edge. The edge is not modified. Extending means that the first point is shifted by -d along the edge, the second by d. The length of the edge will increase by 2*d.

extend is a version that modifies self (in-place).

This method has been introduced in version 0.23.

from_iedge

Signature: *[static]* new DEdge ptr **from_iedge** (const Edge edge)

Description: Creates a floating-point coordinate edge from an integer coordinate edge

Use of this method is deprecated. Use new instead

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_iedge'.

Python specific notes:
This method is the default initializer of the object.

from_s

Signature: *[static]* new DEdge ptr **from_s** (string s)

Description: Creates an object from a string

Creates the object from a string representation (as returned by to_s)

This method has been added in version 0.23.

hash

Signature: *[const]* unsigned long **hash**

Description: Computes a hash value

Returns a hash value for the given edge. This method enables edges as hash keys.

This method has been introduced in version 0.25.

Python specific notes:
This method is also available as 'hash(object)'.

intersect?

Signature: *[const]* bool **intersect?** (const DEdge e)

Description: Intersection test.

e: The edge to test.

Use of this method is deprecated. Use intersects? instead

Returns true if the edges intersect. Two edges intersect if they share at least one point. If the edges coincide, they also intersect. If one of the edges is degenerate (both points are identical), that point is required to sit exaclty on the other edge. If both edges are degenerate, their points are required to be identical.

The 'intersects' (with an 's') synonym has been introduced in version 0.28.12.

intersection_point

Signature: *[const]* variant **intersection_point** (const DEdge e)

Description: Returns the intersection point of two edges.

e: The edge to test.

Returns: The point where the edges intersect.

This method delivers the intersection point. If the edges do not intersect, the result will be nil.

This method has been introduced in version 0.19. From version 0.26.2, this method will return nil in case of non-intersection.

intersects?

Signature: *[const]* bool **intersects?** (const DEdge e)

Description: Intersection test.

e: The edge to test.

Returns true if the edges intersect. Two edges intersect if they share at least one point. If the edges coincide, they also intersect. If one of the edges is degenerate (both points are identical), that point is required to sit exaclty on the other edge. If both edges are degenerate, their points are required to be identical.

The 'intersects' (with an 's') synonym has been introduced in version 0.28.12.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_degenerate?

Signature: *[const]* bool **is_degenerate?**

Description: Test for degenerated edge

An edge is degenerate, if both end and start point are identical.

is_parallel?

Signature: *[const]* bool **is_parallel?** (const DEdge e)

Description: Test for being parallel

e: The edge to test against

Returns: True if both edges are parallel

length

Signature: *[const]* double **length**

Description: The length of the edge

move

(1) Signature: DEdge **move** (const DVector p)

Description: Moves the edge.

p: The distance to move the edge.

Returns: The moved edge.

Moves the edge by the given offset and returns the moved edge. The edge is overwritten.

(2) Signature: DEdge **move** (double dx, double dy)

Description: Moves the edge.

dx: The x distance to move the edge.

dy: The y distance to move the edge.

Returns: The moved edge.

Moves the edge by the given offset and returns the moved edge. The edge is overwritten.

This version has been added in version 0.23.

moved

(1) Signature: *[const]* DEdge **moved** (const DVector p)

Description: Returns the moved edge (does not modify self)

p:	The distance to move the edge.
Returns:	The moved edge.

Moves the edge by the given offset and returns the moved edge. The edge is not modified.

(2) Signature: *[const]* DEdge **moved** (double dx, double dy)

Description: Returns the moved edge (does not modify self)

dx:	The x distance to move the edge.
dy:	The y distance to move the edge.
Returns:	The moved edge.

Moves the edge by the given offset and returns the moved edge. The edge is not modified.

This version has been added in version 0.23.

new

(1) Signature: *[static]* new DEdge ptr **new** (const Edge edge)

Description: Creates a floating-point coordinate edge from an integer coordinate edge

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_iedge'.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new DEdge ptr **new**

Description: Default constructor: creates a degenerated edge 0,0 to 0,0

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new DEdge ptr **new** (double x1, double y1, double x2, double y2)

Description: Constructor with two coordinates given as single values

Two points are given to create a new edge.

Python specific notes:
This method is the default initializer of the object.

(4) Signature: *[static]* new DEdge ptr **new** (const DPoint p1, const DPoint p2)

Description: Constructor with two points

Two points are given to create a new edge.

Python specific notes:
This method is the default initializer of the object.

new_pp

Signature: *[static]* new DEdge ptr **new_pp** (const DPoint p1, const DPoint p2)

Description: Constructor with two points

Use of this method is deprecated. Use new instead

Two points are given to create a new edge.

Python specific notes:
This method is the default initializer of the object.

new_xyxy

Signature: *[static]* new DEdge ptr **new_xyxy** (double x1, double y1, double x2, double y2)

Description: Constructor with two coordinates given as single values

Use of this method is deprecated. Use new instead

Two points are given to create a new edge.

Python specific notes:
This method is the default initializer of the object.

ortho_length

Signature: *[const]* double **ortho_length**

Description: The orthogonal length of the edge ("manhattan-length")

Returns: The orthogonal length (abs(dx)+abs(dy))

p1

Signature: *[const]* DPoint **p1**

Description: The first point.

Python specific notes:
The object exposes a readable attribute 'p1'. This is the getter.

p1=

Signature: void **p1=** (const DPoint point)

Description: Sets the first point.

This method has been added in version 0.23.

Python specific notes:
The object exposes a writable attribute 'p1'. This is the setter.

p2

Signature: *[const]* DPoint **p2**

Description: The second point.

Python specific notes:
The object exposes a readable attribute 'p2'. This is the getter.

p2=

Signature: void **p2=** (const DPoint point)

Description: Sets the second point.

This method has been added in version 0.23.

Python specific notes:
The object exposes a writable attribute 'p2'. This is the setter.

shift

Signature: DEdge **shift** (double d)

Description: Shifts the edge (modifies self)

d: The distance by which to shift the edge.

Returns: The shifted edge (self).

Shifts the edge by the given distance and returns the shifted edge. The edge is not modified. Shifting by a positive value will produce an edge which is shifted by d to the left. Shifting by a negative value will produce an edge which is shifted by d to the right.

shifted is a version that does not modify self but returns the extended edges.

This method has been introduced in version 0.23.

shifted

Signature: *[const]* DEdge **shifted** (double d)

Description: Returns the shifted edge (does not modify self)

d: The distance by which to shift the edge.

Returns: The shifted edge.

Shifts the edge by the given distance and returns the shifted edge. The edge is not modified. Shifting by a positive value will produce an edge which is shifted by d to the left. Shifting by a negative value will produce an edge which is shifted by d to the right.

shift is a version that modifies self (in-place).

This method has been introduced in version 0.23.

side_of

Signature: *[const]* int **side_of** (const DPoint p)

Description: Indicates at which side the point is located relative to the edge.

p: The point to test.

Returns: The side value

Returns 1 if the point is "left" of the edge, 0 if on and -1 if the point is "right" of the edge.

sq_length

Signature: *[const]* double **sq_length**

Description: The square of the length of the edge

swap_points

Signature: DEdge **swap_points**

Description: Swap the points of the edge

This version modifies self. A version that does not modify self is swapped_points. Swapping the points basically reverses the direction of the edge.

This method has been introduced in version 0.23.

swapped_points

Signature: *[const]* DEdge **swapped_points**

Description: Returns an edge in which both points are swapped

Swapping the points basically reverses the direction of the edge.

This method has been introduced in version 0.23.

to_itype

Signature: *[const]* Edge **to_itype** (double dbu = 1)

Description: Converts the edge to an integer coordinate edge

The database unit can be specified to translate the floating-point coordinate edge in micron units to an integer-coordinate edge in database units. The edges coordinates will be divided by the database unit.

This method has been introduced in version 0.25.

to_s

Signature: *[const]* string **to_s** (double dbu = 0)

Description: Returns a string representing the edge

If a DBU is given, the output units will be micrometers.

The DBU argument has been added in version 0.27.6.

Python specific notes:

This method is also available as 'str(object)'.

transformed

(1) Signature: *[const]* Edge **transformed** (const VCplxTrans t)

Description: Transforms the edge with the given complex transformation

t:	The magnifying transformation to apply
Returns:	The transformed edge (in this case an integer coordinate edge)

This method has been introduced in version 0.25.

(2) Signature: *[const]* DEdge **transformed** (const DTrans t)

Description: Transform the edge.

t:	The transformation to apply.
Returns:	The transformed edge.

Transforms the edge with the given transformation. Does not modify the edge but returns the transformed edge.

(3) Signature: *[const]* DEdge **transformed** (const DCplxTrans t)

Description: Transform the edge.

t:	The transformation to apply.
Returns:	The transformed edge.

Transforms the edge with the given complex transformation. Does not modify the edge but returns the transformed edge.

transformed_cplx

Signature: *[const]* DEdge **transformed_cplx** (const DCplxTrans t)

Description: Transform the edge.

t:	The transformation to apply.
Returns:	The transformed edge.

Use of this method is deprecated. Use transformed instead

Transforms the edge with the given complex transformation. Does not modify the edge but returns the transformed edge.

x1

Signature: *[const]* double **x1**

Description: Shortcut for p1.x

Python specific notes:
The object exposes a readable attribute 'x1'. This is the getter.

x1=

Signature: void **x1=** (double coord)

Description: Sets p1.x

This method has been added in version 0.23.

Python specific notes:
The object exposes a writable attribute 'x1'. This is the setter.

x2

Signature: *[const]* double **x2**

Description: Shortcut for p2.x

Python specific notes:

	The object exposes a readable attribute 'x2'. This is the getter.
x2=	**Signature**: void **x2=** (double coord) **Description**: Sets p2.x This method has been added in version 0.23. **Python specific notes:** The object exposes a writable attribute 'x2'. This is the setter.
y1	**Signature**: *[const]* double **y1** **Description**: Shortcut for p1.y **Python specific notes:** The object exposes a readable attribute 'y1'. This is the getter.
y1=	**Signature**: void **y1=** (double coord) **Description**: Sets p1.y This method has been added in version 0.23. **Python specific notes:** The object exposes a writable attribute 'y1'. This is the setter.
y2	**Signature**: *[const]* double **y2** **Description**: Shortcut for p2.y **Python specific notes:** The object exposes a readable attribute 'y2'. This is the getter.
y2=	**Signature**: void **y2=** (double coord) **Description**: Sets p2.y This method has been added in version 0.23. **Python specific notes:** The object exposes a writable attribute 'y2'. This is the setter.

4.35. API reference - Class EdgePair

Notation used in Ruby API documentation

Module: db

Description: An edge pair (a pair of two edges)

Edge pairs are objects representing two edges or parts of edges. They play a role mainly in the context of DRC functions, where they specify a DRC violation by connecting two edges which violate the condition checked. Within the framework of polygon and edge collections which provide DRC functionality, edges pairs are used in the form of edge pair collections (EdgePairs).

Edge pairs basically consist of two edges, called first and second. If created by a two-layer DRC function, the first edge will correspond to edges from the first layer and the second to edges from the second layer.

This class has been introduced in version 0.23.

Public constructors

new EdgePair ptr	**new**	(const DEdgePair dedge_pair)	Creates an integer coordinate edge pair from a floating-point coordinate edge pair
new EdgePair ptr	**new**		Default constructor
new EdgePair ptr	**new**	(const Edge first, const Edge second, bool symmetric = false)	Constructor from two edges

Public methods

[const]	bool	**!=**	(const EdgePair box)	Inequality
[const]	bool	**<**	(const EdgePair box)	Less operator
[const]	bool	**==**	(const EdgePair box)	Equality
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	long	**area**		Gets the area between the edges of the edge pair
	void	**assign**	(const EdgePair other)	Assigns another object to self

[const]	Box	**bbox**		Gets the bounding box of the edge pair
[const]	unsigned int	**distance**		Gets the distance of the edges in the edge pair
[const]	new EdgePair ptr	**dup**		Creates a copy of self
[const]	Edge	**first**		Gets the first edge
	void	**first=**	(const Edge edge)	Sets the first edge
[const]	Edge	**greater**		Gets the 'greater' edge for symmetric edge pairs
[const]	unsigned long	**hash**		Computes a hash value
[const]	Edge	**lesser**		Gets the 'lesser' edge for symmetric edge pairs
[const]	EdgePair	**normalized**		Normalizes the edge pair
[const]	unsigned long	**perimeter**		Gets the perimeter of the edge pair
[const]	Polygon	**polygon**	(int e)	Convert an edge pair to a polygon
[const]	Edge	**second**		Gets the second edge
	void	**second=**	(const Edge edge)	Sets the second edge
[const]	SimplePolygon	**simple_polygon**	(int e)	Convert an edge pair to a simple polygon
	void	**symmetric=**	(bool flag)	Sets a value indicating whether the edge pair is symmetric
[const]	bool	**symmetric?**		Returns a value indicating whether the edge pair is symmetric
[const]	DEdgePair	**to_dtype**	(double dbu = 1)	Converts the edge pair to a floating-point coordinate edge pair
[const]	string	**to_s**	(double dbu = 0)	Returns a string representing the edge pair
[const]	EdgePair	**transformed**	(const ICplxTrans t)	Returns the transformed edge pair
[const]	EdgePair	**transformed**	(const Trans t)	Returns the transformed pair
[const]	DEdgePair	**transformed**	(const CplxTrans t)	Returns the transformed edge pair

Public static methods and constants

new EdgePair ptr	**from_s**	(string s)	Creates an object from a string

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=

Signature: *[const]* bool **!=** (const EdgePair box)

Description: Inequality

Returns true, if this edge pair and the given one are not equal

This method has been introduced in version 0.25.

<

Signature: *[const]* bool **<** (const EdgePair box)

Description: Less operator

Returns true, if this edge pair is 'less' with respect to first and second edge

This method has been introduced in version 0.25.

==

Signature: *[const]* bool **==** (const EdgePair box)

Description: Equality

Returns true, if this edge pair and the given one are equal

This method has been introduced in version 0.25.

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

area

Signature: *[const]* long **area**

Description: Gets the area between the edges of the edge pair

This attribute has been introduced in version 0.28.

assign

Signature: void **assign** (const EdgePair other)

Description: Assigns another object to self

bbox

Signature: *[const]* Box **bbox**

Description: Gets the bounding box of the edge pair

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

distance

Signature: *[const]* unsigned int **distance**

Description: Gets the distance of the edges in the edge pair

The distance between the two edges is defined as the minimum distance between any two points on the two edges.

This attribute has been introduced in version 0.28.14.

dup

Signature: *[const]* new EdgePair ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

first

Signature: *[const]* Edge **first**

Description: Gets the first edge

Python specific notes:
The object exposes a readable attribute 'first'. This is the getter.

first=

Signature: void **first=** (const Edge edge)

Description: Sets the first edge

Python specific notes:
The object exposes a writable attribute 'first'. This is the setter.

from_s

Signature: *[static]* new EdgePair ptr **from_s** (string s)

Description: Creates an object from a string

Creates the object from a string representation (as returned by to_s)

This method has been added in version 0.23.

greater

Signature: *[const]* Edge **greater**

Description: Gets the 'greater' edge for symmetric edge pairs

As first and second edges are commutable for symmetric edge pairs (see symmetric?), this accessor allows retrieving a 'second' edge in a way independent on the actual assignment.

This read-only attribute has been introduced in version 0.27.

hash

Signature: *[const]* unsigned long **hash**

Description: Computes a hash value

Returns a hash value for the given edge pair. This method enables edge pairs as hash keys.

This method has been introduced in version 0.25.

Python specific notes:
This method is also available as 'hash(object)'.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

lesser

Signature: *[const]* Edge **lesser**

Description: Gets the 'lesser' edge for symmetric edge pairs

As first and second edges are commutable for symmetric edge pairs (see symmetric?), this accessor allows retrieving a 'first' edge in a way independent on the actual assignment.

This read-only attribute has been introduced in version 0.27.

new

(1) Signature: *[static]* new EdgePair ptr **new** (const DEdgePair dedge_pair)

Description: Creates an integer coordinate edge pair from a floating-point coordinate edge pair

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_dedge_pair'.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new EdgePair ptr **new**

Description: Default constructor

This constructor creates an default edge pair.

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new EdgePair ptr **new** (const Edge first, const Edge second, bool symmetric = false)

Description: Constructor from two edges

This constructor creates an edge pair from the two edges given. See symmetric? for a description of this attribute.

Python specific notes:
This method is the default initializer of the object.

normalized

Signature: *[const]* EdgePair **normalized**

Description: Normalizes the edge pair

This method normalized the edge pair such that when connecting the edges at their start and end points a closed loop is formed which is oriented clockwise. To achieve this, the points of the first and/or first and second edge are swapped. Normalization is a first step recommended before converting an edge pair to a polygon, because that way the polygons won't be self-overlapping and the enlargement parameter is applied properly.

perimeter

Signature: *[const]* unsigned long **perimeter**

Description: Gets the perimeter of the edge pair

The perimeter is defined as the sum of the lengths of both edges ('active perimeter').

This attribute has been introduced in version 0.28.

polygon

Signature: *[const]* Polygon **polygon** (int e)

Description: Convert an edge pair to a polygon

e: The enlargement (set to zero for exact representation)

The polygon is formed by connecting the end and start points of the edges. It is recommended to use normalized before converting the edge pair to a polygon.

The enlargement parameter applies the specified enlargement parallel and perpendicular to the edges. Basically this introduces a bias which blows up edge pairs by the specified amount. That parameter is useful to convert degenerated edge pairs to valid polygons, i.e. edge pairs with coincident edges and edge pairs consisting of two point-like edges.

Another version for converting edge pairs to simple polygons is simple_polygon which renders a SimplePolygon object.

second

Signature: *[const]* Edge **second**

Description: Gets the second edge

Python specific notes:
The object exposes a readable attribute 'second'. This is the getter.

second=

Signature: void **second=** (const Edge edge)

Description: Sets the second edge

Python specific notes:
The object exposes a writable attribute 'second'. This is the setter.

simple_polygon

Signature: *[const]* SimplePolygon **simple_polygon** (int e)

Description: Convert an edge pair to a simple polygon

e: The enlargement (set to zero for exact representation)

The polygon is formed by connecting the end and start points of the edges. It is recommended to use normalized before converting the edge pair to a polygon.

The enlargement parameter applies the specified enlargement parallel and perpendicular to the edges. Basically this introduces a bias which blows up edge pairs by the specified amount. That parameter is useful to convert degenerated edge pairs to valid polygons, i.e. edge pairs with coincident edges and edge pairs consisting of two point-like edges.

Another version for converting edge pairs to polygons is polygon which renders a Polygon object.

symmetric=

Signature: void **symmetric=** (bool flag)

Description: Sets a value indicating whether the edge pair is symmetric

See symmetric? for a description of this attribute.

Symmetric edge pairs have been introduced in version 0.27.

Python specific notes:
The object exposes a writable attribute 'symmetric'. This is the setter.

symmetric?

Signature: *[const]* bool **symmetric?**

Description: Returns a value indicating whether the edge pair is symmetric

For symmetric edge pairs, the edges are commutable. Specifically, a symmetric edge pair with (e1,e2) is identical to (e2,e1). Symmetric edge pairs are generated by some checks for which there is no directed error marker (width, space, notch, isolated).

Symmetric edge pairs have been introduced in version 0.27.

Python specific notes:

The object exposes a readable attribute 'symmetric'. This is the getter.

to_dtype

Signature: *[const]* DEdgePair **to_dtype** (double dbu = 1)

Description: Converts the edge pair to a floating-point coordinate edge pair

The database unit can be specified to translate the integer-coordinate edge pair into a floating-point coordinate edge pair in micron units. The database unit is basically a scaling factor.

This method has been introduced in version 0.25.

to_s

Signature: *[const]* string **to_s** (double dbu = 0)

Description: Returns a string representing the edge pair

If a DBU is given, the output units will be micrometers.

The DBU argument has been added in version 0.27.6.

Python specific notes:
This method is also available as 'str(object)'.

transformed

(1) Signature: *[const]* EdgePair **transformed** (const ICplxTrans t)

Description: Returns the transformed edge pair

t:	The transformation to apply.
Returns:	The transformed edge pair (in this case an integer coordinate edge pair).

Transforms the edge pair with the given complex transformation. Does not modify the edge pair but returns the transformed edge.

(2) Signature: *[const]* EdgePair **transformed** (const Trans t)

Description: Returns the transformed pair

t:	The transformation to apply.
Returns:	The transformed edge pair

Transforms the edge pair with the given transformation. Does not modify the edge pair but returns the transformed edge.

(3) Signature: *[const]* DEdgePair **transformed** (const CplxTrans t)

Description: Returns the transformed edge pair

t:	The transformation to apply.
Returns:	The transformed edge pair

Transforms the edge pair with the given complex transformation. Does not modify the edge pair but returns the transformed edge.

4.36. API reference - Class DEdgePair

Notation used in Ruby API documentation

Module: db

Description: An edge pair (a pair of two edges)

Edge pairs are objects representing two edges or parts of edges. They play a role mainly in the context of DRC functions, where they specify a DRC violation by connecting two edges which violate the condition checked. Within the framework of polygon and edge collections which provide DRC functionality, edges pairs with integer coordinates (EdgePair type) are used in the form of edge pair collections (EdgePairs).

Edge pairs basically consist of two edges, called first and second. If created by a two-layer DRC function, the first edge will correspond to edges from the first layer and the second to edges from the second layer.

This class has been introduced in version 0.23.

Public constructors

new DEdgePair ptr	**new**	(const EdgePair edge_pair)	Creates a floating-point coordinate edge pair from an integer coordinate edge
new DEdgePair ptr	**new**		Default constructor
new DEdgePair ptr	**new**	(const DEdge first, const DEdge second, bool symmetric = false)	Constructor from two edges

Public methods

[const]	bool	**!=**	(const DEdgePair box)	Inequality
[const]	bool	**<**	(const DEdgePair box)	Less operator
[const]	bool	**==**	(const DEdgePair box)	Equality
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	double	**area**		Gets the area between the edges of the edge pair

	void	**assign**	(const DEdgePair other)	Assigns another object to self
[const]	DBox	**bbox**		Gets the bounding box of the edge pair
[const]	double	**distance**		Gets the distance of the edges in the edge pair
[const]	new DEdgePair ptr	**dup**		Creates a copy of self
[const]	DEdge	**first**		Gets the first edge
	void	**first=**	(const DEdge edge)	Sets the first edge
[const]	DEdge	**greater**		Gets the 'greater' edge for symmetric edge pairs
[const]	unsigned long	**hash**		Computes a hash value
[const]	DEdge	**lesser**		Gets the 'lesser' edge for symmetric edge pairs
[const]	DEdgePair	**normalized**		Normalizes the edge pair
[const]	double	**perimeter**		Gets the perimeter of the edge pair
[const]	DPolygon	**polygon**	(double e)	Convert an edge pair to a polygon
[const]	DEdge	**second**		Gets the second edge
	void	**second=**	(const DEdge edge)	Sets the second edge
[const]	DSimplePolygon	**simple_polygon**	(double e)	Convert an edge pair to a simple polygon
	void	**symmetric=**	(bool flag)	Sets a value indicating whether the edge pair is symmetric
[const]	bool	**symmetric?**		Returns a value indicating whether the edge pair is symmetric
[const]	EdgePair	**to_itype**	(double dbu = 1)	Converts the edge pair to an integer coordinate edge pair
[const]	string	**to_s**	(double dbu = 0)	Returns a string representing the edge pair
[const]	EdgePair	**transformed**	(const VCplxTrans t)	Transforms the edge pair with the given complex transformation
[const]	DEdgePair	**transformed**	(const DTrans t)	Returns the transformed pair
[const]	DEdgePair	**transformed**	(const DCplxTrans t)	Returns the transformed edge pair

Public static methods and constants

new DEdgePair ptr	**from_s**	(string s)	Creates an object from a string

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=

Signature: *[const]* bool **!=** (const DEdgePair box)

Description: Inequality

Returns true, if this edge pair and the given one are not equal

This method has been introduced in version 0.25.

<

Signature: *[const]* bool **<** (const DEdgePair box)

Description: Less operator

Returns true, if this edge pair is 'less' with respect to first and second edge

This method has been introduced in version 0.25.

==

Signature: *[const]* bool **==** (const DEdgePair box)

Description: Equality

Returns true, if this edge pair and the given one are equal

This method has been introduced in version 0.25.

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

area

Signature: *[const]* double **area**

Description: Gets the area between the edges of the edge pair

This attribute has been introduced in version 0.28.

assign

Signature: void **assign** (const DEdgePair other)

Description: Assigns another object to self

bbox

Signature: *[const]* DBox **bbox**

Description: Gets the bounding box of the edge pair

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

distance

Signature: *[const]* double **distance**

Description: Gets the distance of the edges in the edge pair

The distance between the two edges is defined as the minimum distance between any two points on the two edges.

This attribute has been introduced in version 0.28.14.

dup

Signature: *[const]* new DEdgePair ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

first

Signature: *[const]* DEdge **first**

Description: Gets the first edge

Python specific notes:
The object exposes a readable attribute 'first'. This is the getter.

first=

Signature: void **first=** (const DEdge edge)

Description: Sets the first edge

Python specific notes:
The object exposes a writable attribute 'first'. This is the setter.

from_s

Signature: *[static]* new DEdgePair ptr **from_s** (string s)

Description: Creates an object from a string

Creates the object from a string representation (as returned by to_s)

This method has been added in version 0.23.

greater

Signature: *[const]* DEdge **greater**

Description: Gets the 'greater' edge for symmetric edge pairs

As first and second edges are commutable for symmetric edge pairs (see symmetric?), this accessor allows retrieving a 'second' edge in a way independent on the actual assignment.

This read-only attribute has been introduced in version 0.27.

hash

Signature: *[const]* unsigned long **hash**

Description: Computes a hash value

Returns a hash value for the given edge pair. This method enables edge pairs as hash keys.

This method has been introduced in version 0.25.

Python specific notes:
This method is also available as 'hash(object)'.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

lesser

Signature: *[const]* DEdge **lesser**

Description: Gets the 'lesser' edge for symmetric edge pairs

As first and second edges are commutable for symmetric edge pairs (see symmetric?), this accessor allows retrieving a 'first' edge in a way independent on the actual assignment.

This read-only attribute has been introduced in version 0.27.

new

(1) Signature: *[static]* new DEdgePair ptr **new** (const EdgePair edge_pair)

Description: Creates a floating-point coordinate edge pair from an integer coordinate edge

This constructor has been introduced in version 0.25 and replaces the previous static method 'from_iedge_pair'.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new DEdgePair ptr **new**

Description: Default constructor

This constructor creates an default edge pair.

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new DEdgePair ptr **new** (const DEdge first, const DEdge second, bool symmetric = false)

Description: Constructor from two edges

This constructor creates an edge pair from the two edges given. See symmetric? for a description of this attribute.

Python specific notes:
This method is the default initializer of the object.

normalized

Signature: *[const]* DEdgePair **normalized**

Description: Normalizes the edge pair

This method normalized the edge pair such that when connecting the edges at their start and end points a closed loop is formed which is oriented clockwise. To achieve this, the points of the first and/or first and second edge are swapped. Normalization is a first step recommended before converting an edge pair to a polygon, because that way the polygons won't be self-overlapping and the enlargement parameter is applied properly.

perimeter

Signature: *[const]* double **perimeter**

Description: Gets the perimeter of the edge pair

The perimeter is defined as the sum of the lengths of both edges ('active perimeter').

This attribute has been introduced in version 0.28.

polygon

Signature: *[const]* DPolygon **polygon** (double e)

Description: Convert an edge pair to a polygon

e: The enlargement (set to zero for exact representation)

The polygon is formed by connecting the end and start points of the edges. It is recommended to use normalized before converting the edge pair to a polygon.

The enlargement parameter applies the specified enlargement parallel and perpendicular to the edges. Basically this introduces a bias which blows up edge pairs by the specified amount. That parameter is useful to convert degenerated edge pairs to valid polygons, i.e. edge pairs with coincident edges and edge pairs consisting of two point-like edges.

Another version for converting edge pairs to simple polygons is simple_polygon which renders a SimplePolygon object.

second

Signature: *[const]* DEdge **second**

Description: Gets the second edge

Python specific notes:
The object exposes a readable attribute 'second'. This is the getter.

second=

Signature: void **second=** (const DEdge edge)

Description: Sets the second edge

Python specific notes:
The object exposes a writable attribute 'second'. This is the setter.

simple_polygon

Signature: *[const]* DSimplePolygon **simple_polygon** (double e)

Description: Convert an edge pair to a simple polygon

e: The enlargement (set to zero for exact representation)

The polygon is formed by connecting the end and start points of the edges. It is recommended to use normalized before converting the edge pair to a polygon.

The enlargement parameter applies the specified enlargement parallel and perpendicular to the edges. Basically this introduces a bias which blows up edge pairs by the specified amount. That parameter is useful to convert degenerated edge pairs to valid polygons, i.e. edge pairs with coincident edges and edge pairs consisting of two point-like edges.

Another version for converting edge pairs to polygons is polygon which renders a Polygon object.

symmetric=

Signature: void **symmetric=** (bool flag)

Description: Sets a value indicating whether the edge pair is symmetric

See symmetric? for a description of this attribute.

Symmetric edge pairs have been introduced in version 0.27.

Python specific notes:
The object exposes a writable attribute 'symmetric'. This is the setter.

symmetric?

Signature: *[const]* bool **symmetric?**

Description: Returns a value indicating whether the edge pair is symmetric

For symmetric edge pairs, the edges are commutable. Specifically, a symmetric edge pair with (e1,e2) is identical to (e2,e1). Symmetric edge pairs are generated by some checks for which there is no directed error marker (width, space, notch, isolated).

Symmetric edge pairs have been introduced in version 0.27.

Python specific notes:
The object exposes a readable attribute 'symmetric'. This is the getter.

to_itype

Signature: *[const]* EdgePair **to_itype** (double dbu = 1)

Description: Converts the edge pair to an integer coordinate edge pair

The database unit can be specified to translate the floating-point coordinate edge pair in micron units to an integer-coordinate edge pair in database units. The edge pair's' coordinates will be divided by the database unit.

This method has been introduced in version 0.25.

to_s

Signature: *[const]* string **to_s** (double dbu = 0)

Description: Returns a string representing the edge pair

If a DBU is given, the output units will be micrometers.

The DBU argument has been added in version 0.27.6.

Python specific notes:
This method is also available as 'str(object)'.

transformed

(1) Signature: *[const]* EdgePair **transformed** (const VCplxTrans t)

Description: Transforms the edge pair with the given complex transformation

t:	The magnifying transformation to apply
Returns:	The transformed edge pair (in this case an integer coordinate edge pair)

This method has been introduced in version 0.25.

(2) Signature: *[const]* DEdgePair **transformed** (const DTrans t)

Description: Returns the transformed pair

t:	The transformation to apply.
Returns:	The transformed edge pair

Transforms the edge pair with the given transformation. Does not modify the edge pair but returns the transformed edge.

(3) Signature: *[const]* DEdgePair **transformed** (const DCplxTrans t)

Description: Returns the transformed edge pair

t:	The transformation to apply.
Returns:	The transformed edge pair

Transforms the edge pair with the given complex transformation. Does not modify the edge pair but returns the transformed edge.

4.37. API reference - Class EdgePairFilter

Notation used in Ruby API documentation

Module: db

Description: A generic edge pair filter adaptor

EdgePair filters are an efficient way to filter edge pairs from a EdgePairs collection. To apply a filter, derive your own filter class and pass an instance to EdgePairs#filter or EdgePairs#filtered method.

Conceptually, these methods take each edge pair from the collection and present it to the filter's 'selected' method. Based on the result of this evaluation, the edge pair is kept or discarded.

The magic happens when deep mode edge pair collections are involved. In that case, the filter will use as few calls as possible and exploit the hierarchical compression if possible. It needs to know however, how the filter behaves. You need to configure the filter by calling is_isotropic, is_scale_invariant or is_isotropic_and_scale_invariant before using the filter.

You can skip this step, but the filter algorithm will assume the worst case then. This usually leads to cell variant formation which is not always desired and blows up the hierarchy.

Here is some example that filters edge pairs where the edges are perpendicular:

```
class PerpendicularEdgesFilter < RBA::EdgePairFilter

  # Constructor
  def initialize
    self.is_isotropic_and_scale_invariant   # orientation and scale do not matter
  end

  # Select edge pairs where the edges are perpendicular
  def selected(edge_pair)
    return edge_pair.first.d.sprod_sign(edge_pair.second.d) == 0
  end

end

edge_pairs = ... # some EdgePairs object
perpendicular_only = edge_pairs.filtered(PerpendicularEdgesFilter::new)
```

This class has been introduced in version 0.29.

Public constructors

new EdgePairFilter ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**	Ensures the C++ object is created
	void	**_destroy**	Explicitly destroys the object
[const]	bool	**_destroyed?**	Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**	Returns a value indicating whether the reference is a const reference
	void	**_manage**	Marks the object as managed by the script side.

	void	_unmanage		Marks the object as no longer owned by the script side.
	void	is_isotropic		Indicates that the filter has isotropic properties
	void	is_isotropic_and_scale_invariant		Indicates that the filter is isotropic and scale invariant
	void	is_scale_invariant		Indicates that the filter is scale invariant
[virtual,const]	bool	selected	(const EdgePair text)	Selects an edge pair
	void	wants_variants=	(bool flag)	Sets a value indicating whether the filter prefers cell variants
[const]	bool	wants_variants?		Gets a value indicating whether the filter prefers cell variants

Deprecated methods (protected, public, static, non-static and constructors)

	void	create	Use of this method is deprecated. Use _create instead
	void	destroy	Use of this method is deprecated. Use _destroy instead
[const]	bool	destroyed?	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	is_const_object?	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void _**create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void _**destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool _**destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool _**is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_isotropic

Signature: void **is_isotropic**

Description: Indicates that the filter has isotropic properties

Call this method before using the filter to indicate that the selection is independent of the orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

Examples for isotropic (polygon) filters are area or perimeter filters. The area or perimeter of a polygon depends on the scale, but not on the orientation of the polygon.

is_isotropic_and_scale_invariant

Signature: void **is_isotropic_and_scale_invariant**

Description: Indicates that the filter is isotropic and scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale and orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for such a (polygon) filter is the square selector. Whether a polygon is a square or not does not depend on the polygon's orientation nor scale.

is_scale_invariant

Signature: void **is_scale_invariant**

Description: Indicates that the filter is scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for a scale invariant (polygon) filter is the bounding box aspect ratio (height/width) filter. The definition of heigh and width depends on the orientation, but the ratio is independent on scale.

new

Signature: *[static]* new EdgePairFilter ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

selected

Signature: *[virtual,const]* bool **selected** (const EdgePair text)

Description: Selects an edge pair

This method is the actual payload. It needs to be reimplemented in a derived class. It needs to analyze the edge pair and return 'true' if it should be kept and 'false' if it should be discarded.

wants_variants=

Signature: void **wants_variants=** (bool flag)

Description: Sets a value indicating whether the filter prefers cell variants

This flag must be set before using this filter for hierarchical applications (deep mode). It tells the filter implementation whether cell variants should be created (true, the default) or shape propagation will be applied (false).

This decision needs to be made, if the filter indicates that it will deliver different results for scaled or rotated versions of the shape (see is_isotropic and the other hints). If a cell is present with different qualities - as seen from the top cell - the respective instances need to be differentiated. Cell variant formation is one way, shape propagation the other way. Typically, cell variant formation is less expensive, but the hierarchy will be modified.

Python specific notes:
The object exposes a writable attribute 'wants_variants'. This is the setter.

wants_variants?

Signature: *[const]* bool **wants_variants?**

Description: Gets a value indicating whether the filter prefers cell variants

See wants_variants= for details.

Python specific notes:
The object exposes a readable attribute 'wants_variants'. This is the getter.

4.38. API reference - Class EdgePairOperator

Notation used in Ruby API documentation

Module: db

Description: A generic edge-pair operator

Edge pair processors are an efficient way to process edge pairs from an edge pair collection. To apply a processor, derive your own operator class and pass an instance to the EdgePairs#processed or EdgePairs#process method.

Conceptually, these methods take each edge pair from the edge pair collection and present it to the operator's 'process' method. The result of this call is a list of zero to many output edge pairs derived from the input edge pair. The output edge pair collection is the sum over all these individual results.

The magic happens when deep mode edge pair collections are involved. In that case, the processor will use as few calls as possible and exploit the hierarchical compression if possible. It needs to know however, how the operator behaves. You need to configure the operator by calling is_isotropic, is_scale_invariant or is_isotropic_and_scale_invariant before using it.

You can skip this step, but the processor algorithm will assume the worst case then. This usually leads to cell variant formation which is not always desired and blows up the hierarchy.

Here is some example that flips the edge pairs (swaps first and second edge):

```
class FlipEdgePairs < RBA::EdgePairOperator

  # Constructor
  def initialize
    self.is_isotropic_and_scale_invariant   # orientation and scale do not matter
  end

  # Flips the edge pair
  def process(edge_pair)
    return [ RBA::EdgePair::new(edge_pair.second, edge_pair.first) ]
  end

end

edge_pairs = ... # some EdgePairs object
flipped = edge_pairs.processed(FlipEdgePairs::new)
```

This class has been introduced in version 0.29.

Public constructors

new EdgePairOperator ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**	Ensures the C++ object is created
	void	**_destroy**	Explicitly destroys the object
[const]	bool	**_destroyed?**	Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**	Returns a value indicating whether the reference is a const reference
	void	**_manage**	Marks the object as managed by the script side.

	void	_unmanage		Marks the object as no longer owned by the script side.
	void	is_isotropic		Indicates that the filter has isotropic properties
	void	is_isotropic_and_scale_invariant		Indicates that the filter is isotropic and scale invariant
	void	is_scale_invariant		Indicates that the filter is scale invariant
[virtual,const]	EdgePair[]	process	(const EdgePair shape)	Processes a shape
	void	wants_variants=	(bool flag)	Sets a value indicating whether the filter prefers cell variants
[const]	bool	wants_variants?		Gets a value indicating whether the filter prefers cell variants

Deprecated methods (protected, public, static, non-static and constructors)

	void	create	Use of this method is deprecated. Use _create instead
	void	destroy	Use of this method is deprecated. Use _destroy instead
[const]	bool	destroyed?	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	is_const_object?	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void _**create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void _**destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool _**destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool _**is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_isotropic

Signature: void **is_isotropic**

Description: Indicates that the filter has isotropic properties

Call this method before using the filter to indicate that the selection is independent of the orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

Examples for isotropic (polygon) processors are size or shrink operators. Size or shrink is not dependent on orientation unless size or shrink needs to be different in x and y direction.

is_isotropic_and_scale_invariant

Signature: void **is_isotropic_and_scale_invariant**

Description: Indicates that the filter is isotropic and scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale and orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for such a (polygon) processor is the convex decomposition operator. The decomposition of a polygon into convex parts is an operation that is not depending on scale nor orientation.

is_scale_invariant

Signature: void **is_scale_invariant**

Description: Indicates that the filter is scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for a scale invariant (polygon) processor is the rotation operator. Rotation is not depending on scale, but on the original orientation as mirrored versions need to be rotated differently.

new

Signature: *[static]* new EdgePairOperator ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

process

Signature: *[virtual,const]* EdgePair[] **process** (const EdgePair shape)

Description: Processes a shape

This method is the actual payload. It needs to be reimplemented in a derived class. If needs to process the input shape and deliver a list of output shapes. The output list may be empty to entirely discard the input shape. It may also contain more than a single shape. In that case, the number of total shapes may grow during application of the processor.

wants_variants=

Signature: void **wants_variants=** (bool flag)

Description: Sets a value indicating whether the filter prefers cell variants

This flag must be set before using this filter for hierarchical applications (deep mode). It tells the filter implementation whether cell variants should be created (true, the default) or shape propagation will be applied (false).

This decision needs to be made, if the filter indicates that it will deliver different results for scaled or rotated versions of the shape (see is_isotropic and the other hints). If a cell is present with different qualities - as seen from the top cell - the respective instances need to be differentiated. Cell variant formation is one way, shape propagation the other way. Typically, cell variant formation is less expensive, but the hierarchy will be modified.

Python specific notes:
The object exposes a writable attribute 'wants_variants'. This is the setter.

wants_variants?

Signature: *[const]* bool **wants_variants?**

Description: Gets a value indicating whether the filter prefers cell variants

See wants_variants= for details.

Python specific notes:
The object exposes a readable attribute 'wants_variants'. This is the getter.

4.39. API reference - Class EdgePairToPolygonOperator

Notation used in Ruby API documentation

Module: db

Description: A generic edge-pair-to-polygon operator

Edge pair processors are an efficient way to process edge pairs from an edge pair collection. To apply a processor, derive your own operator class and pass an instance to the EdgePairs#processed method.

Conceptually, these methods take each edge pair from the edge pair collection and present it to the operator's 'process' method. The result of this call is a list of zero to many output polygons derived from the input edge pair. The output region is the sum over all these individual results.

The magic happens when deep mode edge pair collections are involved. In that case, the processor will use as few calls as possible and exploit the hierarchical compression if possible. It needs to know however, how the operator behaves. You need to configure the operator by calling is_isotropic, is_scale_invariant or is_isotropic_and_scale_invariant before using it.

You can skip this step, but the processor algorithm will assume the worst case then. This usually leads to cell variant formation which is not always desired and blows up the hierarchy.

For a basic example see the EdgeToPolygonOperator class, with the exception that this incarnation receives edge pairs.

This class has been introduced in version 0.29.

Public constructors

new EdgePairToPolygonOperator ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**is_isotropic**		Indicates that the filter has isotropic properties
	void	**is_isotropic_and_scale_invariant**		Indicates that the filter is isotropic and scale invariant
	void	**is_scale_invariant**		Indicates that the filter is scale invariant
[virtual,const]	Polygon[]	**process**	(const EdgePair shape)	Processes a shape
	void	**wants_variants=**	(bool flag)	Sets a value indicating whether the filter prefers cell variants

[const]	bool	wants_variants?	Gets a value indicating whether the filter prefers cell variants

Deprecated methods (protected, public, static, non-static and constructors)

	void	create	Use of this method is deprecated. Use _create instead
	void	destroy	Use of this method is deprecated. Use _destroy instead
[const]	bool	destroyed?	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	is_const_object?	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void _**create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void _**destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool _**destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool _**is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void _**manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void _**unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_isotropic

Signature: void **is_isotropic**

Description: Indicates that the filter has isotropic properties

Call this method before using the filter to indicate that the selection is independent of the orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

Examples for isotropic (polygon) processors are size or shrink operators. Size or shrink is not dependent on orientation unless size or shrink needs to be different in x and y direction.

is_isotropic_and_scale_invariant

Signature: void **is_isotropic_and_scale_invariant**

Description: Indicates that the filter is isotropic and scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale and orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for such a (polygon) processor is the convex decomposition operator. The decomposition of a polygon into convex parts is an operation that is not depending on scale nor orientation.

is_scale_invariant

Signature: void **is_scale_invariant**

Description: Indicates that the filter is scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for a scale invariant (polygon) processor is the rotation operator. Rotation is not depending on scale, but on the original orientation as mirrored versions need to be rotated differently.

new

Signature: *[static]* new EdgePairToPolygonOperator ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

process

Signature: *[virtual,const]* Polygon[] **process** (const EdgePair shape)

Description: Processes a shape

This method is the actual payload. It needs to be reimplemented in a derived class. If needs to process the input shape and deliver a list of output shapes. The output list may be empty to entirely discard the input shape. It may also contain more than a single shape. In that case, the number of total shapes may grow during application of the processor.

wants_variants=

Signature: void **wants_variants=** (bool flag)

Description: Sets a value indicating whether the filter prefers cell variants

This flag must be set before using this filter for hierarchical applications (deep mode). It tells the filter implementation whether cell variants should be created (true, the default) or shape propagation will be applied (false).

This decision needs to be made, if the filter indicates that it will deliver different results for scaled or rotated versions of the shape (see is_isotropic and the other hints). If a cell is present with different qualities - as seen from the top cell - the respective instances need to be differentiated. Cell variant formation is one way, shape propagation the other way. Typically, cell variant formation is less expensive, but the hierarchy will be modified.

Python specific notes:
The object exposes a writable attribute 'wants_variants'. This is the setter.

wants_variants?

Signature: *[const]* bool **wants_variants?**

Description: Gets a value indicating whether the filter prefers cell variants

See wants_variants= for details.

Python specific notes:
The object exposes a readable attribute 'wants_variants'. This is the getter.

4.40. API reference - Class EdgePairToEdgeOperator

Notation used in Ruby API documentation

Module: db

Description: A generic edge-pair-to-edge operator

Edge processors are an efficient way to process edge pairs from an edge pair collection. To apply a processor, derive your own operator class and pass an instance to EdgePairs#processed method.

Conceptually, these methods take each edge from the edge collection and present it to the operator's 'process' method. The result of this call is a list of zero to many output edges derived from the input edge pair. The output edge pair collection is the sum over all these individual results.

The magic happens when deep mode edge pair collections are involved. In that case, the processor will use as few calls as possible and exploit the hierarchical compression if possible. It needs to know however, how the operator behaves. You need to configure the operator by calling is_isotropic, is_scale_invariant or is_isotropic_and_scale_invariant before using it.

You can skip this step, but the processor algorithm will assume the worst case then. This usually leads to cell variant formation which is not always desired and blows up the hierarchy.

For a basic example see the EdgeToEdgePairOperator class, with the exception that this incarnation has to deliver edges and takes edge pairs.

This class has been introduced in version 0.29.

Public constructors

new EdgePairToEdgeOperator ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**is_isotropic**		Indicates that the filter has isotropic properties
	void	**is_isotropic_and_scale_invariant**		Indicates that the filter is isotropic and scale invariant
	void	**is_scale_invariant**		Indicates that the filter is scale invariant
[virtual,const]	Edge[]	**process**	(const EdgePair shape)	Processes a shape
	void	**wants_variants=**	(bool flag)	Sets a value indicating whether the filter prefers cell variants

[const]	bool	**wants_variants?**	Gets a value indicating whether the filter prefers cell variants

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_isotropic

Signature: void **is_isotropic**

Description: Indicates that the filter has isotropic properties

Call this method before using the filter to indicate that the selection is independent of the orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

Examples for isotropic (polygon) processors are size or shrink operators. Size or shrink is not dependent on orientation unless size or shrink needs to be different in x and y direction.

is_isotropic_and_scale_invariant

Signature: void **is_isotropic_and_scale_invariant**

Description: Indicates that the filter is isotropic and scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale and orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for such a (polygon) processor is the convex decomposition operator. The decomposition of a polygon into convex parts is an operation that is not depending on scale nor orientation.

is_scale_invariant

Signature: void **is_scale_invariant**

Description: Indicates that the filter is scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for a scale invariant (polygon) processor is the rotation operator. Rotation is not depending on scale, but on the original orientation as mirrored versions need to be rotated differently.

new

Signature: *[static]* new EdgePairToEdgeOperator ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

process

Signature: *[virtual,const]* Edge[] **process** (const EdgePair shape)

Description: Processes a shape

This method is the actual payload. It needs to be reimplemented in a derived class. If needs to process the input shape and deliver a list of output shapes. The output list may be empty to entirely discard the input shape. It may also contain more than a single shape. In that case, the number of total shapes may grow during application of the processor.

wants_variants=

Signature: void **wants_variants=** (bool flag)

Description: Sets a value indicating whether the filter prefers cell variants

This flag must be set before using this filter for hierarchical applications (deep mode). It tells the filter implementation whether cell variants should be created (true, the default) or shape propagation will be applied (false).

This decision needs to be made, if the filter indicates that it will deliver different results for scaled or rotated versions of the shape (see is_isotropic and the other hints). If a cell is present with different qualities - as seen from the top cell - the respective instances need to be differentiated. Cell variant formation is one way, shape propagation the other way. Typically, cell variant formation is less expensive, but the hierarchy will be modified.

Python specific notes:
The object exposes a writable attribute 'wants_variants'. This is the setter.

wants_variants?

Signature: *[const]* bool **wants_variants?**

Description: Gets a value indicating whether the filter prefers cell variants

See wants_variants= for details.

Python specific notes:
The object exposes a readable attribute 'wants_variants'. This is the getter.

4.41. API reference - Class EdgePairs

Notation used in Ruby API documentation

Module: db

Description: EdgePairs (a collection of edge pairs)

Class hierarchy: EdgePairs » ShapeCollection

Edge pairs are used mainly in the context of the DRC functions (width_check, space_check etc.) of Region and Edges. A single edge pair represents two edges participating in a DRC violation. In the two-layer checks (inside, overlap) The first edge represents an edge from the first layer and the second edge an edge from the second layer. For single-layer checks (width, space) the order of the edges is arbitrary.

This class has been introduced in version 0.23.

Public constructors

new EdgePairs ptr	**new**		Default constructor
new EdgePairs ptr	**new**	(EdgePair[] array)	Constructor from an edge pair array
new EdgePairs ptr	**new**	(const EdgePair edge_pair)	Constructor from a single edge pair object
new EdgePairs ptr	**new**	(const Shapes shapes)	Shapes constructor
new EdgePairs ptr	**new**	(const RecursiveShapeIterator shape_iterator)	Constructor from a hierarchical shape set
new EdgePairs ptr	**new**	(const RecursiveShapeIterator shape_iterator, const ICplxTrans trans)	Constructor from a hierarchical shape set with a transformation
new EdgePairs ptr	**new**	(const RecursiveShapeIterator shape_iterator, DeepShapeStore dss)	Creates a hierarchical edge pair collection from an original layer
new EdgePairs ptr	**new**	(const RecursiveShapeIterator shape_iterator, DeepShapeStore dss, const ICplxTrans trans)	Creates a hierarchical edge pair collection from an original layer with a transformation

Public methods

[const]	EdgePairs	**+**	(const EdgePairs other)	Returns the combined edge pair collection of self and the other one
	EdgePairs	**+=**	(const EdgePairs other)	Adds the edge pairs of the other edge pair collection to self
[const]	const EdgePair ptr	**[]**	(unsigned long n)	Returns the nth edge pair
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed

[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const EdgePairs other)	Assigns another object to self
[const]	Box	**bbox**		Return the bounding box of the edge pair collection
	void	**clear**		Clears the edge pair collection
[const]	unsigned long	**count**		Returns the (flat) number of edge pairs in the edge pair collection
[const]	unsigned long	**data_id**		Returns the data ID (a unique identifier for the underlying data storage)
	void	**disable_progress**		Disable progress reporting
[const]	new EdgePairs ptr	**dup**		Creates a copy of self
[const,iter]	EdgePair	**each**		Returns each edge pair of the edge pair collection
[const]	Edges	**edges**		Decomposes the edge pairs into single edges
	void	**enable_progress**	(string label)	Enable progress reporting
	void	**enable_properties**		Enables properties for the given container.
[const]	Region	**extents**		Returns a region with the bounding boxes of the edge pairs
[const]	Region	**extents**	(int d)	Returns a region with the enlarged bounding boxes of the edge pairs
[const]	Region	**extents**	(int dx, int dy)	Returns a region with the enlarged bounding boxes of the edge pairs
	void	**filter**	(const EdgePairFilter ptr filter)	Applies a generic filter in place (replacing the edge pairs from the EdgePair collection)
	void	**filter_properties**	(variant[] keys)	Filters properties by certain keys.
[const]	EdgePairs	**filtered**	(const EdgePairFilter ptr filtered)	Applies a generic filter and returns a filtered copy
[const]	Edges	**first_edges**		Returns the first one of all edges
	void	**flatten**		Explicitly flattens an edge pair collection

[const]	bool	**has_valid_edge_pai**		Returns true if the edge pair collection is flat and individual edge pairs can be accessed randomly
[const]	unsigned long	**hier_count**		Returns the (hierarchical) number of edge pairs in the edge pair collection
	void	**insert**	(const Edge first, const Edge second)	Inserts an edge pair into the collection
	void	**insert**	(const EdgePair edge_pair)	Inserts an edge pair into the collection
	void	**insert**	(const EdgePairs edge_pairs)	Inserts all edge pairs from the other edge pair collection into this edge pair collection
[const]	void	**insert_into**	(Layout ptr layout, unsigned int cell_index, unsigned int layer)	Inserts this edge pairs into the given layout, below the given cell and into the given layer.
[const]	void	**insert_into_as_polyg**	(Layout ptr layout, unsigned int cell_index, unsigned int layer, int e)	Inserts this edge pairs into the given layout, below the given cell and into the given layer.
[const]	bool	**is_deep?**		Returns true if the edge pair collection is a deep (hierarchical) one
[const]	bool	**is_empty?**		Returns true if the collection is empty
[const]	EdgePairs	**join**	(const EdgePairs other)	Returns the combined edge pair collection of self and the other one
	EdgePairs	**join_with**	(const EdgePairs other)	Adds the edge pairs of the other edge pair collection to self
	void	**map_properties**	(map<variant,variant> key_map)	Maps properties by name key.
	EdgePairs	**move**	(const Vector p)	Moves the edge pair collection
	EdgePairs	**move**	(int x, int y)	Moves the edge pair collection
[const]	EdgePairs	**moved**	(const Vector p)	Returns the moved edge pair collection (does not modify self)
[const]	EdgePairs	**moved**	(int x, int y)	Returns the moved edge pair collection (does not modify self)
[const]	Region	**polygons**		Converts the edge pairs to polygons
[const]	Region	**polygons**	(int e)	Converts the edge pairs to polygons
	void	**process**	(const EdgePairOperator ptr process)	Applies a generic edge pair processor in place (replacing the edge pairs from the EdgePairs collection)

[const]	EdgePairs	**processed**	(const EdgePairOperator ptr processed)	Applies a generic edge pair processor and returns a processed copy
[const]	Edges	**processed**	(const EdgePairToEdgeOperator ptr processed)	Applies a generic edge-pair-to-edge processor and returns an edge collection with the results
[const]	Region	**processed**	(const EdgePairToPolygonOperator ptr processed)	Applies a generic edge-pair-to-polygon processor and returns an Region with the results
	void	**remove_properties**		Removes properties for the given container.
[const]	Edges	**second_edges**		Returns the second one of all edges
	void	**swap**	(EdgePairs other)	Swap the contents of this collection with the contents of another collection
[const]	string	**to_s**		Converts the edge pair collection to a string
[const]	string	**to_s**	(unsigned long max_count)	Converts the edge pair collection to a string
	EdgePairs	**transform**	(const Trans t)	Transform the edge pair collection (modifies self)
	EdgePairs	**transform**	(const ICplxTrans t)	Transform the edge pair collection with a complex transformation (modifies self)
	EdgePairs	**transform**	(const IMatrix2d t)	Transform the edge pair collection (modifies self)
	EdgePairs	**transform**	(const IMatrix3d t)	Transform the edge pair collection (modifies self)
[const]	EdgePairs	**transformed**	(const Trans t)	Transform the edge pair collection
[const]	EdgePairs	**transformed**	(const ICplxTrans t)	Transform the edge pair collection with a complex transformation
[const]	EdgePairs	**transformed**	(const IMatrix2d t)	Transform the edge pair collection
[const]	EdgePairs	**transformed**	(const IMatrix3d t)	Transform the edge pair collection
[const]	EdgePairs	**with_angle**	(double angle, bool inverse)	Filter the edge pairs by orientation of their edges
[const]	EdgePairs	**with_angle**	(double min_angle, double max_angle, bool inverse, bool include_min_angle = true, bool include_max_angle = false)	Filter the edge pairs by orientation of their edges

[const]	EdgePairs	**with_angle**	(Edges::EdgeType type, bool inverse)	Filter the edge pairs by orientation of their edges
[const]	EdgePairs	**with_angle_both**	(double angle, bool inverse)	Filter the edge pairs by orientation of both of their edges
[const]	EdgePairs	**with_angle_both**	(double min_angle, double max_angle, bool inverse, bool include_min_angle = true, bool include_max_angle = false)	Filter the edge pairs by orientation of both of their edges
[const]	EdgePairs	**with_angle_both**	(Edges::EdgeType type, bool inverse)	Filter the edge pairs by orientation of their edges
[const]	EdgePairs	**with_area**	(long area, bool inverse)	Filters the edge pairs by the enclosed area
[const]	EdgePairs	**with_area**	(long min_area, long max_area, bool inverse)	Filters the edge pairs by the enclosed area
[const]	EdgePairs	**with_distance**	(unsigned int distance, bool inverse)	Filters the edge pairs by the distance of the edges
[const]	EdgePairs	**with_distance**	(variant min_distance, variant max_distance, bool inverse)	Filters the edge pairs by the distance of the edges
[const]	EdgePairs	**with_internal_angle**	(double angle, bool inverse)	Filters the edge pairs by the angle between their edges
[const]	EdgePairs	**with_internal_angle**	(double min_angle, double max_angle, bool inverse, bool include_min_angle = true, bool include_max_angle = false)	Filters the edge pairs by the angle between their edges
[const]	EdgePairs	**with_length**	(unsigned int length, bool inverse)	Filters the edge pairs by length of one of their edges
[const]	EdgePairs	**with_length**	(variant min_length, variant max_length, bool inverse)	Filters the edge pairs by length of one of their edges
[const]	EdgePairs	**with_length_both**	(unsigned int length, bool inverse)	Filters the edge pairs by length of both of their edges

[const]	EdgePairs	**with_length_both**	(variant min_length, variant max_length, bool inverse)	Filters the edge pairs by length of both of their edges
[const]	void	**write**	(string filename)	Writes the region to a file

[const]	EdgePairs	**transformed_icplx**	(const ICplxTrans t)	Use of this method is deprecated. Use transformed instead

Detailed description

+

Signature: *[const]* EdgePairs **+** (const EdgePairs other)

Description: Returns the combined edge pair collection of self and the other one

Returns: The resulting edge pair collection

This operator adds the edge pairs of the other collection to self and returns a new combined set.

This method has been introduced in version 0.24. The 'join' alias has been introduced in version 0.28.12.

+=

Signature: EdgePairs **+=** (const EdgePairs other)

Description: Adds the edge pairs of the other edge pair collection to self

Returns: The edge pair collection after modification (self)

This operator adds the edge pairs of the other collection to self.

This method has been introduced in version 0.24.

Note that in Ruby, the '+=' operator actually does not exist, but is emulated by '+' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'join_with' instead.

The 'join_with' alias has been introduced in version 0.28.12.

[]

Signature: *[const]* const EdgePair ptr **[]** (unsigned long n)

Description: Returns the nth edge pair

This method returns nil if the index is out of range. It is available for flat edge pairs only - i.e. those for which has_valid_edge_pairs? is true. Use flatten to explicitly flatten an edge pair collection.

The each iterator is the more general approach to access the edge pairs.

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const EdgePairs other)

Description: Assigns another object to self

bbox

Signature: *[const]* Box **bbox**

Description: Return the bounding box of the edge pair collection

The bounding box is the box enclosing all points of all edge pairs.

clear

Signature: void **clear**

Description: Clears the edge pair collection

count

Signature: *[const]* unsigned long **count**

Description: Returns the (flat) number of edge pairs in the edge pair collection

The count is computed 'as if flat', i.e. edge pairs inside a cell are multiplied by the number of times a cell is instantiated.

Starting with version 0.27, the method is called 'count' for consistency with Region. 'size' is still provided as an alias.

Python specific notes:
This method is also available as 'len(object)'.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

data_id

Signature: *[const]* unsigned long **data_id**

Description: Returns the data ID (a unique identifier for the underlying data storage)

This method has been added in version 0.26.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

disable_progress

Signature: void **disable_progress**

Description: Disable progress reporting

Calling this method will disable progress reporting. See enable_progress.

dup

Signature: *[const]* new EdgePairs ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

each

Signature: *[const,iter]* EdgePair **each**

Description: Returns each edge pair of the edge pair collection

Python specific notes:
This method enables iteration of the object.

edges

Signature: *[const]* Edges **edges**

Description: Decomposes the edge pairs into single edges

Returns: An edge collection containing the individual edges

enable_progress

Signature: void **enable_progress** (string label)

Description: Enable progress reporting

After calling this method, the edge pair collection will report the progress through a progress bar while expensive operations are running. The label is a text which is put in front of the progress bar. Using a progress bar will imply a performance penalty of a few percent typically.

enable_properties

Signature: void **enable_properties**

Description: Enables properties for the given container.

This method has an effect mainly on original layers and will import properties from such layers. By default, properties are not enabled on original layers. Alternatively you can apply filter_properties or map_properties to enable properties with a specific name key.

This method has been introduced in version 0.28.4.

extents

(1) Signature: *[const]* Region **extents**

Description: Returns a region with the bounding boxes of the edge pairs

This method will return a region consisting of the bounding boxes of the edge pairs. The boxes will not be merged, so it is possible to determine overlaps of these boxes for example.

(2) Signature: *[const]* Region **extents** (int d)

Description: Returns a region with the enlarged bounding boxes of the edge pairs

This method will return a region consisting of the bounding boxes of the edge pairs enlarged by the given distance d. The enlargement is specified per edge, i.e the width and height will be increased by 2*d. The boxes will not be merged, so it is possible to determine overlaps of these boxes for example.

(3) Signature: *[const]* Region **extents** (int dx, int dy)

Description: Returns a region with the enlarged bounding boxes of the edge pairs

This method will return a region consisting of the bounding boxes of the edge pairs enlarged by the given distance dx in x direction and dy in y direction. The enlargement is specified per edge, i.e the width will be increased by 2*dx. The boxes will not be merged, so it is possible to determine overlaps of these boxes for example.

filter

Signature: void **filter** (const EdgePairFilter ptr filter)

Description: Applies a generic filter in place (replacing the edge pairs from the EdgePair collection)

See EdgePairFilter for a description of this feature.

This method has been introduced in version 0.29.

filter_properties

Signature: void **filter_properties** (variant[] keys)

Description: Filters properties by certain keys.

Calling this method on a container will reduce the properties to values with name keys from the 'keys' list. As a side effect, this method enables properties on original layers.

This method has been introduced in version 0.28.4.

filtered

Signature: *[const]* EdgePairs **filtered** (const EdgePairFilter ptr filtered)

Description: Applies a generic filter and returns a filtered copy

See EdgePairFilter for a description of this feature.

This method has been introduced in version 0.29.

first_edges

Signature: *[const]* Edges **first_edges**

Description: Returns the first one of all edges

Returns: An edge collection containing the first edges

flatten

Signature: void **flatten**

Description: Explicitly flattens an edge pair collection

If the collection is already flat (i.e. has_valid_edge_pairs? returns true), this method will not change the collection.

This method has been introduced in version 0.26.

has_valid_edge_pairs?

Signature: *[const]* bool **has_valid_edge_pairs?**

Description: Returns true if the edge pair collection is flat and individual edge pairs can be accessed randomly

This method has been introduced in version 0.26.

hier_count

Signature: *[const]* unsigned long **hier_count**

Description: Returns the (hierarchical) number of edge pairs in the edge pair collection

The count is computed 'hierarchical', i.e. edge pairs inside a cell are counted once even if the cell is instantiated multiple times.

This method has been introduced in version 0.27.

insert

(1) Signature: void **insert** (const Edge first, const Edge second)

Description: Inserts an edge pair into the collection

(2) Signature: void **insert** (const EdgePair edge_pair)

Description: Inserts an edge pair into the collection

(3) Signature: void **insert** (const EdgePairs edge_pairs)

Description: Inserts all edge pairs from the other edge pair collection into this edge pair collection

This method has been introduced in version 0.25.

insert_into

Signature: *[const]* void **insert_into** (Layout ptr layout, unsigned int cell_index, unsigned int layer)

Description: Inserts this edge pairs into the given layout, below the given cell and into the given layer.

If the edge pair collection is a hierarchical one, a suitable hierarchy will be built below the top cell or and existing hierarchy will be reused.

This method has been introduced in version 0.26.

insert_into_as_polygons

Signature: *[const]* void **insert_into_as_polygons** (Layout ptr layout, unsigned int cell_index, unsigned int layer, int e)

Description: Inserts this edge pairs into the given layout, below the given cell and into the given layer.

If the edge pair collection is a hierarchical one, a suitable hierarchy will be built below the top cell or and existing hierarchy will be reused.

The edge pairs will be converted to polygons with the enlargement value given be 'e'.

This method has been introduced in version 0.26.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_deep?

Signature: *[const]* bool **is_deep?**

Description: Returns true if the edge pair collection is a deep (hierarchical) one

This method has been added in version 0.26.

is_empty?

Signature: *[const]* bool **is_empty?**

Description: Returns true if the collection is empty

join

Signature: *[const]* EdgePairs **join** (const EdgePairs other)

Description: Returns the combined edge pair collection of self and the other one

Returns: The resulting edge pair collection

This operator adds the edge pairs of the other collection to self and returns a new combined set.

This method has been introduced in version 0.24. The 'join' alias has been introduced in version 0.28.12.

join_with

Signature: EdgePairs **join_with** (const EdgePairs other)

Description: Adds the edge pairs of the other edge pair collection to self

Returns: The edge pair collection after modification (self)

This operator adds the edge pairs of the other collection to self.

This method has been introduced in version 0.24.

Note that in Ruby, the '+=' operator actually does not exist, but is emulated by '+' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'join_with' instead.

The 'join_with' alias has been introduced in version 0.28.12.

map_properties

Signature: void **map_properties** (map<variant,variant> key_map)

Description: Maps properties by name key.

Calling this method on a container will reduce the properties to values with name keys from the 'keys' hash and renames the properties. Properties not listed in the key map will be removed. As a side effect, this method enables properties on original layers.

This method has been introduced in version 0.28.4.

move

(1) Signature: EdgePairs **move** (const Vector p)

Description: Moves the edge pair collection

p:	The distance to move the edge pairs.
Returns:	The moved edge pairs (self).

Moves the edge pairs by the given offset and returns the moved edge pair collection. The edge pair collection is overwritten.

Starting with version 0.25 the displacement is of vector type.

(2) Signature: EdgePairs **move** (int x, int y)

Description: Moves the edge pair collection

x:	The x distance to move the edge pairs.
y:	The y distance to move the edge pairs.
Returns:	The moved edge pairs (self).

Moves the edge pairs by the given offset and returns the moved edge pairs. The edge pair collection is overwritten.

moved

(1) Signature: *[const]* EdgePairs **moved** (const Vector p)

Description: Returns the moved edge pair collection (does not modify self)

p:	The distance to move the edge pairs.
Returns:	The moved edge pairs.

Moves the edge pairs by the given offset and returns the moved edge pairs. The edge pair collection is not modified.

Starting with version 0.25 the displacement is of vector type.

(2) Signature: *[const]* EdgePairs **moved** (int x, int y)

Description: Returns the moved edge pair collection (does not modify self)

x:	The x distance to move the edge pairs.
y:	The y distance to move the edge pairs.
Returns:	The moved edge pairs.

Moves the edge pairs by the given offset and returns the moved edge pairs. The edge pair collection is not modified.

new

(1) Signature: *[static]* new EdgePairs ptr **new**

Description: Default constructor

This constructor creates an empty edge pair collection.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new EdgePairs ptr **new** (EdgePair[] array)

Description: Constructor from an edge pair array

This constructor creates an edge pair collection from an array of EdgePair objects.

This constructor has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new EdgePairs ptr **new** (const EdgePair edge_pair)

Description: Constructor from a single edge pair object

This constructor creates an edge pair collection with a single edge pair.

This constructor has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

(4) Signature: *[static]* new EdgePairs ptr **new** (const Shapes shapes)

Description: Shapes constructor

This constructor creates an edge pair collection from a Shapes collection.

This constructor has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

(5) Signature: *[static]* new EdgePairs ptr **new** (const RecursiveShapeIterator shape_iterator)

Description: Constructor from a hierarchical shape set

This constructor creates an edge pair collection from the shapes delivered by the given recursive shape iterator. Only edge pairs are taken from the shape set and other shapes are ignored. This method allows feeding the edge pair collection from a hierarchy of cells. Edge pairs in layout objects are somewhat special as most formats don't support reading or writing of edge pairs. Still they are useful objects and can be created and manipulated inside layouts.

```
layout = ... # a layout
cell   = ... # the index of the initial cell
layer  = ... # the index of the layer from where to take the shapes from
r = RBA::EdgePairs::new(layout.begin_shapes(cell, layer))
```

This constructor has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

(6) Signature: *[static]* new EdgePairs ptr **new** (const RecursiveShapeIterator shape_iterator, const ICplxTrans trans)

Description: Constructor from a hierarchical shape set with a transformation

This constructor creates an edge pair collection from the shapes delivered by the given recursive shape iterator. Only edge pairs are taken from the shape set and other shapes are ignored. The given transformation is applied to each edge pair taken. This method allows feeding the edge pair collection from a hierarchy of cells. The transformation is useful to scale to a specific database unit for example. Edge pairs in layout objects are somewhat special as most formats don't support reading or writing of edge pairs. Still they are useful objects and can be created and manipulated inside layouts.

```
layout = ... # a layout
cell   = ... # the index of the initial cell
layer  = ... # the index of the layer from where to take the shapes from
dbu    = 0.1 # the target database unit
r = RBA::EdgePairs::new(layout.begin_shapes(cell, layer),
 RBA::ICplxTrans::new(layout.dbu / dbu))
```

This constructor has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

(7) Signature: *[static]* new EdgePairs ptr **new** (const RecursiveShapeIterator shape_iterator, DeepShapeStore dss)

Description: Creates a hierarchical edge pair collection from an original layer

This constructor creates an edge pair collection from the shapes delivered by the given recursive shape iterator. This version will create a hierarchical edge pair collection which supports hierarchical operations. Edge pairs in layout objects are somewhat special as most formats don't support reading or writing of edge pairs. Still they are useful objects and can be created and manipulated inside layouts.

```
dss    = RBA::DeepShapeStore::new
layout = ... # a layout
cell   = ... # the index of the initial cell
layer  = ... # the index of the layer from where to take the shapes from
r = RBA::EdgePairs::new(layout.begin_shapes(cell, layer))
```

This constructor has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

(8) Signature: *[static]* new EdgePairs ptr **new** (const RecursiveShapeIterator shape_iterator, DeepShapeStore dss, const ICplxTrans trans)

Description: Creates a hierarchical edge pair collection from an original layer with a transformation

This constructor creates an edge pair collection from the shapes delivered by the given recursive shape iterator. This version will create a hierarchical edge pair collection which supports hierarchical operations. The transformation is useful to scale to a specific database unit for example. Edge pairs in layout objects are somewhat special as most formats don't support reading or writing of edge pairs. Still they are useful objects and can be created and manipulated inside layouts.

```
dss    = RBA::DeepShapeStore::new
```

```
layout = ... # a layout
cell   = ... # the index of the initial cell
layer  = ... # the index of the layer from where to take the shapes from
dbu    = 0.1 # the target database unit
r = RBA::EdgePairs::new(layout.begin_shapes(cell, layer),
 RBA::ICplxTrans::new(layout.dbu / dbu))
```

This constructor has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

polygons

(1) Signature: *[const]* Region **polygons**

Description: Converts the edge pairs to polygons

This method creates polygons from the edge pairs. Each polygon will be a triangle or quadrangle which connects the start and end points of the edges forming the edge pair.

(2) Signature: *[const]* Region **polygons** (int e)

Description: Converts the edge pairs to polygons

This method creates polygons from the edge pairs. Each polygon will be a triangle or quadrangle which connects the start and end points of the edges forming the edge pair. This version allows one to specify an enlargement which is applied to the edges. The length of the edges is modified by applying the enlargement and the edges are shifted by the enlargement. By specifying an enlargement it is possible to give edge pairs an area which otherwise would not have one (coincident edges, two point-like edges).

process

Signature: void **process** (const EdgePairOperator ptr process)

Description: Applies a generic edge pair processor in place (replacing the edge pairs from the EdgePairs collection)

See EdgePairProcessor for a description of this feature.

This method has been introduced in version 0.29.

processed

(1) Signature: *[const]* EdgePairs **processed** (const EdgePairOperator ptr processed)

Description: Applies a generic edge pair processor and returns a processed copy

See EdgePairProcessor for a description of this feature.

This method has been introduced in version 0.29.

(2) Signature: *[const]* Edges **processed** (const EdgePairToEdgeOperator ptr processed)

Description: Applies a generic edge-pair-to-edge processor and returns an edge collection with the results

See EdgePairToEdgeProcessor for a description of this feature.

This method has been introduced in version 0.29.

(3) Signature: *[const]* Region **processed** (const EdgePairToPolygonOperator ptr processed)

Description: Applies a generic edge-pair-to-polygon processor and returns an Region with the results

See EdgePairToPolygonProcessor for a description of this feature.

This method has been introduced in version 0.29.

remove_properties

Signature: void **remove_properties**

Description: Removes properties for the given container.

This will remove all properties on the given container.

This method has been introduced in version 0.28.4.

second_edges

Signature: *[const]* Edges **second_edges**

Description: Returns the second one of all edges

Returns: An edge collection containing the second edges

size

Signature: *[const]* unsigned long **size**

Description: Returns the (flat) number of edge pairs in the edge pair collection

Use of this method is deprecated. Use count instead

The count is computed 'as if flat', i.e. edge pairs inside a cell are multiplied by the number of times a cell is instantiated.

Starting with version 0.27, the method is called 'count' for consistency with Region. 'size' is still provided as an alias.

Python specific notes:
This method is also available as 'len(object)'.

swap

Signature: void **swap** (EdgePairs other)

Description: Swap the contents of this collection with the contents of another collection

This method is useful to avoid excessive memory allocation in some cases. For managed memory languages such as Ruby, those cases will be rare.

to_s

(1) Signature: *[const]* string **to_s**

Description: Converts the edge pair collection to a string

The length of the output is limited to 20 edge pairs to avoid giant strings on large regions. For full output use "to_s" with a maximum count parameter.

Python specific notes:
This method is also available as 'str(object)'.

(2) Signature: *[const]* string **to_s** (unsigned long max_count)

Description: Converts the edge pair collection to a string

This version allows specification of the maximum number of edge pairs contained in the string.

transform

(1) Signature: EdgePairs **transform** (const Trans t)

Description: Transform the edge pair collection (modifies self)

t: The transformation to apply.

Returns: The transformed edge pair collection.

Transforms the edge pair collection with the given transformation. This version modifies the edge pair collection and returns a reference to self.

(2) Signature: EdgePairs **transform** (const ICplxTrans t)

Description: Transform the edge pair collection with a complex transformation (modifies self)

t: The transformation to apply.

Returns: The transformed edge pair collection.

Transforms the edge pair collection with the given transformation. This version modifies the edge pair collection and returns a reference to self.

(3) Signature: EdgePairs **transform** (const IMatrix2d t)

Description: Transform the edge pair collection (modifies self)

t: The transformation to apply.

Returns: The transformed edge pair collection.

Transforms the edge pair collection with the given 2d matrix transformation. This version modifies the edge pair collection and returns a reference to self.

This variant has been introduced in version 0.27.

(4) Signature: EdgePairs **transform** (const IMatrix3d t)

Description: Transform the edge pair collection (modifies self)

t: The transformation to apply.

Returns: The transformed edge pair collection.

Transforms the edge pair collection with the given 3d matrix transformation. This version modifies the edge pair collection and returns a reference to self.

This variant has been introduced in version 0.27.

transform_icplx

Signature: EdgePairs **transform_icplx** (const ICplxTrans t)

Description: Transform the edge pair collection with a complex transformation (modifies self)

t: The transformation to apply.

Returns: The transformed edge pair collection.

Use of this method is deprecated. Use transform instead

Transforms the edge pair collection with the given transformation. This version modifies the edge pair collection and returns a reference to self.

transformed

(1) Signature: *[const]* EdgePairs **transformed** (const Trans t)

Description: Transform the edge pair collection

t: The transformation to apply.

Returns: The transformed edge pairs.

Transforms the edge pairs with the given transformation. Does not modify the edge pair collection but returns the transformed edge pairs.

(2) Signature: *[const]* EdgePairs **transformed** (const ICplxTrans t)

Description: Transform the edge pair collection with a complex transformation

t: The transformation to apply.

Returns: The transformed edge pairs.

Transforms the edge pairs with the given complex transformation. Does not modify the edge pair collection but returns the transformed edge pairs.

(3) Signature: *[const]* EdgePairs **transformed** (const IMatrix2d t)

Description: Transform the edge pair collection

t: The transformation to apply.

Returns: The transformed edge pairs.

Transforms the edge pairs with the given 2d matrix transformation. Does not modify the edge pair collection but returns the transformed edge pairs.

This variant has been introduced in version 0.27.

(4) Signature: *[const]* EdgePairs **transformed** (const IMatrix3d t)

Description: Transform the edge pair collection

t: The transformation to apply.

Returns: The transformed edge pairs.

Transforms the edge pairs with the given 3d matrix transformation. Does not modify the edge pair collection but returns the transformed edge pairs.

This variant has been introduced in version 0.27.

transformed_icplx

Signature: *[const]* EdgePairs **transformed_icplx** (const ICplxTrans t)

Description: Transform the edge pair collection with a complex transformation

t: The transformation to apply.

Returns: The transformed edge pairs.

Use of this method is deprecated. Use transformed instead

Transforms the edge pairs with the given complex transformation. Does not modify the edge pair collection but returns the transformed edge pairs.

with_angle

(1) Signature: *[const]* EdgePairs **with_angle** (double angle, bool inverse)

Description: Filter the edge pairs by orientation of their edges

Filters the edge pairs in the edge pair collection by orientation. If "inverse" is false, only edge pairs with at least one edge having the given angle to the x-axis are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

This will filter edge pairs with at least one horizontal edge:

```
horizontal = edge_pairs.with_angle(0, false)
```

Note that the inverse **result** of with_angle is delivered by with_angle_both with the inverse flag set as edge pairs are unselected when both edges fail to meet the criterion. I.e

```
result = edge_pairs.with_angle(0, false)
others = edge_pairs.with_angle_both(0, true)
```

This method has been added in version 0.27.1.

(2) Signature: *[const]* EdgePairs **with_angle** (double min_angle, double max_angle, bool inverse, bool include_min_angle = true, bool include_max_angle = false)

Description: Filter the edge pairs by orientation of their edges

Filters the edge pairs in the edge pair collection by orientation. If "inverse" is false, only edge pairs with at least one edge having an angle between min_angle and max_angle are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

With "include_min_angle" set to true (the default), the minimum angle is included in the criterion while with false, the minimum angle itself is not included. Same for "include_max_angle" where the default is false, meaning the maximum angle is not included in the range.

Note that the inverse **result** of with_angle is delivered by with_angle_both with the inverse flag set as edge pairs are unselected when both edges fail to meet the criterion. I.e

```
result = edge_pairs.with_angle(0, 45, false)
others = edge_pairs.with_angle_both(0, 45, true)
```

This method has been added in version 0.27.1.

(3) Signature: *[const]* EdgePairs **with_angle** (Edges::EdgeType type, bool inverse)

Description: Filter the edge pairs by orientation of their edges

Filters the edge pairs in the edge pair collection by orientation. If "inverse" is false, only edge pairs with at least one edge having an angle of the given type are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

This version allows specifying an edge type instead of an angle. Edge types include multiple distinct orientations and are specified using one of the Edges#OrthoEdges, Edges#DiagonalEdges or Edges#OrthoDiagonalEdges types.

Note that the inverse **result** of with_angle is delivered by with_angle_both with the inverse flag set as edge pairs are unselected when both edges fail to meet the criterion. I.e

```
result = edge_pairs.with_angle(RBA::Edges::Ortho, false)
others = edge_pairs.with_angle_both(RBA::Edges::Ortho, true)
```

This method has been added in version 0.28.

with_angle_both

(1) Signature: *[const]* EdgePairs **with_angle_both** (double angle, bool inverse)

Description: Filter the edge pairs by orientation of both of their edges

Filters the edge pairs in the edge pair collection by orientation. If "inverse" is false, only edge pairs with both edges having the given angle to the x-axis are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

This will filter edge pairs with at least one horizontal edge:

```
horizontal = edge_pairs.with_angle_both(0, false)
```

Note that the inverse **result** of with_angle_both is delivered by with_angle with the inverse flag set as edge pairs are unselected when one edge fails to meet the criterion. I.e

```
result = edge_pairs.with_angle_both(0, false)
others = edge_pairs.with_angle(0, true)
```

This method has been added in version 0.27.1.

(2) Signature: *[const]* EdgePairs **with_angle_both** (double min_angle, double max_angle, bool inverse, bool include_min_angle = true, bool include_max_angle = false)

Description: Filter the edge pairs by orientation of both of their edges

Filters the edge pairs in the edge pair collection by orientation. If "inverse" is false, only edge pairs with both edges having an angle between min_angle and max_angle are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

With "include_min_angle" set to true (the default), the minimum angle is included in the criterion while with false, the minimum angle itself is not included. Same for "include_max_angle" where the default is false, meaning the maximum angle is not included in the range.

Note that the inverse **result** of with_angle_both is delivered by with_angle with the inverse flag set as edge pairs are unselected when one edge fails to meet the criterion. I.e

```
result = edge_pairs.with_angle_both(0, 45, false)
others = edge_pairs.with_angle(0, 45, true)
```

This method has been added in version 0.27.1.

(3) Signature: *[const]* EdgePairs **with_angle_both** (Edges::EdgeType type, bool inverse)

Description: Filter the edge pairs by orientation of their edges

Filters the edge pairs in the edge pair collection by orientation. If "inverse" is false, only edge pairs with both edges having an angle of the given type are returned. If "inverse" is true, edge pairs not fulfilling this criterion for both edges are returned.

This version allows specifying an edge type instead of an angle. Edge types include multiple distinct orientations and are specified using one of the Edges#OrthoEdges, Edges#DiagonalEdges or Edges#OrthoDiagonalEdges types.

Note that the inverse **result** of with_angle_both is delivered by with_angle with the inverse flag set as edge pairs are unselected when one edge fails to meet the criterion. I.e

```
result = edge_pairs.with_angle_both(RBA::Edges::Ortho, false)
others = edge_pairs.with_angle(RBA::Edges::Ortho, true)
```

This method has been added in version 0.28.

with_area

(1) Signature: *[const]* EdgePairs **with_area** (long area, bool inverse)

Description: Filters the edge pairs by the enclosed area

Filters the edge pairs in the edge pair collection by enclosed area. If "inverse" is false, only edge pairs with the given area are returned. If "inverse" is true, edge pairs not with the given area are returned.

This method has been added in version 0.27.2.

(2) Signature: *[const]* EdgePairs **with_area** (long min_area, long max_area, bool inverse)

Description: Filters the edge pairs by the enclosed area

Filters the edge pairs in the edge pair collection by enclosed area. If "inverse" is false, only edge pairs with an area between min_area and max_area (max_area itself is excluded) are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

This method has been added in version 0.27.2.

with_distance

(1) Signature: *[const]* EdgePairs **with_distance** (unsigned int distance, bool inverse)

Description: Filters the edge pairs by the distance of the edges

Filters the edge pairs in the edge pair collection by distance of the edges. If "inverse" is false, only edge pairs where both edges have the given distance are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

Distance is measured as the shortest distance between any of the points on the edges.

This method has been added in version 0.27.1.

(2) Signature: *[const]* EdgePairs **with_distance** (variant min_distance, variant max_distance, bool inverse)

Description: Filters the edge pairs by the distance of the edges

Filters the edge pairs in the edge pair collection by distance of the edges. If "inverse" is false, only edge pairs where both edges have a distance between min_distance and max_distance (max_distance itself is excluded) are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

Distance is measured as the shortest distance between any of the points on the edges.

This method has been added in version 0.27.1.

with_internal_angle

(1) Signature: *[const]* EdgePairs **with_internal_angle** (double angle, bool inverse)

Description: Filters the edge pairs by the angle between their edges

Filters the edge pairs in the edge pair collection by the angle between their edges. If "inverse" is false, only edge pairs with the given angle are returned. If "inverse" is true, edge pairs not with the given angle are returned.

The angle is measured between the two edges. It is between 0 (parallel or anti-parallel edges) and 90 degree (perpendicular edges).

This method has been added in version 0.27.2.

(2) Signature: *[const]* EdgePairs **with_internal_angle** (double min_angle, double max_angle, bool inverse, bool include_min_angle = true, bool include_max_angle = false)

Description: Filters the edge pairs by the angle between their edges

Filters the edge pairs in the edge pair collection by the angle between their edges. If "inverse" is false, only edge pairs with an angle between min_angle and max_angle (max_angle itself is excluded) are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

The angle is measured between the two edges. It is between 0 (parallel or anti-parallel edges) and 90 degree (perpendicular edges).

With "include_min_angle" set to true (the default), the minimum angle is included in the criterion while with false, the minimum angle itself is not included. Same for "include_max_angle" where the default is false, meaning the maximum angle is not included in the range.

This method has been added in version 0.27.2.

with_length

(1) Signature: *[const]* EdgePairs **with_length** (unsigned int length, bool inverse)

Description: Filters the edge pairs by length of one of their edges

Filters the edge pairs in the edge pair collection by length of at least one of their edges. If "inverse" is false, only edge pairs with at least one edge having the given length are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

This method has been added in version 0.27.1.

(2) Signature: *[const]* EdgePairs **with_length** (variant min_length, variant max_length, bool inverse)

Description: Filters the edge pairs by length of one of their edges

Filters the edge pairs in the edge pair collection by length of at least one of their edges. If "inverse" is false, only edge pairs with at least one edge having a length between min_length and max_length (excluding max_length itself) are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

If you don't want to specify a lower or upper limit, pass nil to that parameter.

This method has been added in version 0.27.1.

with_length_both

(1) Signature: *[const]* EdgePairs **with_length_both** (unsigned int length, bool inverse)

Description: Filters the edge pairs by length of both of their edges

Filters the edge pairs in the edge pair collection by length of both of their edges. If "inverse" is false, only edge pairs where both edges have the given length are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

This method has been added in version 0.27.1.

(2) Signature: *[const]* EdgePairs **with_length_both** (variant min_length, variant max_length, bool inverse)

Description: Filters the edge pairs by length of both of their edges

Filters the edge pairs in the edge pair collection by length of both of their edges. If "inverse" is false, only edge pairs with both edges having a length between min_length and max_length (excluding max_length itself) are returned. If "inverse" is true, edge pairs not fulfilling this criterion are returned.

If you don't want to specify a lower or upper limit, pass nil to that parameter.

This method has been added in version 0.27.1.

write

Signature: *[const]* void **write** (string filename)

Description: Writes the region to a file

This method is provided for debugging purposes. It writes the object to a flat layer 0/0 in a single top cell.

This method has been introduced in version 0.29.

4.42. API reference - Class EdgeProcessor

Notation used in Ruby API documentation

Module: db

Description: The edge processor (boolean, sizing, merge)

The edge processor implements the boolean and edge set operations (size, merge). Because the edge processor might allocate resources which can be reused in later operations, it is implemented as an object that can be used several times.

Here is a simple example of how to use the edge processor:

```
ep = RBA::EdgeProcessor::new
# Prepare two boxes
a = [ RBA::Polygon::new(RBA::Box::new(0, 0, 300, 300)) ]
b = [ RBA::Polygon::new(RBA::Box::new(100, 100, 200, 200)) ]
# Run an XOR -> creates a polygon with a hole, since the 'resolve_holes' parameter
# is false:
out = ep.boolean_p2p(a, b, RBA::EdgeProcessor::ModeXor, false, false)
out.to_s    # -> [(0,0;0,300;300,300;300,0/100,100;200,100;200,200;100,200)]
```

Public constructors

new EdgeProcessor ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const EdgeProcessor other)	Assigns another object to self
	Edge[]	**boolean_e2e**	(Edge[] a, Edge[] b, int mode)	Boolean operation for a set of given edges, creating edges
	Polygon[]	**boolean_e2p**	(Edge[] a, Edge[] b, int mode, bool resolve_holes, bool min_coherence)	Boolean operation for a set of given edges, creating polygons

	Edge[]	**boolean_p2e**	(Polygon[] a, Polygon[] b, int mode)	Boolean operation for a set of given polygons, creating edges
	Polygon[]	**boolean_p2p**	(Polygon[] a, Polygon[] b, int mode, bool resolve_holes, bool min_coherence)	Boolean operation for a set of given polygons, creating polygons
	void	**disable_progress**		Disable progress reporting
[const]	new EdgeProcessor ptr	**dup**		Creates a copy of self
	void	**enable_progress**	(string label)	Enable progress reporting
	Edge[]	**merge_p2e**	(Polygon[] in, unsigned int min_wc)	Merge the given polygons
	Polygon[]	**merge_p2p**	(Polygon[] in, unsigned int min_wc, bool resolve_holes, bool min_coherence)	Merge the given polygons
	Edge[]	**simple_merge_e2e**	(Edge[] in)	Merge the given edges in a simple "non-zero wrapcount" fashion
	Edge[]	**simple_merge_e2e**	(Edge[] in, int mode)	Merge the given polygons and specify the merge mode
	Polygon[]	**simple_merge_e2p**	(Edge[] in, bool resolve_holes, bool min_coherence)	Merge the given edges in a simple "non-zero wrapcount" fashion into polygons
	Polygon[]	**simple_merge_e2p**	(Edge[] in, bool resolve_holes, bool min_coherence, int mode)	Merge the given polygons and specify the merge mode
	Edge[]	**simple_merge_p2e**	(Polygon[] in)	Merge the given polygons in a simple "non-zero wrapcount" fashion
	Edge[]	**simple_merge_p2e**	(Polygon[] in, int mode)	Merge the given polygons and specify the merge mode
	Polygon[]	**simple_merge_p2p**	(Polygon[] in, bool resolve_holes, bool min_coherence)	Merge the given polygons in a simple "non-zero wrapcount" fashion into polygons
	Polygon[]	**simple_merge_p2p**	(Polygon[] in, bool resolve_holes, bool min_coherence, int mode)	Merge the given polygons and specify the merge mode
	Edge[]	**size_p2e**	(Polygon[] in, int dx, int dy,	Size the given polygons

		unsigned int mode)	
Edge[]	size_p2e	(Polygon[] in, int d, unsigned int mode)	Size the given polygons (isotropic)
Polygon[]	size_p2p	(Polygon[] in, int dx, int dy, unsigned int mode, bool resolve_holes, bool min_coherence)	Size the given polygons into polygons
Polygon[]	size_p2p	(Polygon[] in, int d, unsigned int mode, bool resolve_holes, bool min_coherence)	Size the given polygons into polygons (isotropic)

Public static methods and constants

int	ModeANotB	boolean method's mode value for A NOT B operation
int	ModeAnd	boolean method's mode value for AND operation
int	ModeBNotA	boolean method's mode value for B NOT A operation
int	ModeOr	boolean method's mode value for OR operation
int	ModeXor	boolean method's mode value for XOR operation

Deprecated methods (protected, public, static, non-static and constructors)

Edge[]	boolean	(Polygon[] a, Polygon[] b, int mode)	Use of this method is deprecated. Use boolean_p2e instead
Edge[]	boolean	(Edge[] a, Edge[] b, int mode)	Use of this method is deprecated. Use boolean_e2e instead
Polygon[]	boolean_to_polygon	(Polygon[] a, Polygon[] b, int mode, bool resolve_holes, bool min_coherence)	Use of this method is deprecated. Use boolean_p2p instead
Polygon[]	boolean_to_polygon	(Edge[] a, Edge[] b, int mode, bool resolve_holes, bool min_coherence)	Use of this method is deprecated. Use boolean_e2p instead
void	create		Use of this method is deprecated. Use _create instead

	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead
	Edge[]	**merge**	(Polygon[] in, unsigned int min_wc)	Use of this method is deprecated. Use merge_p2e instead
	Polygon[]	**merge_to_polygon**	(Polygon[] in, unsigned int min_wc, bool resolve_holes, bool min_coherence)	Use of this method is deprecated. Use merge_p2p instead
[static]	int	**mode_and**		Use of this method is deprecated. Use ModeAnd instead
[static]	int	**mode_anotb**		Use of this method is deprecated. Use ModeANotB instead
[static]	int	**mode_bnota**		Use of this method is deprecated. Use ModeBNotA instead
[static]	int	**mode_or**		Use of this method is deprecated. Use ModeOr instead
[static]	int	**mode_xor**		Use of this method is deprecated. Use ModeXor instead
	Edge[]	**simple_merge**	(Polygon[] in)	Use of this method is deprecated. Use simple_merge_p2e instead
	Edge[]	**simple_merge**	(Polygon[] in, int mode)	Use of this method is deprecated. Use simple_merge_p2e instead
	Edge[]	**simple_merge**	(Edge[] in)	Use of this method is deprecated. Use simple_merge_e2e instead
	Edge[]	**simple_merge**	(Edge[] in, int mode)	Use of this method is deprecated. Use simple_merge_e2e instead
	Polygon[]	**simple_merge_to_polygon**	(Polygon[] in, bool resolve_holes, bool min_coherence)	Use of this method is deprecated. Use simple_merge_p2p instead
	Polygon[]	**simple_merge_to_pol**	(Polygon[] in, bool resolve_holes, bool min_coherence, int mode)	Use of this method is deprecated. Use simple_merge_p2p instead
	Polygon[]	**simple_merge_to_polygon**	(Edge[] in, bool resolve_holes, bool min_coherence)	Use of this method is deprecated. Use simple_merge_e2p instead
	Polygon[]	**simple_merge_to_pol**	(Edge[] in, bool resolve_holes, bool min_coherence,	Use of this method is deprecated. Use simple_merge_e2p instead

		int mode)	
Edge[]	size	(Polygon[] in, int dx, int dy, unsigned int mode)	Use of this method is deprecated. Use size_p2e instead
Edge[]	size	(Polygon[] in, int d, unsigned int mode)	Use of this method is deprecated. Use size_p2e instead
Polygon[]	size_to_polygon	(Polygon[] in, int dx, int dy, unsigned int mode, bool resolve_holes, bool min_coherence)	Use of this method is deprecated. Use size_p2p instead
Polygon[]	size_to_polygon	(Polygon[] in, int d, unsigned int mode, bool resolve_holes, bool min_coherence)	Use of this method is deprecated. Use size_p2p instead

Detailed description

ModeANotB

Signature: *[static]* int **ModeANotB**

Description: boolean method's mode value for A NOT B operation

Python specific notes:
The object exposes a readable attribute 'ModeANotB'. This is the getter.

ModeAnd

Signature: *[static]* int **ModeAnd**

Description: boolean method's mode value for AND operation

Python specific notes:
The object exposes a readable attribute 'ModeAnd'. This is the getter.

ModeBNotA

Signature: *[static]* int **ModeBNotA**

Description: boolean method's mode value for B NOT A operation

Python specific notes:
The object exposes a readable attribute 'ModeBNotA'. This is the getter.

ModeOr

Signature: *[static]* int **ModeOr**

Description: boolean method's mode value for OR operation

Python specific notes:
The object exposes a readable attribute 'ModeOr'. This is the getter.

ModeXor

Signature: *[static]* int **ModeXor**

Description: boolean method's mode value for XOR operation

Python specific notes:
The object exposes a readable attribute 'ModeXor'. This is the getter.

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const EdgeProcessor other)

Description: Assigns another object to self

boolean

(1) Signature: Edge[] **boolean** (Polygon[] a, Polygon[] b, int mode)

Description: Boolean operation for a set of given polygons, creating edges

a:	The input polygons (first operand)
b:	The input polygons (second operand)
mode:	The boolean mode
Returns:	The output edges

Use of this method is deprecated. Use boolean_p2e instead

This method computes the result for the given boolean operation on two sets of polygons. The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a Boolean operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'boolean'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Edge[] **boolean** (Edge[] a, Edge[] b, int mode)

Description: Boolean operation for a set of given edges, creating edges

a:	The input edges (first operand)
b:	The input edges (second operand)
mode:	The boolean mode (one of the Mode.. values)
Returns:	The output edges

Use of this method is deprecated. Use boolean_e2e instead

This method computes the result for the given boolean operation on two sets of edges. The input edges must form closed contours where holes and hulls must be oriented differently. The input edges are processed with a simple non-zero wrap count rule as a whole.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

Prior to version 0.21 this method was called 'boolean'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

boolean_e2e

Signature: Edge[] **boolean_e2e** (Edge[] a, Edge[] b, int mode)

Description: Boolean operation for a set of given edges, creating edges

a:	The input edges (first operand)
b:	The input edges (second operand)
mode:	The boolean mode (one of the Mode.. values)
Returns:	The output edges

This method computes the result for the given boolean operation on two sets of edges. The input edges must form closed contours where holes and hulls must be oriented differently. The input edges are processed with a simple non-zero wrap count rule as a whole.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

Prior to version 0.21 this method was called 'boolean'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

boolean_e2p

Signature: Polygon[] **boolean_e2p** (Edge[] a, Edge[] b, int mode, bool resolve_holes, bool min_coherence)

Description: Boolean operation for a set of given edges, creating polygons

a:	The input polygons (first operand)
b:	The input polygons (second operand)
mode:	The boolean mode (one of the Mode.. values)
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours

Returns: The output polygons

This method computes the result for the given boolean operation on two sets of edges. The input edges must form closed contours where holes and hulls must be oriented differently. The input edges are processed with a simple non-zero wrap count rule as a whole.

This method produces polygons on output and allows fine-tuning of the parameters for that purpose.

Prior to version 0.21 this method was called 'boolean_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

boolean_p2e

Signature: Edge[] **boolean_p2e** (Polygon[] a, Polygon[] b, int mode)

Description: Boolean operation for a set of given polygons, creating edges

a:	The input polygons (first operand)
b:	The input polygons (second operand)
mode:	The boolean mode
Returns:	The output edges

This method computes the result for the given boolean operation on two sets of polygons. The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a Boolean operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'boolean'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

boolean_p2p

Signature: Polygon[] **boolean_p2p** (Polygon[] a, Polygon[] b, int mode, bool resolve_holes, bool min_coherence)

Description: Boolean operation for a set of given polygons, creating polygons

a:	The input polygons (first operand)
b:	The input polygons (second operand)
mode:	The boolean mode (one of the Mode.. values)
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

This method computes the result for the given boolean operation on two sets of polygons. This method produces polygons on output and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a Boolean operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'boolean_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

boolean_to_polygon

(1) Signature: Polygon[] **boolean_to_polygon** (Polygon[] a, Polygon[] b, int mode, bool resolve_holes, bool min_coherence)

Description: Boolean operation for a set of given polygons, creating polygons

a:	The input polygons (first operand)
b:	The input polygons (second operand)
mode:	The boolean mode (one of the Mode.. values)
resolve_holes:	true, if holes should be resolved into the hull

min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

Use of this method is deprecated. Use boolean_p2p instead

This method computes the result for the given boolean operation on two sets of polygons. This method produces polygons on output and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a Boolean operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'boolean_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Polygon[] **boolean_to_polygon** (Edge[] a, Edge[] b, int mode, bool resolve_holes, bool min_coherence)

Description: Boolean operation for a set of given edges, creating polygons

a:	The input polygons (first operand)
b:	The input polygons (second operand)
mode:	The boolean mode (one of the Mode.. values)
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

Use of this method is deprecated. Use boolean_e2p instead

This method computes the result for the given boolean operation on two sets of edges. The input edges must form closed contours where holes and hulls must be oriented differently. The input edges are processed with a simple non-zero wrap count rule as a whole.

This method produces polygons on output and allows fine-tuning of the parameters for that purpose.

Prior to version 0.21 this method was called 'boolean_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

disable_progress

Signature: void **disable_progress**

Description: Disable progress reporting

Calling this method will stop the edge processor from showing a progress bar. See enable_progress.

This method has been introduced in version 0.23.

dup

Signature: *[const]* new EdgeProcessor ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

enable_progress

Signature: void **enable_progress** (string label)

Description: Enable progress reporting

After calling this method, the edge processor will report the progress through a progress bar. The label is a text which is put in front of the progress bar. Using a progress bar will imply a performance penalty of a few percent typically.

This method has been introduced in version 0.23.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

merge

Signature: Edge[] **merge** (Polygon[] in, unsigned int min_wc)

Description: Merge the given polygons

in:	The input polygons
min_wc:	The minimum wrap count for output (0: all polygons, 1: at least two overlapping)
Returns:	The output edges

Use of this method is deprecated. Use merge_p2e instead

In contrast to "simple_merge", this merge implementation considers each polygon individually before merging them. Thus self-overlaps are effectively removed before the output is computed and holes are correctly merged with the hull. In addition, this method allows selecting areas with a higher wrap count which in turn allows computing overlaps of polygons on the same layer. Because this method merges the polygons before the overlap is computed, self-overlapping polygons do not contribute to higher wrap count areas.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

Prior to version 0.21 this method was called 'merge'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

merge_p2e

Signature: Edge[] **merge_p2e** (Polygon[] in, unsigned int min_wc)

Description: Merge the given polygons

in:	The input polygons

min_wc: The minimum wrap count for output (0: all polygons, 1: at least two overlapping)

Returns: The output edges

In contrast to "simple_merge", this merge implementation considers each polygon individually before merging them. Thus self-overlaps are effectively removed before the output is computed and holes are correctly merged with the hull. In addition, this method allows selecting areas with a higher wrap count which in turn allows computing overlaps of polygons on the same layer. Because this method merges the polygons before the overlap is computed, self-overlapping polygons do not contribute to higher wrap count areas.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

Prior to version 0.21 this method was called 'merge'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

merge_p2p

Signature: Polygon[] **merge_p2p** (Polygon[] in, unsigned int min_wc, bool resolve_holes, bool min_coherence)

Description: Merge the given polygons

in: The input polygons

min_wc: The minimum wrap count for output (0: all polygons, 1: at least two overlapping)

resolve_holes: true, if holes should be resolved into the hull

min_coherence: true, if touching corners should be resolved into less connected contours

Returns: The output polygons

In contrast to "simple_merge", this merge implementation considers each polygon individually before merging them. Thus self-overlaps are effectively removed before the output is computed and holes are correctly merged with the hull. In addition, this method allows selecting areas with a higher wrap count which in turn allows computing overlaps of polygons on the same layer. Because this method merges the polygons before the overlap is computed, self-overlapping polygons do not contribute to higher wrap count areas.

This method produces polygons and allows fine-tuning of the parameters for that purpose.

Prior to version 0.21 this method was called 'merge_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

merge_to_polygon

Signature: Polygon[] **merge_to_polygon** (Polygon[] in, unsigned int min_wc, bool resolve_holes, bool min_coherence)

Description: Merge the given polygons

in: The input polygons

min_wc: The minimum wrap count for output (0: all polygons, 1: at least two overlapping)

resolve_holes: true, if holes should be resolved into the hull

min_coherence: true, if touching corners should be resolved into less connected contours

Returns: The output polygons

Use of this method is deprecated. Use merge_p2p instead

In contrast to "simple_merge", this merge implementation considers each polygon individually before merging them. Thus self-overlaps are effectively removed before the output is computed and holes are correctly merged with the hull. In addition, this method allows selecting areas with a higher wrap count which in turn allows computing overlaps of polygons on the same layer. Because this method merges

	the polygons before the overlap is computed, self-overlapping polygons do not contribute to higher wrap count areas. This method produces polygons and allows fine-tuning of the parameters for that purpose. Prior to version 0.21 this method was called 'merge_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.
mode_and	**Signature**: *[static]* int **mode_and** **Description**: boolean method's mode value for AND operation Use of this method is deprecated. Use ModeAnd instead **Python specific notes:** The object exposes a readable attribute 'ModeAnd'. This is the getter.
mode_anotb	**Signature**: *[static]* int **mode_anotb** **Description**: boolean method's mode value for A NOT B operation Use of this method is deprecated. Use ModeANotB instead **Python specific notes:** The object exposes a readable attribute 'ModeANotB'. This is the getter.
mode_bnota	**Signature**: *[static]* int **mode_bnota** **Description**: boolean method's mode value for B NOT A operation Use of this method is deprecated. Use ModeBNotA instead **Python specific notes:** The object exposes a readable attribute 'ModeBNotA'. This is the getter.
mode_or	**Signature**: *[static]* int **mode_or** **Description**: boolean method's mode value for OR operation Use of this method is deprecated. Use ModeOr instead **Python specific notes:** The object exposes a readable attribute 'ModeOr'. This is the getter.
mode_xor	**Signature**: *[static]* int **mode_xor** **Description**: boolean method's mode value for XOR operation Use of this method is deprecated. Use ModeXor instead **Python specific notes:** The object exposes a readable attribute 'ModeXor'. This is the getter.
new	**Signature**: *[static]* new EdgeProcessor ptr **new** **Description**: Creates a new object of this class **Python specific notes:** This method is the default initializer of the object.
simple_merge	**(1) Signature**: Edge[] **simple_merge** (Polygon[] in) **Description**: Merge the given polygons in a simple "non-zero wrapcount" fashion **in**: The input polygons **Returns**: The output edges Use of this method is deprecated. Use simple_merge_p2e instead

The wrapcount is computed over all polygons, i.e. overlapping polygons may "cancel" if they have different orientation (since a polygon is oriented by construction that is not easy to achieve). The other merge operation provided for this purpose is "merge" which normalizes each polygon individually before merging them. "simple_merge" is somewhat faster and consumes less memory.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'simple_merge'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Edge[] **simple_merge** (Polygon[] in, int mode)

Description: Merge the given polygons and specify the merge mode

mode:	See description
in:	The input polygons
Returns:	The output edges

Use of this method is deprecated. Use simple_merge_p2e instead

The wrapcount is computed over all polygons, i.e. overlapping polygons may "cancel" if they have different orientation (since a polygon is oriented by construction that is not easy to achieve). The other merge operation provided for this purpose is "merge" which normalizes each polygon individually before merging them. "simple_merge" is somewhat faster and consumes less memory.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

This method has been added in version 0.22.

The mode specifies the rule to use when producing output. A value of 0 specifies the even-odd rule. A positive value specifies the wrap count threshold (positive only). A negative value specifies the threshold of the absolute value of the wrap count (i.e. -1 is non-zero rule).

(3) Signature: Edge[] **simple_merge** (Edge[] in)

Description: Merge the given edges in a simple "non-zero wrapcount" fashion

in:	The input edges
Returns:	The output edges

Use of this method is deprecated. Use simple_merge_e2e instead

The edges provided must form valid closed contours. Contours oriented differently "cancel" each other. Overlapping contours are merged when the orientation is the same.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'simple_merge'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(4) Signature: Edge[] **simple_merge** (Edge[] in, int mode)

Description: Merge the given polygons and specify the merge mode

mode:	See description
in:	The input edges

Returns: The output edges

Use of this method is deprecated. Use simple_merge_e2e instead

The edges provided must form valid closed contours. Contours oriented differently "cancel" each other. Overlapping contours are merged when the orientation is the same.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

This method has been added in version 0.22.

The mode specifies the rule to use when producing output. A value of 0 specifies the even-odd rule. A positive value specifies the wrap count threshold (positive only). A negative value specifies the threshold of the absolute value of the wrap count (i.e. -1 is non-zero rule).

simple_merge_e2e

(1) Signature: Edge[] **simple_merge_e2e** (Edge[] in)

Description: Merge the given edges in a simple "non-zero wrapcount" fashion

in: The input edges

Returns: The output edges

The edges provided must form valid closed contours. Contours oriented differently "cancel" each other. Overlapping contours are merged when the orientation is the same.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'simple_merge'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Edge[] **simple_merge_e2e** (Edge[] in, int mode)

Description: Merge the given polygons and specify the merge mode

mode: See description

in: The input edges

Returns: The output edges

The edges provided must form valid closed contours. Contours oriented differently "cancel" each other. Overlapping contours are merged when the orientation is the same.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

This method has been added in version 0.22.

The mode specifies the rule to use when producing output. A value of 0 specifies the even-odd rule. A positive value specifies the wrap count threshold (positive only). A negative value specifies the threshold of the absolute value of the wrap count (i.e. -1 is non-zero rule).

simple_merge_e2p

(1) Signature: Polygon[] **simple_merge_e2p** (Edge[] in, bool resolve_holes, bool min_coherence)

Description: Merge the given edges in a simple "non-zero wrapcount" fashion into polygons

in: The input edges

resolve_holes: true, if holes should be resolved into the hull

min_coherence: true, if touching corners should be resolved into less connected contours

Returns: The output polygons

The edges provided must form valid closed contours. Contours oriented differently "cancel" each other. Overlapping contours are merged when the orientation is the same.

This method produces polygons and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'simple_merge_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Polygon[] **simple_merge_e2p** (Edge[] in, bool resolve_holes, bool min_coherence, int mode)

Description: Merge the given polygons and specify the merge mode

mode: See description

in: The input edges

resolve_holes: true, if holes should be resolved into the hull

min_coherence: true, if touching corners should be resolved into less connected contours

Returns: The output polygons

The edges provided must form valid closed contours. Contours oriented differently "cancel" each other. Overlapping contours are merged when the orientation is the same.

This method produces polygons and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

This method has been added in version 0.22.

The mode specifies the rule to use when producing output. A value of 0 specifies the even-odd rule. A positive value specifies the wrap count threshold (positive only). A negative value specifies the threshold of the absolute value of the wrap count (i.e. -1 is non-zero rule).

simple_merge_p2e

(1) Signature: Edge[] **simple_merge_p2e** (Polygon[] in)

Description: Merge the given polygons in a simple "non-zero wrapcount" fashion

in: The input polygons

Returns: The output edges

The wrapcount is computed over all polygons, i.e. overlapping polygons may "cancel" if they have different orientation (since a polygon is oriented by construction that is not easy to achieve). The other merge operation provided for this purpose is "merge" which normalizes each polygon individually before merging them. "simple_merge" is somewhat faster and consumes less memory.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'simple_merge'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Edge[] **simple_merge_p2e** (Polygon[] in, int mode)

Description: Merge the given polygons and specify the merge mode

mode:	See description
in:	The input polygons
Returns:	The output edges

The wrapcount is computed over all polygons, i.e. overlapping polygons may "cancel" if they have different orientation (since a polygon is oriented by construction that is not easy to achieve). The other merge operation provided for this purpose is "merge" which normalizes each polygon individually before merging them. "simple_merge" is somewhat faster and consumes less memory.

The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

This method has been added in version 0.22.

The mode specifies the rule to use when producing output. A value of 0 specifies the even-odd rule. A positive value specifies the wrap count threshold (positive only). A negative value specifies the threshold of the absolute value of the wrap count (i.e. -1 is non-zero rule).

simple_merge_p2p

(1) Signature: Polygon[] **simple_merge_p2p** (Polygon[] in, bool resolve_holes, bool min_coherence)

Description: Merge the given polygons in a simple "non-zero wrapcount" fashion into polygons

in:	The input polygons
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

The wrapcount is computed over all polygons, i.e. overlapping polygons may "cancel" if they have different orientation (since a polygon is oriented by construction that is not easy to achieve). The other merge operation provided for this purpose is "merge" which normalizes each polygon individually before merging them. "simple_merge" is somewhat faster and consumes less memory.

This method produces polygons and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'simple_merge_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Polygon[] **simple_merge_p2p** (Polygon[] in, bool resolve_holes, bool min_coherence, int mode)

Description: Merge the given polygons and specify the merge mode

mode:	See description
in:	The input polygons
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

The wrapcount is computed over all polygons, i.e. overlapping polygons may "cancel" if they have different orientation (since a polygon is oriented by construction that is not easy to achieve). The other merge operation provided for this purpose is "merge" which normalizes each polygon individually before merging them. "simple_merge" is somewhat faster and consumes less memory.

This method produces polygons and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

This method has been added in version 0.22.

The mode specifies the rule to use when producing output. A value of 0 specifies the even-odd rule. A positive value specifies the wrap count threshold (positive only). A negative value specifies the threshold of the absolute value of the wrap count (i.e. -1 is non-zero rule).

simple_merge_to_polygon

(1) Signature: Polygon[] **simple_merge_to_polygon** (Polygon[] in, bool resolve_holes, bool min_coherence)

Description: Merge the given polygons in a simple "non-zero wrapcount" fashion into polygons

in:	The input polygons
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

Use of this method is deprecated. Use simple_merge_p2p instead

The wrapcount is computed over all polygons, i.e. overlapping polygons may "cancel" if they have different orientation (since a polygon is oriented by construction that is not easy to achieve). The other merge operation provided for this purpose is "merge" which normalizes each polygon individually before merging them. "simple_merge" is somewhat faster and consumes less memory.

This method produces polygons and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'simple_merge_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Polygon[] **simple_merge_to_polygon** (Polygon[] in, bool resolve_holes, bool min_coherence, int mode)

Description: Merge the given polygons and specify the merge mode

mode:	See description
in:	The input polygons
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

Use of this method is deprecated. Use simple_merge_p2p instead

The wrapcount is computed over all polygons, i.e. overlapping polygons may "cancel" if they have different orientation (since a polygon is oriented by construction that is not easy to achieve). The other merge operation provided for this purpose is "merge" which normalizes each polygon individually before merging them. "simple_merge" is somewhat faster and consumes less memory.

This method produces polygons and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

This method has been added in version 0.22.

The mode specifies the rule to use when producing output. A value of 0 specifies the even-odd rule. A positive value specifies the wrap count threshold (positive only). A negative value specifies the threshold of the absolute value of the wrap count (i.e. -1 is non-zero rule).

(3) Signature: Polygon[] **simple_merge_to_polygon** (Edge[] in, bool resolve_holes, bool min_coherence)

Description: Merge the given edges in a simple "non-zero wrapcount" fashion into polygons

in:	The input edges
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

Use of this method is deprecated. Use simple_merge_e2p instead

The edges provided must form valid closed contours. Contours oriented differently "cancel" each other. Overlapping contours are merged when the orientation is the same.

This method produces polygons and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

Prior to version 0.21 this method was called 'simple_merge_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(4) Signature: Polygon[] **simple_merge_to_polygon** (Edge[] in, bool resolve_holes, bool min_coherence, int mode)

Description: Merge the given polygons and specify the merge mode

mode:	See description
in:	The input edges
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

Use of this method is deprecated. Use simple_merge_e2p instead

The edges provided must form valid closed contours. Contours oriented differently "cancel" each other. Overlapping contours are merged when the orientation is the same.

This method produces polygons and allows fine-tuning of the parameters for that purpose.

This is a convenience method that bundles filling of the edges, processing with a SimpleMerge operator and puts the result into an output vector.

This method has been added in version 0.22.

The mode specifies the rule to use when producing output. A value of 0 specifies the even-odd rule. A positive value specifies the wrap count threshold (positive only). A negative value specifies the threshold of the absolute value of the wrap count (i.e. -1 is non-zero rule).

size

(1) Signature: Edge[] **size** (Polygon[] in, int dx, int dy, unsigned int mode)

Description: Size the given polygons

in:	The input polygons
dx:	The sizing value in x direction
dy:	The sizing value in y direction
mode:	The sizing mode (standard is 2)
Returns:	The output edges

Use of this method is deprecated. Use size_p2e instead

This method sizes a set of polygons. Before the sizing is applied, the polygons are merged. After that, sizing is applied on the individual result polygons of the merge step. The result may contain overlapping contours, but no self-overlaps.

dx and dy describe the sizing. A positive value indicates oversize (outwards) while a negative one describes undersize (inwards). The sizing applied can be chosen differently in x and y direction. In this case, the sign must be identical for both dx and dy.

The 'mode' parameter describes the corner fill strategy. Mode 0 connects all corner segments directly. Mode 1 is the 'octagon' strategy in which square corners are interpolated with a partial octagon. Mode 2 is the standard mode in which corners are filled by expanding edges unless these edges form a sharp bend with an angle of more than 90 degree. In that case, the corners are cut off. In Mode 3, no cutoff occurs up to a bending angle of 135 degree. Mode 4 and 5 are even more aggressive and allow very sharp bends without cutoff. This strategy may produce long spikes on sharply bending corners. The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

Prior to version 0.21 this method was called 'size'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Edge[] **size** (Polygon[] in, int d, unsigned int mode)

Description: Size the given polygons (isotropic)

in:	The input polygons
d:	The sizing value in x direction
mode:	The sizing mode
Returns:	The output edges

Use of this method is deprecated. Use size_p2e instead

This method is equivalent to calling the anisotropic version with identical dx and dy.

Prior to version 0.21 this method was called 'size'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

size_p2e

(1) Signature: Edge[] **size_p2e** (Polygon[] in, int dx, int dy, unsigned int mode)

Description: Size the given polygons

in:	The input polygons
dx:	The sizing value in x direction
dy:	The sizing value in y direction
mode:	The sizing mode (standard is 2)
Returns:	The output edges

This method sizes a set of polygons. Before the sizing is applied, the polygons are merged. After that, sizing is applied on the individual result polygons of the merge step. The result may contain overlapping contours, but no self-overlaps.

dx and dy describe the sizing. A positive value indicates oversize (outwards) while a negative one describes undersize (inwards). The sizing applied can be chosen differently in x and y direction. In this case, the sign must be identical for both dx and dy.

The 'mode' parameter describes the corner fill strategy. Mode 0 connects all corner segments directly. Mode 1 is the 'octagon' strategy in which square corners are interpolated with a partial octagon. Mode 2 is the standard mode in which corners are filled by expanding edges unless these edges form a sharp bend with an angle of more than 90 degree. In that case, the corners are cut off. In Mode 3, no cutoff occurs up to a bending angle of 135 degree. Mode 4 and 5 are even more aggressive and allow very sharp bends without cutoff. This strategy may produce long spikes on sharply bending corners. The result is presented as a set of edges forming closed contours. Hulls are oriented clockwise while holes are oriented counter-clockwise.

Prior to version 0.21 this method was called 'size'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Edge[] **size_p2e** (Polygon[] in, int d, unsigned int mode)

Description: Size the given polygons (isotropic)

in:	The input polygons
d:	The sizing value in x direction
mode:	The sizing mode
Returns:	The output edges

This method is equivalent to calling the anisotropic version with identical dx and dy.

Prior to version 0.21 this method was called 'size'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

size_p2p

(1) Signature: Polygon[] **size_p2p** (Polygon[] in, int dx, int dy, unsigned int mode, bool resolve_holes, bool min_coherence)

Description: Size the given polygons into polygons

in:	The input polygons
dx:	The sizing value in x direction
dy:	The sizing value in y direction
mode:	The sizing mode (standard is 2)
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

This method sizes a set of polygons. Before the sizing is applied, the polygons are merged. After that, sizing is applied on the individual result polygons of the merge step. The result may contain overlapping polygons, but no self-overlapping ones. Polygon overlap occurs if the polygons are close enough, so a positive sizing makes polygons overlap.

dx and dy describe the sizing. A positive value indicates oversize (outwards) while a negative one describes undersize (inwards). The sizing applied can be chosen differently in x and y direction. In this case, the sign must be identical for both dx and dy.

The 'mode' parameter describes the corner fill strategy. Mode 0 connects all corner segments directly. Mode 1 is the 'octagon' strategy in which square corners are interpolated with a partial octagon. Mode 2 is the standard mode in which corners are filled by expanding edges unless these edges form a sharp bend with an angle of more than 90 degree. In that case, the corners are cut off. In Mode 3, no cutoff occurs up to a bending angle of 135 degree. Mode 4 and 5 are even more aggressive and allow very sharp bends without cutoff. This strategy may produce long spikes on sharply bending corners. This method produces polygons and allows fine-tuning of the parameters for that purpose.

Prior to version 0.21 this method was called 'size_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Polygon[] **size_p2p** (Polygon[] in, int d, unsigned int mode, bool resolve_holes, bool min_coherence)

Description: Size the given polygons into polygons (isotropic)

in:	The input polygons
d:	The sizing value in x direction
mode:	The sizing mode
resolve_holes:	true, if holes should be resolved into the hull

min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

This method is equivalent to calling the anisotropic version with identical dx and dy.

Prior to version 0.21 this method was called 'size_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

size_to_polygon

(1) Signature: Polygon[] **size_to_polygon** (Polygon[] in, int dx, int dy, unsigned int mode, bool resolve_holes, bool min_coherence)

Description: Size the given polygons into polygons

in:	The input polygons
dx:	The sizing value in x direction
dy:	The sizing value in y direction
mode:	The sizing mode (standard is 2)
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

Use of this method is deprecated. Use size_p2p instead

This method sizes a set of polygons. Before the sizing is applied, the polygons are merged. After that, sizing is applied on the individual result polygons of the merge step. The result may contain overlapping polygons, but no self-overlapping ones. Polygon overlap occurs if the polygons are close enough, so a positive sizing makes polygons overlap.

dx and dy describe the sizing. A positive value indicates oversize (outwards) while a negative one describes undersize (inwards). The sizing applied can be chosen differently in x and y direction. In this case, the sign must be identical for both dx and dy.

The 'mode' parameter describes the corner fill strategy. Mode 0 connects all corner segments directly. Mode 1 is the 'octagon' strategy in which square corners are interpolated with a partial octagon. Mode 2 is the standard mode in which corners are filled by expanding edges unless these edges form a sharp bend with an angle of more than 90 degree. In that case, the corners are cut off. In Mode 3, no cutoff occurs up to a bending angle of 135 degree. Mode 4 and 5 are even more aggressive and allow very sharp bends without cutoff. This strategy may produce long spikes on sharply bending corners. This method produces polygons and allows fine-tuning of the parameters for that purpose.

Prior to version 0.21 this method was called 'size_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

(2) Signature: Polygon[] **size_to_polygon** (Polygon[] in, int d, unsigned int mode, bool resolve_holes, bool min_coherence)

Description: Size the given polygons into polygons (isotropic)

in:	The input polygons
d:	The sizing value in x direction
mode:	The sizing mode
resolve_holes:	true, if holes should be resolved into the hull
min_coherence:	true, if touching corners should be resolved into less connected contours
Returns:	The output polygons

Use of this method is deprecated. Use size_p2p instead

This method is equivalent to calling the anisotropic version with identical dx and dy.

Prior to version 0.21 this method was called 'size_to_polygon'. Is was renamed to avoid ambiguities for empty input arrays. The old version is still available but deprecated.

4.43. API reference - Class EdgeFilter

Notation used in Ruby API documentation

Module: db

Description: A generic edge filter adaptor

Edge filters are an efficient way to filter edge from a Edges collection. To apply a filter, derive your own filter class and pass an instance to the Edges#filter or Edges#filtered method.

Conceptually, these methods take each edge from the collection and present it to the filter's 'selected' method. Based on the result of this evaluation, the edge is kept or discarded.

The magic happens when deep mode edge collections are involved. In that case, the filter will use as few calls as possible and exploit the hierarchical compression if possible. It needs to know however, how the filter behaves. You need to configure the filter by calling is_isotropic, is_scale_invariant or is_isotropic_and_scale_invariant before using the filter.

You can skip this step, but the filter algorithm will assume the worst case then. This usually leads to cell variant formation which is not always desired and blows up the hierarchy.

Here is some example that filters edges parallel to a given one:

```
class ParallelFilter < RBA::EdgeFilter

  # Constructor
  def initialize(ref_edge)
    self.is_scale_invariant   # orientation matters, but scale does not
    @ref_edge = ref_edge
  end

  # Select only parallel ones
  def selected(edge)
    return edge.is_parallel?(@ref_edge)
  end

end

edges = ... # some Edges object
ref_edge = ... # some Edge
parallel_only = edges.filtered(ParallelFilter::new(ref_edge))
```

This class has been introduced in version 0.29.

Public constructors

new EdgeFilter ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**	Ensures the C++ object is created
	void	**_destroy**	Explicitly destroys the object
[const]	bool	**_destroyed?**	Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**	Returns a value indicating whether the reference is a const reference
	void	**_manage**	Marks the object as managed by the script side.

	void	_unmanage		Marks the object as no longer owned by the script side.
	void	is_isotropic		Indicates that the filter has isotropic properties
	void	is_isotropic_and_scale_invariant		Indicates that the filter is isotropic and scale invariant
	void	is_scale_invariant		Indicates that the filter is scale invariant
	void	requires_raw_input=	(bool flag)	Sets a value indicating whether the filter needs raw (unmerged) input
[const]	bool	requires_raw_input?		Gets a value indicating whether the filter needs raw (unmerged) input
[virtual,const]	bool	selected	(const Edge edge)	Selects an edge
	void	wants_variants=	(bool flag)	Sets a value indicating whether the filter prefers cell variants
[const]	bool	wants_variants?		Gets a value indicating whether the filter prefers cell variants

Deprecated methods (protected, public, static, non-static and constructors)

	void	create	Use of this method is deprecated. Use _create instead
	void	destroy	Use of this method is deprecated. Use _destroy instead
[const]	bool	destroyed?	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	is_const_object?	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_isotropic

Signature: void **is_isotropic**

Description: Indicates that the filter has isotropic properties

Call this method before using the filter to indicate that the selection is independent of the orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

Examples for isotropic (polygon) filters are area or perimeter filters. The area or perimeter of a polygon depends on the scale, but not on the orientation of the polygon.

is_isotropic_and_scale_invariant

Signature: void **is_isotropic_and_scale_invariant**

Description: Indicates that the filter is isotropic and scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale and orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for such a (polygon) filter is the square selector. Whether a polygon is a square or not does not depend on the polygon's orientation nor scale.

is_scale_invariant

Signature: void **is_scale_invariant**

Description: Indicates that the filter is scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for a scale invariant (polygon) filter is the bounding box aspect ratio (height/width) filter. The definition of heigh and width depends on the orientation, but the ratio is independent on scale.

new

Signature: *[static]* new EdgeFilter ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

requires_raw_input=

Signature: void **requires_raw_input=** (bool flag)

Description: Sets a value indicating whether the filter needs raw (unmerged) input

This flag must be set before using this filter. It tells the filter implementation whether the filter wants to have raw input (unmerged). The default value is 'false', meaning that the filter will receive merged polygons ('merged semantics').

Setting this value to false potentially saves some CPU time needed for merging the polygons. Also, raw input means that strange shapes such as dot-like edges, self-overlapping polygons, empty or degenerated polygons are preserved.

Python specific notes:
The object exposes a writable attribute 'requires_raw_input'. This is the setter.

requires_raw_input?

Signature: *[const]* bool **requires_raw_input?**

Description: Gets a value indicating whether the filter needs raw (unmerged) input

See requires_raw_input= for details.

Python specific notes:
The object exposes a readable attribute 'requires_raw_input'. This is the getter.

selected

Signature: *[virtual,const]* bool **selected** (const Edge edge)

Description: Selects an edge

This method is the actual payload. It needs to be reimplemented in a derived class. It needs to analyze the edge and return 'true' if it should be kept and 'false' if it should be discarded.

wants_variants=

Signature: void **wants_variants=** (bool flag)

Description: Sets a value indicating whether the filter prefers cell variants

This flag must be set before using this filter for hierarchical applications (deep mode). It tells the filter implementation whether cell variants should be created (true, the default) or shape propagation will be applied (false).

This decision needs to be made, if the filter indicates that it will deliver different results for scaled or rotated versions of the shape (see is_isotropic and the other hints). If a cell is present with different qualities - as seen from the top cell - the respective instances need to be differentiated. Cell variant formation is one way, shape propagation the other way. Typically, cell variant formation is less expensive, but the hierarchy will be modified.

Python specific notes:
The object exposes a writable attribute 'wants_variants'. This is the setter.

wants_variants?

Signature: *[const]* bool **wants_variants?**

Description: Gets a value indicating whether the filter prefers cell variants

See wants_variants= for details.

Python specific notes:
The object exposes a readable attribute 'wants_variants'. This is the getter.

4.44. API reference - Class EdgeOperator

Notation used in Ruby API documentation

Module: db

Description: A generic edge-to-polygon operator

Edge processors are an efficient way to process edges from an edge collection. To apply a processor, derive your own operator class and pass an instance to the Edges#processed method.

Conceptually, these methods take each edge from the edge collection and present it to the operator's 'process' method. The result of this call is a list of zero to many output edges derived from the input edge. The output edge collection is the sum over all these individual results.

The magic happens when deep mode edge collections are involved. In that case, the processor will use as few calls as possible and exploit the hierarchical compression if possible. It needs to know however, how the operator behaves. You need to configure the operator by calling is_isotropic, is_scale_invariant or is_isotropic_and_scale_invariant before using it.

You can skip this step, but the processor algorithm will assume the worst case then. This usually leads to cell variant formation which is not always desired and blows up the hierarchy.

Here is some example that shrinks every edge to half of the size, but does not change the position. In this example the 'position' is defined by the center of the edge:

```
class ShrinkToHalf < RBA::EdgeOperator

  # Constructor
  def initialize
    self.is_isotropic_and_scale_invariant   # scale or orientation do not matter
  end

  # Shrink to half size
  def process(edge)
    shift = edge.bbox.center - RBA::Point::new   # shift vector
    return [ (edge.moved(-shift) * 0.5).moved(shift) ]
  end

end

edges = ... # some Edges collection
shrinked_to_half = edges.processed(ShrinkToHalf::new)
```

This class has been introduced in version 0.29.

Public constructors

new EdgeOperator ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**	Ensures the C++ object is created
	void	**_destroy**	Explicitly destroys the object
[const]	bool	**_destroyed?**	Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**	Returns a value indicating whether the reference is a const reference

	void	_manage		Marks the object as managed by the script side.
	void	_unmanage		Marks the object as no longer owned by the script side.
	void	is_isotropic		Indicates that the filter has isotropic properties
	void	is_isotropic_and_scale_invariant		Indicates that the filter is isotropic and scale invariant
	void	is_scale_invariant		Indicates that the filter is scale invariant
[virtual,const]	Edge[]	process	(const Edge shape)	Processes a shape
	void	requires_raw_input=	(bool flag)	Sets a value indicating whether the processor needs raw (unmerged) input
[const]	bool	requires_raw_input?		Gets a value indicating whether the processor needs raw (unmerged) input
	void	result_is_merged=	(bool flag)	Sets a value indicating whether the processor delivers merged output
[const]	bool	result_is_merged?		Gets a value indicating whether the processor delivers merged output
	void	result_must_not_be_merge	(bool flag)	Sets a value indicating whether the processor's output must not be merged
[const]	bool	result_must_not_be_merged?		Gets a value indicating whether the processor's output must not be merged
	void	wants_variants=	(bool flag)	Sets a value indicating whether the filter prefers cell variants
[const]	bool	wants_variants?		Gets a value indicating whether the filter prefers cell variants

Deprecated methods (protected, public, static, non-static and constructors)

	void	create	Use of this method is deprecated. Use _create instead
	void	destroy	Use of this method is deprecated. Use _destroy instead
[const]	bool	destroyed?	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	is_const_object?	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void _**create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_isotropic

Signature: void **is_isotropic**

Description: Indicates that the filter has isotropic properties

Call this method before using the filter to indicate that the selection is independent of the orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

Examples for isotropic (polygon) processors are size or shrink operators. Size or shrink is not dependent on orientation unless size or shrink needs to be different in x and y direction.

is_isotropic_and_scale_invariant

Signature: void **is_isotropic_and_scale_invariant**

Description: Indicates that the filter is isotropic and scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale and orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for such a (polygon) processor is the convex decomposition operator. The decomposition of a polygon into convex parts is an operation that is not depending on scale nor orientation.

is_scale_invariant

Signature: void **is_scale_invariant**

Description: Indicates that the filter is scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for a scale invariant (polygon) processor is the rotation operator. Rotation is not depending on scale, but on the original orientation as mirrored versions need to be rotated differently.

new

Signature: *[static]* new EdgeOperator ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

process

Signature: *[virtual,const]* Edge[] **process** (const Edge shape)

Description: Processes a shape

	This method is the actual payload. It needs to be reimplemented in a derived class. If needs to process the input shape and deliver a list of output shapes. The output list may be empty to entirely discard the input shape. It may also contain more than a single shape. In that case, the number of total shapes may grow during application of the processor.
requires_raw_input=	**Signature**: void **requires_raw_input=** (bool flag) **Description**: Sets a value indicating whether the processor needs raw (unmerged) input This flag must be set before using this processor. It tells the processor implementation whether the processor wants to have raw input (unmerged). The default value is 'false', meaning that the processor will receive merged polygons ('merged semantics'). Setting this value to false potentially saves some CPU time needed for merging the polygons. Also, raw input means that strange shapes such as dot-like edges, self-overlapping polygons, empty or degenerated polygons are preserved. **Python specific notes:** The object exposes a writable attribute 'requires_raw_input'. This is the setter.
requires_raw_input?	**Signature**: *[const]* bool **requires_raw_input?** **Description**: Gets a value indicating whether the processor needs raw (unmerged) input See requires_raw_input= for details. **Python specific notes:** The object exposes a readable attribute 'requires_raw_input'. This is the getter.
result_is_merged=	**Signature**: void **result_is_merged=** (bool flag) **Description**: Sets a value indicating whether the processor delivers merged output This flag must be set before using this processor. If the processor maintains the merged condition by design (output is merged if input is), it is a good idea to set this predicate to 'true'. This will avoid additional merge steps when the resulting collection is used in further operations that need merged input . **Python specific notes:** The object exposes a writable attribute 'result_is_merged'. This is the setter.
result_is_merged?	**Signature**: *[const]* bool **result_is_merged?** **Description**: Gets a value indicating whether the processor delivers merged output See result_is_merged= for details. **Python specific notes:** The object exposes a readable attribute 'result_is_merged'. This is the getter.
result_must_not_be_merged=	**Signature**: void **result_must_not_be_merged=** (bool flag) **Description**: Sets a value indicating whether the processor's output must not be merged This flag must be set before using this processor. The processor can set this flag if it wants to deliver shapes that must not be merged - e.g. point-like edges or strange or degenerated polygons. . **Python specific notes:** The object exposes a writable attribute 'result_must_not_be_merged'. This is the setter.
result_must_not_be_merged	**Signature**: *[const]* bool **result_must_not_be_merged?** **Description**: Gets a value indicating whether the processor's output must not be merged See result_must_not_be_merged= for details. **Python specific notes:**

	The object exposes a readable attribute 'result_must_not_be_merged'. This is the getter.
wants_variants=	**Signature**: void **wants_variants=** (bool flag) **Description**: Sets a value indicating whether the filter prefers cell variants This flag must be set before using this filter for hierarchical applications (deep mode). It tells the filter implementation whether cell variants should be created (true, the default) or shape propagation will be applied (false). This decision needs to be made, if the filter indicates that it will deliver different results for scaled or rotated versions of the shape (see is_isotropic and the other hints). If a cell is present with different qualities - as seen from the top cell - the respective instances need to be differentiated. Cell variant formation is one way, shape propagation the other way. Typically, cell variant formation is less expensive, but the hierarchy will be modified. **Python specific notes:** The object exposes a writable attribute 'wants_variants'. This is the setter.
wants_variants?	**Signature**: *[const]* bool **wants_variants?** **Description**: Gets a value indicating whether the filter prefers cell variants See wants_variants= for details. **Python specific notes:** The object exposes a readable attribute 'wants_variants'. This is the getter.

4.45. API reference - Class EdgeToPolygonOperator

Notation used in Ruby API documentation

Module: db

Description: A generic edge-to-polygon operator

Edge processors are an efficient way to process edges from an edge collection. To apply a processor, derive your own operator class and pass an instance to the Edges#processed method.

Conceptually, these methods take each edge from the edge collection and present it to the operator's 'process' method. The result of this call is a list of zero to many output polygons derived from the input edge. The output region is the sum over all these individual results.

The magic happens when deep mode edge collections are involved. In that case, the processor will use as few calls as possible and exploit the hierarchical compression if possible. It needs to know however, how the operator behaves. You need to configure the operator by calling is_isotropic, is_scale_invariant or is_isotropic_and_scale_invariant before using it.

You can skip this step, but the processor algorithm will assume the worst case then. This usually leads to cell variant formation which is not always desired and blows up the hierarchy.

For a basic example see the EdgeOperator class, with the exception that this incarnation has to deliver edges.

This class has been introduced in version 0.29.

Public constructors

new EdgeToPolygonOperator ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_isotropic

Signature: void **is_isotropic**

Description: Indicates that the filter has isotropic properties

Call this method before using the filter to indicate that the selection is independent of the orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

Examples for isotropic (polygon) processors are size or shrink operators. Size or shrink is not dependent on orientation unless size or shrink needs to be different in x and y direction.

is_isotropic_and_scale_invariant

Signature: void **is_isotropic_and_scale_invariant**

Description: Indicates that the filter is isotropic and scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale and orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for such a (polygon) processor is the convex decomposition operator. The decomposition of a polygon into convex parts is an operation that is not depending on scale nor orientation.

is_scale_invariant

Signature: void **is_scale_invariant**

Description: Indicates that the filter is scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for a scale invariant (polygon) processor is the rotation operator. Rotation is not depending on scale, but on the original orientation as mirrored versions need to be rotated differently.

new

Signature: *[static]* new EdgeToPolygonOperator ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

process

Signature: *[virtual,const]* Polygon[] **process** (const Edge shape)

Description: Processes a shape

This method is the actual payload. It needs to be reimplemented in a derived class. If needs to process the input shape and deliver a list of output shapes. The output list may be empty to entirely discard the input shape. It may also contain more than a single shape. In that case, the number of total shapes may grow during application of the processor.

requires_raw_input=

Signature: void **requires_raw_input=** (bool flag)

Description: Sets a value indicating whether the processor needs raw (unmerged) input

This flag must be set before using this processor. It tells the processor implementation whether the processor wants to have raw input (unmerged). The default value is 'false', meaning that the processor will receive merged polygons ('merged semantics').

Setting this value to false potentially saves some CPU time needed for merging the polygons. Also, raw input means that strange shapes such as dot-like edges, self-overlapping polygons, empty or degenerated polygons are preserved.

Python specific notes:
The object exposes a writable attribute 'requires_raw_input'. This is the setter.

requires_raw_input?

Signature: *[const]* bool **requires_raw_input?**

Description: Gets a value indicating whether the processor needs raw (unmerged) input

See requires_raw_input= for details.

Python specific notes:
The object exposes a readable attribute 'requires_raw_input'. This is the getter.

result_is_merged=

Signature: void **result_is_merged=** (bool flag)

Description: Sets a value indicating whether the processor delivers merged output

This flag must be set before using this processor. If the processor maintains the merged condition by design (output is merged if input is), it is a good idea to set this predicate to 'true'. This will avoid additional merge steps when the resulting collection is used in further operations that need merged input .

Python specific notes:
The object exposes a writable attribute 'result_is_merged'. This is the setter.

result_is_merged?

Signature: *[const]* bool **result_is_merged?**

Description: Gets a value indicating whether the processor delivers merged output

See result_is_merged= for details.

Python specific notes:
The object exposes a readable attribute 'result_is_merged'. This is the getter.

result_must_not_be_merged=

Signature: void **result_must_not_be_merged=** (bool flag)

Description: Sets a value indicating whether the processor's output must not be merged

This flag must be set before using this processor. The processor can set this flag if it wants to deliver shapes that must not be merged - e.g. point-like edges or strange or degenerated polygons. .

Python specific notes:
The object exposes a writable attribute 'result_must_not_be_merged'. This is the setter.

result_must_not_be_merged

Signature: *[const]* bool **result_must_not_be_merged?**

Description: Gets a value indicating whether the processor's output must not be merged

See result_must_not_be_merged= for details.

Python specific notes:
The object exposes a readable attribute 'result_must_not_be_merged'. This is the getter.

wants_variants=

Signature: void **wants_variants=** (bool flag)

Description: Sets a value indicating whether the filter prefers cell variants

This flag must be set before using this filter for hierarchical applications (deep mode). It tells the filter implementation whether cell variants should be created (true, the default) or shape propagation will be applied (false).

This decision needs to be made, if the filter indicates that it will deliver different results for scaled or rotated versions of the shape (see is_isotropic and the other hints). If a cell is present with different qualities - as seen from the top cell - the respective instances need to be differentiated. Cell variant formation is one way, shape propagation the other way. Typically, cell variant formation is less expensive, but the hierarchy will be modified.

Python specific notes:
The object exposes a writable attribute 'wants_variants'. This is the setter.

wants_variants?

Signature: *[const]* bool **wants_variants?**

Description: Gets a value indicating whether the filter prefers cell variants

See wants_variants= for details.

Python specific notes:
The object exposes a readable attribute 'wants_variants'. This is the getter.

4.46. API reference - Class EdgeToEdgePairOperator

Notation used in Ruby API documentation

Module: db

Description: A generic edge-to-edge-pair operator

Edge processors are an efficient way to process edges from an edge collection. To apply a processor, derive your own operator class and pass an instance to the Edges#processed method.

Conceptually, these methods take each edge from the edge collection and present it to the operator's 'process' method. The result of this call is a list of zero to many output edge pairs derived from the input edge. The output edge pair collection is the sum over all these individual results.

The magic happens when deep mode edge collections are involved. In that case, the processor will use as few calls as possible and exploit the hierarchical compression if possible. It needs to know however, how the operator behaves. You need to configure the operator by calling is_isotropic, is_scale_invariant or is_isotropic_and_scale_invariant before using it.

You can skip this step, but the processor algorithm will assume the worst case then. This usually leads to cell variant formation which is not always desired and blows up the hierarchy.

For a basic example see the EdgeOperator class, with the exception that this incarnation has to deliver edge pairs.

This class has been introduced in version 0.29.

Public constructors

new EdgeToEdgePairOperator ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**is_isotropic**		Indicates that the filter has isotropic properties
	void	**is_isotropic_and_scale_invariant**		Indicates that the filter is isotropic and scale invariant
	void	**is_scale_invariant**		Indicates that the filter is scale invariant
[virtual,const]	EdgePair[]	**process**	(const Edge shape)	Processes a shape
	void	**requires_raw_input=**	(bool flag)	Sets a value indicating whether the processor needs raw (unmerged) input

[const]	bool	**requires_raw_input?**		Gets a value indicating whether the processor needs raw (unmerged) input
	void	**result_is_merged=**	(bool flag)	Sets a value indicating whether the processor delivers merged output
[const]	bool	**result_is_merged?**		Gets a value indicating whether the processor delivers merged output
	void	**result_must_not_be_merge**	(bool flag)	Sets a value indicating whether the processor's output must not be merged
[const]	bool	**result_must_not_be_merged?**		Gets a value indicating whether the processor's output must not be merged
	void	**wants_variants=**	(bool flag)	Sets a value indicating whether the filter prefers cell variants
[const]	bool	**wants_variants?**		Gets a value indicating whether the filter prefers cell variants

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_isotropic

Signature: void **is_isotropic**

Description: Indicates that the filter has isotropic properties

Call this method before using the filter to indicate that the selection is independent of the orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

Examples for isotropic (polygon) processors are size or shrink operators. Size or shrink is not dependent on orientation unless size or shrink needs to be different in x and y direction.

is_isotropic_and_scale_invariant

Signature: void **is_isotropic_and_scale_invariant**

Description: Indicates that the filter is isotropic and scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale and orientation of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for such a (polygon) processor is the convex decomposition operator. The decomposition of a polygon into convex parts is an operation that is not depending on scale nor orientation.

is_scale_invariant

Signature: void **is_scale_invariant**

Description: Indicates that the filter is scale invariant

Call this method before using the filter to indicate that the selection is independent of the scale of the shape. This helps the filter algorithm optimizing the filter run, specifically in hierarchical mode.

An example for a scale invariant (polygon) processor is the rotation operator. Rotation is not depending on scale, but on the original orientation as mirrored versions need to be rotated differently.

new

Signature: *[static]* new EdgeToEdgePairOperator ptr **new**

Description: Creates a new object of this class

Python specific notes:
This method is the default initializer of the object.

process

Signature: *[virtual,const]* EdgePair[] **process** (const Edge shape)

Description: Processes a shape

This method is the actual payload. It needs to be reimplemented in a derived class. If needs to process the input shape and deliver a list of output shapes. The output list may be empty to entirely discard the input shape. It may also contain more than a single shape. In that case, the number of total shapes may grow during application of the processor.

requires_raw_input=

Signature: void **requires_raw_input=** (bool flag)

Description: Sets a value indicating whether the processor needs raw (unmerged) input

This flag must be set before using this processor. It tells the processor implementation whether the processor wants to have raw input (unmerged). The default value is 'false', meaning that the processor will receive merged polygons ('merged semantics').

Setting this value to false potentially saves some CPU time needed for merging the polygons. Also, raw input means that strange shapes such as dot-like edges, self-overlapping polygons, empty or degenerated polygons are preserved.

Python specific notes:
The object exposes a writable attribute 'requires_raw_input'. This is the setter.

requires_raw_input?

Signature: *[const]* bool **requires_raw_input?**

Description: Gets a value indicating whether the processor needs raw (unmerged) input

See requires_raw_input= for details.

Python specific notes:
The object exposes a readable attribute 'requires_raw_input'. This is the getter.

result_is_merged=

Signature: void **result_is_merged=** (bool flag)

Description: Sets a value indicating whether the processor delivers merged output

This flag must be set before using this processor. If the processor maintains the merged condition by design (output is merged if input is), it is a good idea to set this predicate to 'true'. This will avoid additional merge steps when the resulting collection is used in further operations that need merged input .

Python specific notes:
The object exposes a writable attribute 'result_is_merged'. This is the setter.

result_is_merged?

Signature: *[const]* bool **result_is_merged?**

Description: Gets a value indicating whether the processor delivers merged output

See result_is_merged= for details.

Python specific notes:
The object exposes a readable attribute 'result_is_merged'. This is the getter.

result_must_not_be_merged=

Signature: void **result_must_not_be_merged=** (bool flag)

Description: Sets a value indicating whether the processor's output must not be merged

This flag must be set before using this processor. The processor can set this flag if it wants to deliver shapes that must not be merged - e.g. point-like edges or strange or degenerated polygons. .

Python specific notes:
The object exposes a writable attribute 'result_must_not_be_merged'. This is the setter.

result_must_not_be_merged

Signature: *[const]* bool **result_must_not_be_merged?**

Description: Gets a value indicating whether the processor's output must not be merged

See result_must_not_be_merged= for details.

Python specific notes:
The object exposes a readable attribute 'result_must_not_be_merged'. This is the getter.

wants_variants=

Signature: void **wants_variants=** (bool flag)

Description: Sets a value indicating whether the filter prefers cell variants

This flag must be set before using this filter for hierarchical applications (deep mode). It tells the filter implementation whether cell variants should be created (true, the default) or shape propagation will be applied (false).

This decision needs to be made, if the filter indicates that it will deliver different results for scaled or rotated versions of the shape (see is_isotropic and the other hints). If a cell is present with different qualities - as seen from the top cell - the respective instances need to be differentiated. Cell variant formation is one way, shape propagation the other way. Typically, cell variant formation is less expensive, but the hierarchy will be modified.

Python specific notes:
The object exposes a writable attribute 'wants_variants'. This is the setter.

wants_variants?

Signature: *[const]* bool **wants_variants?**

Description: Gets a value indicating whether the filter prefers cell variants

See wants_variants= for details.

Python specific notes:
The object exposes a readable attribute 'wants_variants'. This is the getter.

4.47. API reference - Class Edges

Notation used in Ruby API documentation

Module: db

Description: A collection of edges (Not necessarily describing closed contours)

Class hierarchy: Edges » ShapeCollection

Sub-classes: EdgeType

This class was introduced to simplify operations on edges sets. See Edge for a description of the individual edge object. The edge collection contains an arbitrary number of edges and supports operations to select edges by various criteria, produce polygons from the edges by applying an extension, filtering edges against other edges collections and checking geometrical relations to other edges (DRC functionality).

The edge collection is supposed to work closely with the Region polygon set. Both are related, although the edge collection has a lower rank since it potentially represents a disconnected collection of edges. Edge collections may form closed contours, for example immediately after they have been derived from a polygon set using Region#edges. But this state is volatile and can easily be destroyed by filtering edges. Hence the connected state does not play an important role in the edge collection's API.

Edge collections may also contain points (degenerated edges with identical start and end points). Such point-like objects participate in some although not all methods of the edge collection class. Edge collections can be used in two different flavors: in raw mode or merged semantics. With merged semantics (the default), connected edges are considered to belong together and are effectively merged. Overlapping parts are counted once in that mode. Dot-like edges are not considered in merged semantics. In raw mode (without merged semantics), each edge is considered as it is. Overlaps between edges may exists and merging has to be done explicitly using the merge method. The semantics can be selected using merged_semantics=.

This class has been introduced in version 0.23.

Public constructors

new Edges ptr	**new**		Default constructor
new Edges ptr	**new**	(const Edge edge)	Constructor from a single edge
new Edges ptr	**new**	(Polygon[] array)	Constructor from a polygon array
new Edges ptr	**new**	(Edge[] array)	Constructor from an edge array
new Edges ptr	**new**	(const Box box)	Box constructor
new Edges ptr	**new**	(const Polygon polygon)	Polygon constructor
new Edges ptr	**new**	(const SimplePolygon polygon)	Simple polygon constructor
new Edges ptr	**new**	(const Path path)	Path constructor
new Edges ptr	**new**	(const Shapes shapes, bool as_edges = true)	Constructor of a flat edge collection from a Shapes container
new Edges ptr	**new**	(const RecursiveShapeIterator shape_iterator, bool as_edges = true)	Constructor of a flat edge collection from a hierarchical shape set
new Edges ptr	**new**	(const RecursiveShapeIterator shape_iterator, const ICplxTrans trans, bool as_edges = true)	Constructor of a flat edge collection from a hierarchical shape set with a transformation

new Edges ptr	new	(const RecursiveShapeIterator shape_iterator, DeepShapeStore dss, bool as_edges = true)	Constructor of a hierarchical edge collection
new Edges ptr	new	(const RecursiveShapeIterator shape_iterator, DeepShapeStore dss, const ICplxTrans trans, bool as_edges = true)	Constructor of a hierarchical edge collection with a transformation
new Edges ptr	new	(const RecursiveShapeIterator shape_iterator, string expr, bool as_pattern = true)	Constructor from a text set
new Edges ptr	new	(const RecursiveShapeIterator shape_iterator, DeepShapeStore dss, string expr, bool as_pattern = true)	Constructor from a text set

Public methods

[const]	Edges	&	(const Edges other)	Returns the boolean AND between self and the other edge collection
[const]	Edges	&	(const Region other)	Returns the parts of the edges inside the given region
	Edges	&=	(const Edges other)	Performs the boolean AND between self and the other edge collection in-place (modifying self)
	Edges	&=	(const Region other)	Selects the parts of the edges inside the given region in-place (modifying self)
[const]	Edges	+	(const Edges other)	Returns the combined edge set of self and the other one
	Edges	+=	(const Edges other)	Adds the edges of the other edge collection to self
[const]	Edges	-	(const Edges other)	Returns the boolean NOT between self and the other edge collection
[const]	Edges	-	(const Region other)	Returns the parts of the edges outside the given region
	Edges	-=	(const Edges other)	Performs the boolean NOT between self and the other edge collection in-place (modifying self)
	Edges	-=	(const Region other)	Selects the parts of the edges outside the given region in-place (modifying self)
[const]	const Edge ptr	[]	(unsigned long n)	Returns the nth edge of the collection

[const]	Edges	^	(const Edges other)	Returns the boolean XOR between self and the other edge collection
	Edges	^=	(const Edges other)	Performs the boolean XOR between self and the other edge collection in-place (modifying self)
	void	_create		Ensures the C++ object is created
	void	_destroy		Explicitly destroys the object
[const]	bool	_destroyed?		Returns a value indicating whether the object was already destroyed
[const]	bool	_is_const_object?		Returns a value indicating whether the reference is a const reference
	void	_manage		Marks the object as managed by the script side.
	void	_unmanage		Marks the object as no longer owned by the script side.
[const]	Edges	and	(const Edges other)	Returns the boolean AND between self and the other edge collection
[const]	Edges	and	(const Region other)	Returns the parts of the edges inside the given region
	Edges	and_with	(const Edges other)	Performs the boolean AND between self and the other edge collection in-place (modifying self)
	Edges	and_with	(const Region other)	Selects the parts of the edges inside the given region in-place (modifying self)
[const]	Edges[]	andnot	(const Edges other)	Returns the boolean AND and NOT between self and the other edge set
[const]	Edges[]	andnot	(const Region other)	Returns the boolean AND and NOT between self and the region
	void	assign	(const Edges other)	Assigns another object to self
[const]	Box	bbox		Returns the bounding box of the edge collection
[const]	Edges	centers	(unsigned int length, double fraction)	Returns edges representing the center part of the edges
	void	clear		Clears the edge collection
[const]	unsigned long	count		Returns the (flat) number of edges in the edge collection
[const]	unsigned long	data_id		Returns the data ID (a unique identifier for the underlying data storage)
	void	disable_progress		Disable progress reporting

[const]	new Edges ptr	**dup**		Creates a copy of self
[const,iter]	Edge	**each**		Returns each edge of the region
[const,iter]	Edge	**each_merged**		Returns each edge of the region
	void	**enable_progress**	(string label)	Enable progress reporting
	void	**enable_properties**		Enables properties for the given container.
[const]	EdgePairs	**enclosed_check**	(const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)	Performs an inside check with options
[const]	EdgePairs	**enclosing_check**	(const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTo	Performs an enclosing check with options
[const]	Edges	**end_segments**	(unsigned int length, double fraction)	Returns edges representing a part of the edge before the end point
[const]	Region	**extended**	(int b, int e, int o, int i, bool join)	Returns a region with shapes representing the edges with the specified extensions
[const]	Region	**extended_in**	(int e)	Returns a region with shapes representing the edges with the given width
[const]	Region	**extended_out**	(int e)	Returns a region with shapes representing the edges with the given width
[const]	Region	**extents**		Returns a region with the bounding boxes of the edges
[const]	Region	**extents**	(int d)	Returns a region with the enlarged bounding boxes of the edges

[const]	Region	**extents**	(int dx, int dy)	Returns a region with the enlarged bounding boxes of the edges
	void	**filter**	(const EdgeFilter ptr filter)	Applies a generic filter in place (replacing the edges from the Edges collection)
	void	**filter_properties**	(variant[] keys)	Filters properties by certain keys.
[const]	Edges	**filtered**	(const EdgeFilter ptr filtered)	Applies a generic filter and returns a filtered copy
	void	**flatten**		Explicitly flattens an edge collection
[const]	bool	**has_valid_edges?**		Returns true if the edge collection is flat and individual edges can be accessed randomly
[const]	unsigned long	**hier_count**		Returns the (hierarchical) number of edges in the edge collection
[const]	Edges	**in**	(const Edges other)	Returns all edges which are members of the other edge collection
[const]	Edges[]	**in_and_out**	(const Edges other)	Returns all polygons which are members and not members of the other region
	void	**insert**	(const Edge edge)	Inserts an edge
	void	**insert**	(const Box box)	Inserts a box
	void	**insert**	(const Polygon polygon)	Inserts a polygon
	void	**insert**	(const SimplePolygon polygon)	Inserts a simple polygon
	void	**insert**	(const Path path)	Inserts a path
	void	**insert**	(const Edges edges)	Inserts all edges from the other edge collection into this one
	void	**insert**	(const Region region)	Inserts a region
	void	**insert**	(const Shapes shapes)	Inserts all edges from the shape collection into this edge collection
	void	**insert**	(const Shapes shapes, const Trans trans)	Inserts all edges from the shape collection into this edge collection (with transformation)
	void	**insert**	(const Shapes shapes, const ICplxTrans trans)	Inserts all edges from the shape collection into this edge collection with complex transformation
	void	**insert**	(RecursiveShapeIterator shape_iterator)	Inserts all shapes delivered by the recursive shape iterator into this edge collection
	void	**insert**	(RecursiveShapeIterator shape_iterator, ICplxTrans trans)	Inserts all shapes delivered by the recursive shape iterator into this edge collection with a transformation

	void	**insert**	(Polygon[] polygons)	Inserts all polygons from the array into this edge collection
	void	**insert**	(Edge[] edges)	Inserts all edges from the array into this edge collection
[const]	void	**insert_into**	(Layout ptr layout, unsigned int cell_index, unsigned int layer)	Inserts this edge collection into the given layout, below the given cell and into the given layer.
[const]	Edges	**inside**	(const Edges other)	Returns the edges of this edge collection which are inside (completely covered by) edges from the other edge collection
[const]	Edges	**inside**	(const Region other)	Returns the edges from this edge collection which are inside (completely covered by) polygons from the region
[const]	EdgePairs	**inside_check**	(const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)	Performs an inside check with options
[const]	Edges[]	**inside_outside_pa**	(const Region other)	Returns the partial edges inside and outside the given region
[const]	Edges	**inside_part**	(const Region other)	Returns the parts of the edges of this edge collection which are inside the polygons of the region
[const]	Edges	**interacting**	(const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Returns the edges of this edge collection which overlap or touch edges from the other edge collection
[const]	Edges	**interacting**	(const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Returns the edges from this edge collection which overlap or touch polygons from the region
[const]	Edges	**intersections**	(const Edges other)	Computes the intersections between this edges and other edges
[const]	bool	**is_deep?**		Returns true if the edge collection is a deep (hierarchical) one
[const]	bool	**is_empty?**		Returns true if the edge collection is empty

[const]	bool	**is_merged?**		Returns true if the edge collection is merged
[const]	Edges	**join**	(const Edges other)	Returns the combined edge set of self and the other one
	Edges	**join_with**	(const Edges other)	Adds the edges of the other edge collection to self
[const]	unsigned int	**length**		Returns the total length of all edges in the edge collection
[const]	unsigned int	**length**	(const Box rect)	Returns the total length of all edges in the edge collection (restricted to a rectangle)
	void	**map_properties**	(map<variant,variant> key_map)	Maps properties by name key.
[const]	Edges	**members_of**	(const Edges other)	Returns all edges which are members of the other edge collection
	Edges	**merge**		Merge the edges
[const]	Edges	**merged**		Returns the merged edge collection
	void	**merged_semantics**	(bool f)	Enable or disable merged semantics
[const]	bool	**merged_semantics?**		Gets a flag indicating whether merged semantics is enabled
	Edges	**move**	(const Vector v)	Moves the edge collection
	Edges	**move**	(int x, int y)	Moves the edge collection
[const]	Edges	**moved**	(const Vector v)	Returns the moved edge collection (does not modify self)
[const]	Edges	**moved**	(int x, int v)	Returns the moved edge collection (does not modify self)
[const]	Edges	**not**	(const Edges other)	Returns the boolean NOT between self and the other edge collection
[const]	Edges	**not**	(const Region other)	Returns the parts of the edges outside the given region
[const]	Edges	**not_in**	(const Edges other)	Returns all edges which are not members of the other edge collection
[const]	Edges	**not_inside**	(const Edges other)	Returns the edges of this edge collection which are not inside (completely covered by) edges from the other edge collection
[const]	Edges	**not_inside**	(const Region other)	Returns the edges from this edge collection which are not inside (completely covered by) polygons from the region

[const]	Edges	**not_interacting**	(const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Returns the edges of this edge collection which do not overlap or touch edges from the other edge collection
[const]	Edges	**not_interacting**	(const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Returns the edges from this edge collection which do not overlap or touch polygons from the region
[const]	Edges	**not_members_of**	(const Edges other)	Returns all edges which are not members of the other edge collection
[const]	Edges	**not_outside**	(const Edges other)	Returns the edges of this edge collection which are not outside (completely covered by) edges from the other edge collection
[const]	Edges	**not_outside**	(const Region other)	Returns the edges from this edge collection which are not outside (completely covered by) polygons from the region
	Edges	**not_with**	(const Edges other)	Performs the boolean NOT between self and the other edge collection in-place (modifying self)
	Edges	**not_with**	(const Region other)	Selects the parts of the edges outside the given region in-place (modifying self)
[const]	Edges	**or**	(const Edges other)	Returns the boolean OR between self and the other edge set
	Edges	**or_with**	(const Edges other)	Performs the boolean OR between self and the other edge set in-place (modifying self)
[const]	Edges	**outside**	(const Edges other)	Returns the edges of this edge collection which are outside (completely covered by) edges from the other edge collection
[const]	Edges	**outside**	(const Region other)	Returns the edges from this edge collection which are outside (completely covered by) polygons from the region
[const]	Edges	**outside_part**	(const Region other)	Returns the parts of the edges of this edge collection which are outside the polygons of the region
[const]	EdgePairs	**overlap_check**	(const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max,	Performs an overlap check with options

			ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)	
	void	**process**	(const EdgeOperator ptr process)	Applies a generic edge processor in place (replacing the edges from the Edges collection)
[const]	Edges	**processed**	(const EdgeOperator ptr processed)	Applies a generic edge processor and returns a processed copy
[const]	EdgePairs	**processed**	(const EdgeToEdgePairOperator ptr processed)	Applies a generic edge-to-edge-pair processor and returns an edge pair collection with the results
[const]	Region	**processed**	(const EdgeToPolygonOperator ptr processed)	Applies a generic edge-to-polygon processor and returns an edge collection with the results
[const]	Region	**pull_interacting**	(const Region other)	Returns all polygons of "other" which are interacting with (overlapping, touching) edges of this edge set
[const]	Edges	**pull_interacting**	(const Edges other)	Returns all edges of "other" which are interacting with polygons of this edge set
	void	**remove_properties**		Removes properties for the given container.
	Edges	**select_inside**	(const Edges other)	Selects the edges from this edge collection which are inside (completely covered by) edges from the other edge collection
	Edges	**select_inside**	(const Region other)	Selects the edges from this edge collection which are inside (completely covered by) polygons from the region
	Edges	**select_inside_part**	(const Region other)	Selects the parts of the edges from this edge collection which are inside the polygons of the given region
	Edges	**select_interacting**	(const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Selects the edges from this edge collection which overlap or touch edges from the other edge collection
	Edges	**select_interacting**	(const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Selects the edges from this edge collection which overlap or touch polygons from the region
	Edges	**select_not_inside**	(const Edges other)	Selects the edges from this edge collection which are not inside (completely covered by) edges from the other edge collection
	Edges	**select_not_inside**	(const Region other)	Selects the edges from this edge collection which are not inside (completely covered by) polygons from the region

	Edges	select_not_interac	(const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Selects the edges from this edge collection which do not overlap or touch edges from the other edge collection
	Edges	select_not_interacting	(const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Selects the edges from this edge collection which do not overlap or touch polygons from the region
	Edges	select_not_outside	(const Edges other)	Selects the edges from this edge collection which are not outside (completely covered by) edges from the other edge collection
	Edges	select_not_outside	(const Region other)	Selects the edges from this edge collection which are not outside (completely covered by) polygons from the region
	Edges	select_outside	(const Edges other)	Selects the edges from this edge collection which are outside (completely covered by) edges from the other edge collection
	Edges	select_outside	(const Region other)	Selects the edges from this edge collection which are outside (completely covered by) polygons from the region
	Edges	select_outside_pa	(const Region other)	Selects the parts of the edges from this edge collection which are outside the polygons of the given region
[const]	EdgePairs	separation_check	(const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)	Performs an overlap check with options
[const]	EdgePairs	space_check	(int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTo	Performs a space check with options

[const]	Edges[]	**split_inside**	(const Edges other)	Selects the edges from this edge collection which are and are not inside (completely covered by) edges from the other collection
[const]	Edges[]	**split_inside**	(const Region other)	Selects the edges from this edge collection which are and are not inside (completely covered by) polygons from the other region
[const]	Edges[]	**split_interacting**	(const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Selects the edges from this edge collection which do and do not interact with edges from the other collection
[const]	Edges[]	**split_interacting**	(const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)	Selects the edges from this edge collection which do and do not interact with polygons from the other region
[const]	Edges[]	**split_outside**	(const Edges other)	Selects the edges from this edge collection which are and are not outside (completely covered by) edges from the other collection
[const]	Edges[]	**split_outside**	(const Region other)	Selects the edges from this edge collection which are and are not outside (completely covered by) polygons from the other region
[const]	Edges	**start_segments**	(unsigned int length, double fraction)	Returns edges representing a part of the edge after the start point
	void	**swap**	(Edges other)	Swap the contents of this edge collection with the contents of another one
[const]	string	**to_s**		Converts the edge collection to a string
[const]	string	**to_s**	(unsigned long max_count)	Converts the edge collection to a string
	Edges	**transform**	(const Trans t)	Transform the edge collection (modifies self)
	Edges	**transform**	(const ICplxTrans t)	Transform the edge collection with a complex transformation (modifies self)
	Edges	**transform**	(const IMatrix2d t)	Transform the edge collection (modifies self)
	Edges	**transform**	(const IMatrix3d t)	Transform the edge collection (modifies self)
[const]	Edges	**transformed**	(const Trans t)	Transform the edge collection
[const]	Edges	**transformed**	(const ICplxTrans t)	Transform the edge collection with a complex transformation
[const]	Edges	**transformed**	(const IMatrix2d t)	Transform the edge collection
[const]	Edges	**transformed**	(const IMatrix3d t)	Transform the edge collection
[const]	EdgePairs	**width_check**	(int d, bool whole_edges = false,	Performs a width check with options

			Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)	
[const]	Edges	**with_angle**	(double angle, bool inverse)	Filters the edges by orientation
[const]	Edges	**with_angle**	(double min_angle, double max_angle, bool inverse, bool include_min_angle = true, bool include_max_angle = false)	Filters the edges by orientation
[const]	Edges	**with_angle**	(Edges::EdgeType type, bool inverse)	Filters the edges by orientation type
[const]	Edges	**with_length**	(unsigned int length, bool inverse)	Filters the edges by length
[const]	Edges	**with_length**	(variant min_length, variant max_length, bool inverse)	Filters the edges by length
[const]	void	**write**	(string filename)	Writes the region to a file
[const]	Edges	**xor**	(const Edges other)	Returns the boolean XOR between self and the other edge collection
	Edges	**xor_with**	(const Edges other)	Performs the boolean XOR between self and the other edge collection in-place (modifying self)
[const]	Edges	**|**	(const Edges other)	Returns the boolean OR between self and the other edge set
	Edges	**|=**	(const Edges other)	Performs the boolean OR between self and the other edge set in-place (modifying self)

Public static methods and constants

[static,const]	Edges::EdgeType	**DiagonalEdges**	Diagonal edges are selected (-45 and 45 degree)
[static,const]	PropertyConstraint	**DifferentPropertiesConstraint**	Specifies to consider shapes only if their user properties are different
[static,const]	PropertyConstraint	**DifferentPropertiesConstra**	Specifies to consider shapes only if their user properties are different

[static,const]	Metrics	**Euclidian**	Specifies Euclidian metrics for the check functions
[static,const]	PropertyConstraint	**IgnoreProperties**	Specifies to ignore properties
[static,const]	ZeroDistanceMode	**IncludeZeroDistanceWhenCollinearAndTouching**	Specifies that check functions should include edges when they are collinear and touch
[static,const]	ZeroDistanceMode	**IncludeZeroDistanceWhen**	Specifies that check functions should include edges when they overlap
[static,const]	ZeroDistanceMode	**IncludeZeroDistanceWhenTouching**	Specifies that check functions should include edges when they touch
[static,const]	ZeroDistanceMode	**NeverIncludeZeroDistance**	Specifies that check functions should never include edges with zero distance.
[static,const]	PropertyConstraint	**NoPropertyConstraint**	Specifies not to apply any property constraint
[static,const]	Edges::EdgeType	**OrthoDiagonalEdges**	Diagonal or orthogonal edges are selected (0, 90, -45 and 45 degree)
[static,const]	Edges::EdgeType	**OrthoEdges**	Horizontal and vertical edges are selected
[static,const]	Metrics	**Projection**	Specifies projected distance metrics for the check functions
[static,const]	PropertyConstraint	**SamePropertiesConstraint**	Specifies to consider shapes only if their user properties are the same
[static,const]	PropertyConstraint	**SamePropertiesConstraint**	Specifies to consider shapes only if their user properties are the same
[static,const]	Metrics	**Square**	Specifies square metrics for the check functions

Detailed description

&

(1) Signature: *[const]* Edges **&** (const Edges other)

Description: Returns the boolean AND between self and the other edge collection

Returns: The result of the boolean AND operation

The boolean AND operation will return all parts of the edges in this collection which are coincident with parts of the edges in the other collection.The result will be a merged edge collection.

The 'and' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'and_' in Python.

(2) Signature: *[const]* Edges **&** (const Region other)

Description: Returns the parts of the edges inside the given region

Returns: The edges inside the given region

This operation returns the parts of the edges which are inside the given region. Edges on the borders of the polygons are included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24.The 'and' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'and_' in Python.

&=

(1) Signature: Edges **&=** (const Edges other)

Description: Performs the boolean AND between self and the other edge collection in-place (modifying self)

Returns: The edge collection after modification (self)

The boolean AND operation will return all parts of the edges in this collection which are coincident with parts of the edges in the other collection.The result will be a merged edge collection.

Note that in Ruby, the '&=' operator actually does not exist, but is emulated by '&' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'and_with' instead.

The 'and_with' alias has been introduced in version 0.28.12.

(2) Signature: Edges **&=** (const Region other)

Description: Selects the parts of the edges inside the given region in-place (modifying self)

Returns: The edge collection after modification (self)

This operation selects the parts of the edges which are inside the given region. Edges on the borders of the polygons are included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24. Note that in Ruby, the '&=' operator actually does not exist, but is emulated by '&' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'and_with' instead.

The 'and_with' alias has been introduced in version 0.28.12.

+

Signature: *[const]* Edges **+** (const Edges other)

Description: Returns the combined edge set of self and the other one

Returns: The resulting edge set

This operator adds the edges of the other edge set to self and returns a new combined edge set. This usually creates unmerged edge sets and edges may overlap. Use merge if you want to ensure the result edge set is merged.

The 'join' alias has been introduced in version 0.28.12.

+=

Signature: Edges **+=** (const Edges other)

Description: Adds the edges of the other edge collection to self

Returns: The edge set after modification (self)

This operator adds the edges of the other edge set to self. This usually creates unmerged edge sets and edges may overlap. Use merge if you want to ensure the result edge set is merged.

Note that in Ruby, the '+=' operator actually does not exist, but is emulated by '+' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'join_with' instead.

The 'join_with' alias has been introduced in version 0.28.12.

-

(1) Signature: *[const]* Edges **-** (const Edges other)

Description: Returns the boolean NOT between self and the other edge collection

Returns: The result of the boolean NOT operation

The boolean NOT operation will return all parts of the edges in this collection which are not coincident with parts of the edges in the other collection.The result will be a merged edge collection.

The 'not' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'not_' in Python.

(2) Signature: *[const]* Edges **-** (const Region other)

Description: Returns the parts of the edges outside the given region

Returns: The edges outside the given region

This operation returns the parts of the edges which are outside the given region. Edges on the borders of the polygons are not included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24.The 'not' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'not_' in Python.

-=

(1) Signature: Edges **-=** (const Edges other)

Description: Performs the boolean NOT between self and the other edge collection in-place (modifying self)

Returns: The edge collection after modification (self)

The boolean NOT operation will return all parts of the edges in this collection which are not coincident with parts of the edges in the other collection.The result will be a merged edge collection.

Note that in Ruby, the '-=' operator actually does not exist, but is emulated by '-' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'not_with' instead.

The 'not_with' alias has been introduced in version 0.28.12.

(2) Signature: Edges **-=** (const Region other)

Description: Selects the parts of the edges outside the given region in-place (modifying self)

Returns: The edge collection after modification (self)

This operation selects the parts of the edges which are outside the given region. Edges on the borders of the polygons are not included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

Note that in Ruby, the '-=' operator actually does not exist, but is emulated by '-' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'not_with' instead.

This method has been introduced in version 0.24.The 'not_with' alias has been introduced in version 0.28.12.

DiagonalEdges

Signature: *[static,const]* Edges::EdgeType **DiagonalEdges**

Description: Diagonal edges are selected (-45 and 45 degree)

Python specific notes:
The object exposes a readable attribute 'DiagonalEdges'. This is the getter.

DifferentPropertiesConstraint

Signature: *[static,const]* PropertyConstraint **DifferentPropertiesConstraint**

Description: Specifies to consider shapes only if their user properties are different

When using this constraint - for example on a boolean operation - shapes are considered only if their user properties are different. Properties are generated on the output shapes where applicable.

Python specific notes:
The object exposes a readable attribute 'DifferentPropertiesConstraint'. This is the getter.

DifferentPropertiesConstraintDrop

Signature: *[static,const]* PropertyConstraint **DifferentPropertiesConstraintDrop**

Description: Specifies to consider shapes only if their user properties are different

When using this constraint - for example on a boolean operation - shapes are considered only if their user properties are the same. No properties are generated on the output shapes.

Python specific notes:
The object exposes a readable attribute 'DifferentPropertiesConstraintDrop'. This is the getter.

Euclidian

Signature: *[static,const]* Metrics **Euclidian**

Description: Specifies Euclidian metrics for the check functions

This value can be used for the metrics parameter in the check functions, i.e. width_check. This value specifies Euclidian metrics, i.e. the distance between two points is measured by:

```
d = sqrt(dx^2 + dy^2)
```

All points within a circle with radius d around one point are considered to have a smaller distance than d.

Python specific notes:
The object exposes a readable attribute 'Euclidian'. This is the getter.

IgnoreProperties

Signature: *[static,const]* PropertyConstraint **IgnoreProperties**

Description: Specifies to ignore properties

When using this constraint - for example on a boolean operation - properties are ignored and are not generated in the output.

Python specific notes:
The object exposes a readable attribute 'IgnoreProperties'. This is the getter.

IncludeZeroDistanceWhenCollinearAndTouching

Signature: *[static,const]* ZeroDistanceMode **IncludeZeroDistanceWhenCollinearAndTouching**

Description: Specifies that check functions should include edges when they are collinear and touch

With this specification, the check functions will also check edges if they share at least one common point and are collinear. This is the mode that includes checking the 'kissing corner' cases when the kissing edges are collinear. This mode was default up to version 0.28.

Python specific notes:
The object exposes a readable attribute 'IncludeZeroDistanceWhenCollinearAndTouching'. This is the getter.

IncludeZeroDistanceWhe

Signature: *[static,const]* ZeroDistanceMode **IncludeZeroDistanceWhenOverlapping**

Description: Specifies that check functions should include edges when they overlap

With this specification, the check functions will also check edges which are collinear and share more than a single point. This is the mode that excludes the 'kissing corner' cases.

Python specific notes:
The object exposes a readable attribute 'IncludeZeroDistanceWhenOverlapping'. This is the getter.

IncludeZeroDistanceWhenTouching

Signature: *[static,const]* ZeroDistanceMode **IncludeZeroDistanceWhenTouching**

Description: Specifies that check functions should include edges when they touch

With this specification, the check functions will also check edges if they share at least one common point. This is the mode that includes checking the 'kissing corner' cases. This mode is default for version 0.28.16 and later.

Python specific notes:
The object exposes a readable attribute 'IncludeZeroDistanceWhenTouching'. This is the getter.

NeverIncludeZeroDistanc

Signature: *[static,const]* ZeroDistanceMode **NeverIncludeZeroDistance**

Description: Specifies that check functions should never include edges with zero distance.

With this specification, the check functions will ignore edges which are collinear or touch.

Python specific notes:
The object exposes a readable attribute 'NeverIncludeZeroDistance'. This is the getter.

NoPropertyConstraint

Signature: *[static,const]* PropertyConstraint **NoPropertyConstraint**

Description: Specifies not to apply any property constraint

When using this constraint - for example on a boolean operation - shapes are considered regardless of their user properties. Properties are generated on the output shapes where applicable.

Python specific notes:
The object exposes a readable attribute 'NoPropertyConstraint'. This is the getter.

OrthoDiagonalEdges

Signature: *[static,const]* Edges::EdgeType **OrthoDiagonalEdges**

Description: Diagonal or orthogonal edges are selected (0, 90, -45 and 45 degree)

Python specific notes:

The object exposes a readable attribute 'OrthoDiagonalEdges'. This is the getter.

OrthoEdges

Signature: *[static,const]* Edges::EdgeType **OrthoEdges**

Description: Horizontal and vertical edges are selected

Python specific notes:
The object exposes a readable attribute 'OrthoEdges'. This is the getter.

Projection

Signature: *[static,const]* Metrics **Projection**

Description: Specifies projected distance metrics for the check functions

This value can be used for the metrics parameter in the check functions, i.e. width_check. This value specifies projected metrics, i.e. the distance is defined as the minimum distance measured perpendicular to one edge. That implies that the distance is defined only where two edges have a non-vanishing projection onto each other.

Python specific notes:
The object exposes a readable attribute 'Projection'. This is the getter.

SamePropertiesConstraint

Signature: *[static,const]* PropertyConstraint **SamePropertiesConstraint**

Description: Specifies to consider shapes only if their user properties are the same

When using this constraint - for example on a boolean operation - shapes are considered only if their user properties are the same. Properties are generated on the output shapes where applicable.

Python specific notes:
The object exposes a readable attribute 'SamePropertiesConstraint'. This is the getter.

SamePropertiesConstrain

Signature: *[static,const]* PropertyConstraint **SamePropertiesConstraintDrop**

Description: Specifies to consider shapes only if their user properties are the same

When using this constraint - for example on a boolean operation - shapes are considered only if their user properties are the same. No properties are generated on the output shapes.

Python specific notes:
The object exposes a readable attribute 'SamePropertiesConstraintDrop'. This is the getter.

Square

Signature: *[static,const]* Metrics **Square**

Description: Specifies square metrics for the check functions

This value can be used for the metrics parameter in the check functions, i.e. width_check. This value specifies square metrics, i.e. the distance between two points is measured by:

```
d = max(abs(dx), abs(dy))
```

All points within a square with length 2*d around one point are considered to have a smaller distance than d in this metrics.

Python specific notes:
The object exposes a readable attribute 'Square'. This is the getter.

[]

Signature: *[const]* const Edge ptr **[]** (unsigned long n)

Description: Returns the nth edge of the collection

This method returns nil if the index is out of range. It is available for flat edge collections only - i.e. those for which has_valid_edges? is true. Use flatten to explicitly flatten an edge collection. This method returns the raw edge (not merged edges, even if merged semantics is enabled).

The each iterator is the more general approach to access the edges.

^

Signature: *[const]* Edges **^** (const Edges other)

Description: Returns the boolean XOR between self and the other edge collection

Returns: The result of the boolean XOR operation

The boolean XOR operation will return all parts of the edges in this and the other collection except the parts where both are coincident. The result will be a merged edge collection.

The 'xor' alias has been introduced in version 0.28.12.

^=

Signature: Edges **^=** (const Edges other)

Description: Performs the boolean XOR between self and the other edge collection in-place (modifying self)

Returns: The edge collection after modification (self)

The boolean XOR operation will return all parts of the edges in this and the other collection except the parts where both are coincident. The result will be a merged edge collection.

Note that in Ruby, the '^=' operator actually does not exist, but is emulated by '^' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'xor_with' instead.

The 'xor_with' alias has been introduced in version 0.28.12.

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known

not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

and

(1) Signature: *[const]* Edges **and** (const Edges other)

Description: Returns the boolean AND between self and the other edge collection

Returns: The result of the boolean AND operation

The boolean AND operation will return all parts of the edges in this collection which are coincident with parts of the edges in the other collection.The result will be a merged edge collection.

The 'and' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'and_' in Python.

(2) Signature: *[const]* Edges **and** (const Region other)

Description: Returns the parts of the edges inside the given region

Returns: The edges inside the given region

This operation returns the parts of the edges which are inside the given region. Edges on the borders of the polygons are included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24.The 'and' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'and_' in Python.

and_with

(1) Signature: Edges **and_with** (const Edges other)

Description: Performs the boolean AND between self and the other edge collection in-place (modifying self)

Returns: The edge collection after modification (self)

The boolean AND operation will return all parts of the edges in this collection which are coincident with parts of the edges in the other collection.The result will be a merged edge collection.

Note that in Ruby, the '&=' operator actually does not exist, but is emulated by '&' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'and_with' instead.

The 'and_with' alias has been introduced in version 0.28.12.

(2) Signature: Edges **and_with** (const Region other)

Description: Selects the parts of the edges inside the given region in-place (modifying self)

Returns: The edge collection after modification (self)

This operation selects the parts of the edges which are inside the given region. Edges on the borders of the polygons are included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24. Note that in Ruby, the '&=' operator actually does not exist, but is emulated by '&' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'and_with' instead.

The 'and_with' alias has been introduced in version 0.28.12.

andnot

(1) Signature: *[const]* Edges[] **andnot** (const Edges other)

Description: Returns the boolean AND and NOT between self and the other edge set

Returns: A two-element array of edge collections with the first one being the AND result and the second one being the NOT result

This method will compute the boolean AND and NOT between two edge sets simultaneously. Because this requires a single sweep only, using this method is faster than doing AND and NOT separately.

This method has been added in version 0.28.

(2) Signature: *[const]* Edges[] **andnot** (const Region other)

Description: Returns the boolean AND and NOT between self and the region

Returns: A two-element array of edge collections with the first one being the AND result and the second one being the NOT result

This method will compute the boolean AND and NOT simultaneously. Because this requires a single sweep only, using this method is faster than doing AND and NOT separately.

This method has been added in version 0.28.

assign

Signature: void **assign** (const Edges other)

Description: Assigns another object to self

bbox

Signature: *[const]* Box **bbox**

Description: Returns the bounding box of the edge collection

The bounding box is the box enclosing all points of all edges.

centers

Signature: *[const]* Edges **centers** (unsigned int length, double fraction)

Description: Returns edges representing the center part of the edges

Returns: A new collection of edges representing the part around the center

This method allows one to specify the length of these segments in a twofold way: either as a fixed length or by specifying a fraction of the original length:

```
edges = ...  # An edge collection
edges.centers(100, 0.0)     # All segments have a length of 100 DBU
edges.centers(0, 50.0)      # All segments have a length of half the original
 length
edges.centers(100, 50.0)    # All segments have a length of half the original
 length
                            # or 100 DBU, whichever is larger
```

	It is possible to specify 0 for both values. In this case, degenerated edges (points) are delivered which specify the centers of the edges but can't participate in some functions.
clear	**Signature**: void **clear** **Description**: Clears the edge collection
count	**Signature**: *[const]* unsigned long **count** **Description**: Returns the (flat) number of edges in the edge collection This returns the number of raw edges (not merged edges if merged semantics is enabled). The count is computed 'as if flat', i.e. edges inside a cell are multiplied by the number of times a cell is instantiated. Starting with version 0.27, the method is called 'count' for consistency with Region. 'size' is still provided as an alias. **Python specific notes:** This method is also available as 'len(object)'.
create	**Signature**: void **create** **Description**: Ensures the C++ object is created Use of this method is deprecated. Use _create instead Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
data_id	**Signature**: *[const]* unsigned long **data_id** **Description**: Returns the data ID (a unique identifier for the underlying data storage) This method has been added in version 0.26.
destroy	**Signature**: void **destroy** **Description**: Explicitly destroys the object Use of this method is deprecated. Use _destroy instead Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
destroyed?	**Signature**: *[const]* bool **destroyed?** **Description**: Returns a value indicating whether the object was already destroyed Use of this method is deprecated. Use _destroyed? instead This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
disable_progress	**Signature**: void **disable_progress** **Description**: Disable progress reporting Calling this method will disable progress reporting. See enable_progress.
dup	**Signature**: *[const]* new Edges ptr **dup** **Description**: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

each

Signature: *[const,iter]* Edge **each**

Description: Returns each edge of the region

Python specific notes:
This method enables iteration of the object.

each_merged

Signature: *[const,iter]* Edge **each_merged**

Description: Returns each edge of the region

In contrast to each, this method delivers merged edges if merge semantics applies while each delivers the original edges only.

This method has been introduced in version 0.25.

enable_progress

Signature: void **enable_progress** (string label)

Description: Enable progress reporting

After calling this method, the edge collection will report the progress through a progress bar while expensive operations are running. The label is a text which is put in front of the progress bar. Using a progress bar will imply a performance penalty of a few percent typically.

enable_properties

Signature: void **enable_properties**

Description: Enables properties for the given container.

This method has an effect mainly on original layers and will import properties from such layers. By default, properties are not enabled on original layers. Alternatively you can apply filter_properties or map_properties to enable properties with a specific name key.

This method has been introduced in version 0.28.4.

enclosed_check

Signature: *[const]* EdgePairs **enclosed_check** (const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)

Description: Performs an inside check with options

d:	The minimum distance for which the edges are checked
other:	The other edge collection against which to check
whole_edges:	If true, deliver the whole edges
metrics:	Specify the metrics type
ignore_angle:	The threshold angle above which no check is performed
min_projection:	The lower threshold of the projected length of one edge onto another
max_projection:	The upper threshold of the projected length of one edge onto another
zero_distance_mode:	Specifies how to handle edges with zero distance

If "whole_edges" is true, the resulting EdgePairs collection will receive the whole edges which contribute in the width check.

"metrics" can be one of the constants Euclidian, Square or Projection. See there for a description of these constants. Use nil for this value to select the default (Euclidian metrics).

"ignore_angle" specifies the angle threshold of two edges. If two edges form an angle equal or above the given value, they will not contribute in the check. Setting this value to 90 (the default) will exclude edges with an angle of 90 degree or more from the check. Use nil for this value to select the default.

"min_projection" and "max_projection" allow selecting edges by their projected value upon each other. It is sufficient if the projection of one edge on the other matches the specified condition. The projected length must be larger or equal to "min_projection" and less than "max_projection". If you don't want to specify one threshold, pass nil to the respective value.

The 'enclosed_check' alias was introduced in version 0.27.5. 'zero_distance_mode' has been added in version 0.29.

enclosing_check

Signature: *[const]* EdgePairs **enclosing_check** (const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)

Description: Performs an enclosing check with options

d:	The minimum distance for which the edges are checked
other:	The other edge collection against which to check
whole_edges:	If true, deliver the whole edges
metrics:	Specify the metrics type
ignore_angle:	The threshold angle above which no check is performed
min_projection:	The lower threshold of the projected length of one edge onto another
max_projection:	The upper threshold of the projected length of one edge onto another
zero_distance_mode:	Specifies how to handle edges with zero distance

If "whole_edges" is true, the resulting EdgePairs collection will receive the whole edges which contribute in the width check.

"metrics" can be one of the constants Euclidian, Square or Projection. See there for a description of these constants. Use nil for this value to select the default (Euclidian metrics).

"ignore_angle" specifies the angle threshold of two edges. If two edges form an angle equal or above the given value, they will not contribute in the check. Setting this value to 90 (the default) will exclude edges with an angle of 90 degree or more from the check. Use nil for this value to select the default.

"min_projection" and "max_projection" allow selecting edges by their projected value upon each other. It is sufficient if the projection of one edge on the other matches the specified condition. The projected length must be larger or equal to "min_projection" and less than "max_projection". If you don't want to specify one threshold, pass nil to the respective value.

'zero_distance_mode' has been added in version 0.29.

end_segments

Signature: *[const]* Edges **end_segments** (unsigned int length, double fraction)

Description: Returns edges representing a part of the edge before the end point

Returns:	A new collection of edges representing the end part

This method allows one to specify the length of these segments in a twofold way: either as a fixed length or by specifying a fraction of the original length:

```
edges = ...  # An edge collection
edges.end_segments(100, 0.0)     # All segments have a length of 100 DBU
edges.end_segments(0, 50.0)      # All segments have a length of half the
 original length
edges.end_segments(100, 50.0)    # All segments have a length of half the
 original length
```

```
# or 100 DBU, whichever is larger
```

It is possible to specify 0 for both values. In this case, degenerated edges (points) are delivered which specify the end positions of the edges but can't participate in some functions.

extended

Signature: *[const]* Region **extended** (int b, int e, int o, int i, bool join)

Description: Returns a region with shapes representing the edges with the specified extensions

b:	the parallel extension at the start point of the edge
e:	the parallel extension at the end point of the edge
o:	the perpendicular extension to the "outside" (left side as seen in the direction of the edge)
i:	the perpendicular extension to the "inside" (right side as seen in the direction of the edge)
join:	If true, connected edges are joined before the extension is applied
Returns:	A region containing the polygons representing these extended edges

This is a generic version of extended_in and extended_out. It allows one to specify extensions for all four directions of an edge and to join the edges before the extension is applied.

For degenerated edges forming a point, a rectangle with the b, e, o and i used as left, right, top and bottom distance to the center point of this edge is created.

If join is true and edges form a closed loop, the b and e parameters are ignored and a rim polygon is created that forms the loop with the outside and inside extension given by o and i.

extended_in

Signature: *[const]* Region **extended_in** (int e)

Description: Returns a region with shapes representing the edges with the given width

e:	The extension width
Returns:	A region containing the polygons representing these extended edges

The edges are extended to the "inside" by the given distance "e". The distance will be applied to the right side as seen in the direction of the edge. By definition, this is the side pointing to the inside of the polygon if the edge was derived from a polygon.

Other versions of this feature are extended_out and extended.

extended_out

Signature: *[const]* Region **extended_out** (int e)

Description: Returns a region with shapes representing the edges with the given width

e:	The extension width
Returns:	A region containing the polygons representing these extended edges

The edges are extended to the "outside" by the given distance "e". The distance will be applied to the left side as seen in the direction of the edge. By definition, this is the side pointing to the outside of the polygon if the edge was derived from a polygon.

Other versions of this feature are extended_in and extended.

extents

(1) Signature: *[const]* Region **extents**

Description: Returns a region with the bounding boxes of the edges

This method will return a region consisting of the bounding boxes of the edges. The boxes will not be merged, so it is possible to determine overlaps of these boxes for example.

(2) Signature: *[const]* Region **extents** (int d)

Description: Returns a region with the enlarged bounding boxes of the edges

This method will return a region consisting of the bounding boxes of the edges enlarged by the given distance d. The enlargement is specified per edge, i.e the width and height will be increased by 2*d. The boxes will not be merged, so it is possible to determine overlaps of these boxes for example.

(3) Signature: *[const]* Region **extents** (int dx, int dy)

Description: Returns a region with the enlarged bounding boxes of the edges

This method will return a region consisting of the bounding boxes of the edges enlarged by the given distance dx in x direction and dy in y direction. The enlargement is specified per edge, i.e the width will be increased by 2*dx. The boxes will not be merged, so it is possible to determine overlaps of these boxes for example.

filter

Signature: void **filter** (const EdgeFilter ptr filter)

Description: Applies a generic filter in place (replacing the edges from the Edges collection)

See EdgeFilter for a description of this feature.

This method has been introduced in version 0.29.

filter_properties

Signature: void **filter_properties** (variant[] keys)

Description: Filters properties by certain keys.

Calling this method on a container will reduce the properties to values with name keys from the 'keys' list. As a side effect, this method enables properties on original layers.

This method has been introduced in version 0.28.4.

filtered

Signature: *[const]* Edges **filtered** (const EdgeFilter ptr filtered)

Description: Applies a generic filter and returns a filtered copy

See EdgeFilter for a description of this feature.

This method has been introduced in version 0.29.

flatten

Signature: void **flatten**

Description: Explicitly flattens an edge collection

If the collection is already flat (i.e. has_valid_edges? returns true), this method will not change it.

This method has been introduced in version 0.26.

has_valid_edges?

Signature: *[const]* bool **has_valid_edges?**

Description: Returns true if the edge collection is flat and individual edges can be accessed randomly

This method has been introduced in version 0.26.

hier_count

Signature: *[const]* unsigned long **hier_count**

Description: Returns the (hierarchical) number of edges in the edge collection

This returns the number of raw edges (not merged edges if merged semantics is enabled). The count is computed 'hierarchical', i.e. edges inside a cell are counted once even if the cell is instantiated multiple times.

This method has been introduced in version 0.27.

in

Signature: *[const]* Edges **in** (const Edges other)

Description: Returns all edges which are members of the other edge collection

This method returns all edges in self which can be found in the other edge collection as well with exactly the same geometry.

Python specific notes:
This attribute is available as 'in_' in Python.

in_and_out

Signature: *[const]* Edges[] **in_and_out** (const Edges other)

Description: Returns all polygons which are members and not members of the other region

This method is equivalent to calling members_of and not_members_of, but delivers both results at the same time and is more efficient than two separate calls. The first element returned is the members_of part, the second is the not_members_of part.

This method has been introduced in version 0.28.

insert

(1) Signature: void **insert** (const Edge edge)

Description: Inserts an edge

Inserts the edge into the edge collection.

(2) Signature: void **insert** (const Box box)

Description: Inserts a box

Inserts the edges that form the contour of the box into the edge collection.

(3) Signature: void **insert** (const Polygon polygon)

Description: Inserts a polygon

Inserts the edges that form the contour of the polygon into the edge collection.

(4) Signature: void **insert** (const SimplePolygon polygon)

Description: Inserts a simple polygon

Inserts the edges that form the contour of the simple polygon into the edge collection.

(5) Signature: void **insert** (const Path path)

Description: Inserts a path

Inserts the edges that form the contour of the path into the edge collection.

(6) Signature: void **insert** (const Edges edges)

Description: Inserts all edges from the other edge collection into this one

This method has been introduced in version 0.25.

(7) Signature: void **insert** (const Region region)

Description: Inserts a region

Inserts the edges that form the contours of the polygons from the region into the edge collection.

This method has been introduced in version 0.25.

(8) Signature: void **insert** (const Shapes shapes)

Description: Inserts all edges from the shape collection into this edge collection

This method takes each edge from the shape collection and inserts it into the region. "Polygon-like" objects are inserted as edges forming the contours of the polygons. Text objects are ignored.

This method has been introduced in version 0.25.

(9) Signature: void **insert** (const Shapes shapes, const Trans trans)

Description: Inserts all edges from the shape collection into this edge collection (with transformation)

This method acts as the version without transformation, but will apply the given transformation before inserting the edges.

This method has been introduced in version 0.25.

(10) Signature: void **insert** (const Shapes shapes, const ICplxTrans trans)

Description: Inserts all edges from the shape collection into this edge collection with complex transformation

This method acts as the version without transformation, but will apply the given complex transformation before inserting the edges.

This method has been introduced in version 0.25.

(11) Signature: void **insert** (RecursiveShapeIterator shape_iterator)

Description: Inserts all shapes delivered by the recursive shape iterator into this edge collection

For "solid" shapes (boxes, polygons, paths), this method inserts the edges that form the contour of the shape into the edge collection. Edge shapes are inserted as such. Text objects are not inserted, because they cannot be converted to polygons.

(12) Signature: void **insert** (RecursiveShapeIterator shape_iterator, ICplxTrans trans)

Description: Inserts all shapes delivered by the recursive shape iterator into this edge collection with a transformation

For "solid" shapes (boxes, polygons, paths), this method inserts the edges that form the contour of the shape into the edge collection. Edge shapes are inserted as such. Text objects are not inserted, because they cannot be converted to polygons. This variant will apply the given transformation to the shapes. This is useful to scale the shapes to a specific database unit for example.

(13) Signature: void **insert** (Polygon[] polygons)

Description: Inserts all polygons from the array into this edge collection

(14) Signature: void **insert** (Edge[] edges)

Description: Inserts all edges from the array into this edge collection

insert_into

Signature: *[const]* void **insert_into** (Layout ptr layout, unsigned int cell_index, unsigned int layer)

Description: Inserts this edge collection into the given layout, below the given cell and into the given layer.

If the edge collection is a hierarchical one, a suitable hierarchy will be built below the top cell or and existing hierarchy will be reused.

This method has been introduced in version 0.26.

inside

(1) Signature: *[const]* Edges **inside** (const Edges other)

Description: Returns the edges of this edge collection which are inside (completely covered by) edges from the other edge collection

Returns: A new edge collection containing the edges overlapping or touching edges from the other edge collection

This method has been introduced in version 0.28.

(2) Signature: *[const]* Edges **inside** (const Region other)

Description: Returns the edges from this edge collection which are inside (completely covered by) polygons from the region

Returns: A new edge collection containing the edges overlapping or touching polygons from the region

This method has been introduced in version 0.28.

inside_check

Signature: *[const]* EdgePairs **inside_check** (const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)

Description: Performs an inside check with options

d: The minimum distance for which the edges are checked

other: The other edge collection against which to check

whole_edges: If true, deliver the whole edges

metrics: Specify the metrics type

ignore_angle: The threshold angle above which no check is performed

min_projection: The lower threshold of the projected length of one edge onto another

max_projection: The upper threshold of the projected length of one edge onto another

zero_distance_mode: Specifies how to handle edges with zero distance

If "whole_edges" is true, the resulting EdgePairs collection will receive the whole edges which contribute in the width check.

"metrics" can be one of the constants Euclidian, Square or Projection. See there for a description of these constants. Use nil for this value to select the default (Euclidian metrics).

"ignore_angle" specifies the angle threshold of two edges. If two edges form an angle equal or above the given value, they will not contribute in the check. Setting this value to 90 (the default) will exclude edges with an angle of 90 degree or more from the check. Use nil for this value to select the default.

"min_projection" and "max_projection" allow selecting edges by their projected value upon each other. It is sufficient if the projection of one edge on the other matches the specified condition. The projected length must be larger or equal to "min_projection" and less than "max_projection". If you don't want to specify one threshold, pass nil to the respective value.

The 'enclosed_check' alias was introduced in version 0.27.5. 'zero_distance_mode' has been added in version 0.29.

inside_outside_part

Signature: *[const]* Edges[] **inside_outside_part** (const Region other)

Description: Returns the partial edges inside and outside the given region

Returns: A two-element array of edge collections with the first one being the inside_part result and the second one being the outside_part result

This method will compute the results simultaneously. Because this requires a single sweep only, using this method is faster than doing inside_part and outside_part separately.

This method has been added in version 0.28.

inside_part

Signature: *[const]* Edges **inside_part** (const Region other)

Description: Returns the parts of the edges of this edge collection which are inside the polygons of the region

Returns: A new edge collection containing the edge parts inside the region

This operation returns the parts of the edges which are inside the given region. This functionality is similar to the '&' operator, but edges on the borders of the polygons are not included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24.

interacting

(1) Signature: *[const]* Edges **interacting** (const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Returns the edges of this edge collection which overlap or touch edges from the other edge collection

Returns: A new edge collection containing the edges overlapping or touching edges from the other edge collection

'min_count' and 'max_count' impose a constraint on the number of times an edge of this collection has to interact with (different) edges of the other collection to make the edge selected. An edge is selected by this method if the number of edges interacting with an edge of this collection is between min_count and max_count (including max_count).

'min_count' and 'max_count' have been introduced in version 0.29.

(2) Signature: *[const]* Edges **interacting** (const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Returns the edges from this edge collection which overlap or touch polygons from the region

Returns: A new edge collection containing the edges overlapping or touching polygons from the region

'min_count' and 'max_count' impose a constraint on the number of times an edge of this collection has to interact with (different) polygons of the other region to make the edge selected. An edge is selected by this method if the number of polygons interacting with an edge of this collection is between min_count and max_count (including max_count).

'min_count' and 'max_count' have been introduced in version 0.29.

intersections

Signature: *[const]* Edges **intersections** (const Edges other)

Description: Computes the intersections between this edges and other edges

This computation is like an AND operation, but also including crossing points between non-coincident edges as degenerated (point-like) edges.

This method has been introduced in version 0.26.2

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_deep?

Signature: *[const]* bool **is_deep?**

Description: Returns true if the edge collection is a deep (hierarchical) one

This method has been added in version 0.26.

is_empty?

Signature: *[const]* bool **is_empty?**

Description: Returns true if the edge collection is empty

is_merged?

Signature: *[const]* bool **is_merged?**

Description: Returns true if the edge collection is merged

If the region is merged, coincident edges have been merged into single edges. You can ensure merged state by calling merge.

join

Signature: *[const]* Edges **join** (const Edges other)

Description: Returns the combined edge set of self and the other one

Returns: The resulting edge set

This operator adds the edges of the other edge set to self and returns a new combined edge set. This usually creates unmerged edge sets and edges may overlap. Use merge if you want to ensure the result edge set is merged.

The 'join' alias has been introduced in version 0.28.12.

join_with

Signature: Edges **join_with** (const Edges other)

Description: Adds the edges of the other edge collection to self

Returns: The edge set after modification (self)

This operator adds the edges of the other edge set to self. This usually creates unmerged edge sets and edges may overlap. Use merge if you want to ensure the result edge set is merged.

Note that in Ruby, the '+=' operator actually does not exist, but is emulated by '+' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'join_with' instead.

The 'join_with' alias has been introduced in version 0.28.12.

length

(1) Signature: *[const]* unsigned int **length**

Description: Returns the total length of all edges in the edge collection

Merged semantics applies for this method (see merged_semantics= of merged semantics)

(2) Signature: *[const]* unsigned int **length** (const Box rect)

Description: Returns the total length of all edges in the edge collection (restricted to a rectangle)

This version will compute the total length of all edges in the collection, restricting the computation to the given rectangle. Edges along the border are handled in a special way: they are counted when they are oriented with their inside side toward the rectangle (in other words: outside edges must coincide with the rectangle's border in order to be counted).

Merged semantics applies for this method (see merged_semantics= of merged semantics)

map_properties

Signature: void **map_properties** (map<variant,variant> key_map)

Description: Maps properties by name key.

Calling this method on a container will reduce the properties to values with name keys from the 'keys' hash and renames the properties. Properties not listed in the key map will be removed. As a side effect, this method enables properties on original layers.

This method has been introduced in version 0.28.4.

members_of

Signature: *[const]* Edges **members_of** (const Edges other)

Description: Returns all edges which are members of the other edge collection

This method returns all edges in self which can be found in the other edge collection as well with exactly the same geometry.

Python specific notes:
This attribute is available as 'in_' in Python.

merge

Signature: Edges **merge**

Description: Merge the edges

Returns: The edge collection after the edges have been merged (self).

Merging joins parallel edges which overlap or touch. Crossing edges are not merged. If the edge collection is already merged, this method does nothing

merged

Signature: *[const]* Edges **merged**

Description: Returns the merged edge collection

Returns: The edge collection after the edges have been merged.

Merging joins parallel edges which overlap or touch. Crossing edges are not merged. In contrast to merge, this method does not modify the edge collection but returns a merged copy.

merged_semantics=

Signature: void **merged_semantics=** (bool f)

Description: Enable or disable merged semantics

If merged semantics is enabled (the default), colinear, connected or overlapping edges will be considered as single edges.

Python specific notes:
The object exposes a writable attribute 'merged_semantics'. This is the setter.

merged_semantics?

Signature: *[const]* bool **merged_semantics?**

Description: Gets a flag indicating whether merged semantics is enabled

See merged_semantics= for a description of this attribute.

Python specific notes:
The object exposes a readable attribute 'merged_semantics'. This is the getter.

move

(1) Signature: Edges **move** (const Vector v)

Description: Moves the edge collection

v: The distance to move the edge collection.

Returns: The moved edge collection (self).

Moves the polygon by the given offset and returns the moved edge collection. The edge collection is overwritten.

Starting with version 0.25 the displacement type is a vector.

(2) Signature: Edges **move** (int x, int y)

Description: Moves the edge collection

x:	The x distance to move the edge collection.
y:	The y distance to move the edge collection.
Returns:	The moved edge collection (self).

Moves the edge collection by the given offset and returns the moved edge collection. The edge collection is overwritten.

moved

(1) Signature: *[const]* Edges **moved** (const Vector v)

Description: Returns the moved edge collection (does not modify self)

v:	The distance to move the edge collection.
Returns:	The moved edge collection.

Moves the edge collection by the given offset and returns the moved edge collection. The edge collection is not modified.

Starting with version 0.25 the displacement type is a vector.

(2) Signature: *[const]* Edges **moved** (int x, int v)

Description: Returns the moved edge collection (does not modify self)

x:	The x distance to move the edge collection.
y:	The y distance to move the edge collection.
Returns:	The moved edge collection.

Moves the edge collection by the given offset and returns the moved edge collection. The edge collection is not modified.

new

(1) Signature: *[static]* new Edges ptr **new**

Description: Default constructor

This constructor creates an empty edge collection.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new Edges ptr **new** (const Edge edge)

Description: Constructor from a single edge

This constructor creates an edge collection with a single edge.

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new Edges ptr **new** (Polygon[] array)

Description: Constructor from a polygon array

This constructor creates an edge collection from an array of polygons. The edges form the contours of the polygons.

Python specific notes:

This method is the default initializer of the object.

(4) Signature: *[static]* new Edges ptr **new** (Edge[] array)

Description: Constructor from an edge array

This constructor creates an edge collection from an array of edges.

Python specific notes:
This method is the default initializer of the object.

(5) Signature: *[static]* new Edges ptr **new** (const Box box)

Description: Box constructor

This constructor creates an edge collection from a box. The edges form the contour of the box.

Python specific notes:
This method is the default initializer of the object.

(6) Signature: *[static]* new Edges ptr **new** (const Polygon polygon)

Description: Polygon constructor

This constructor creates an edge collection from a polygon. The edges form the contour of the polygon.

Python specific notes:
This method is the default initializer of the object.

(7) Signature: *[static]* new Edges ptr **new** (const SimplePolygon polygon)

Description: Simple polygon constructor

This constructor creates an edge collection from a simple polygon. The edges form the contour of the polygon.

Python specific notes:
This method is the default initializer of the object.

(8) Signature: *[static]* new Edges ptr **new** (const Path path)

Description: Path constructor

This constructor creates an edge collection from a path. The edges form the contour of the path.

Python specific notes:
This method is the default initializer of the object.

(9) Signature: *[static]* new Edges ptr **new** (const Shapes shapes, bool as_edges = true)

Description: Constructor of a flat edge collection from a Shapes container

If 'as_edges' is true, the shapes from the container will be converted to edges (i.e. polygon contours to edges). Otherwise, only edges will be taken from the container.

This method has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

(10) Signature: *[static]* new Edges ptr **new** (const RecursiveShapeIterator shape_iterator, bool as_edges = true)

Description: Constructor of a flat edge collection from a hierarchical shape set

This constructor creates an edge collection from the shapes delivered by the given recursive shape iterator. It feeds the shapes from a hierarchy of cells into a flat edge set.

Text objects are not inserted, because they cannot be converted to edges. Edge objects are inserted as such. If "as_edges" is true, "solid" objects (boxes, polygons, paths) are converted to edges which form the hull of these objects. If "as_edges" is false, solid objects are ignored.

```
layout = ... # a layout
cell   = ... # the index of the initial cell
layer  = ... # the index of the layer from where to take the shapes from
r = RBA::Edges::new(layout.begin_shapes(cell, layer), false)
```

Python specific notes:
This method is the default initializer of the object.

(11) Signature: *[static]* new Edges ptr **new** (const RecursiveShapeIterator shape_iterator, const ICplxTrans trans, bool as_edges = true)

Description: Constructor of a flat edge collection from a hierarchical shape set with a transformation

This constructor creates an edge collection from the shapes delivered by the given recursive shape iterator. It feeds the shapes from a hierarchy of cells into a flat edge set. The transformation is useful to scale to a specific database unit for example.

Text objects are not inserted, because they cannot be converted to edges. Edge objects are inserted as such. If "as_edges" is true, "solid" objects (boxes, polygons, paths) are converted to edges which form the hull of these objects. If "as_edges" is false, solid objects are ignored.

```
layout = ... # a layout
cell   = ... # the index of the initial cell
layer  = ... # the index of the layer from where to take the shapes from
dbu    = 0.1 # the target database unit
r = RBA::Edges::new(layout.begin_shapes(cell, layer),
 RBA::ICplxTrans::new(layout.dbu / dbu))
```

Python specific notes:
This method is the default initializer of the object.

(12) Signature: *[static]* new Edges ptr **new** (const RecursiveShapeIterator shape_iterator, DeepShapeStore dss, bool as_edges = true)

Description: Constructor of a hierarchical edge collection

This constructor creates an edge collection from the shapes delivered by the given recursive shape iterator. It feeds the shapes from a hierarchy of cells into the hierarchical edge set. The edges remain within their original hierarchy unless other operations require the edges to be moved in the hierarchy.

Text objects are not inserted, because they cannot be converted to edges. Edge objects are inserted as such. If "as_edges" is true, "solid" objects (boxes, polygons, paths) are converted to edges which form the hull of these objects. If "as_edges" is false, solid objects are ignored.

```
dss    = RBA::DeepShapeStore::new
layout = ... # a layout
cell   = ... # the index of the initial cell
layer  = ... # the index of the layer from where to take the shapes from
r = RBA::Edges::new(layout.begin_shapes(cell, layer), dss, false)
```

Python specific notes:

This method is the default initializer of the object.

(13) Signature: *[static]* new Edges ptr **new** (const RecursiveShapeIterator shape_iterator, DeepShapeStore dss, const ICplxTrans trans, bool as_edges = true)

Description: Constructor of a hierarchical edge collection with a transformation

This constructor creates an edge collection from the shapes delivered by the given recursive shape iterator. It feeds the shapes from a hierarchy of cells into the hierarchical edge set. The edges remain within their original hierarchy unless other operations require the edges to be moved in the hierarchy. The transformation is useful to scale to a specific database unit for example.

Text objects are not inserted, because they cannot be converted to edges. Edge objects are inserted as such. If "as_edges" is true, "solid" objects (boxes, polygons, paths) are converted to edges which form the hull of these objects. If "as_edges" is false, solid objects are ignored.

```
dss    = RBA::DeepShapeStore::new
layout = ... # a layout
cell   = ... # the index of the initial cell
layer  = ... # the index of the layer from where to take the shapes from
dbu    = 0.1 # the target database unit
r = RBA::Edges::new(layout.begin_shapes(cell, layer), dss,
 RBA::ICplxTrans::new(layout.dbu / dbu), false)
```

Python specific notes:
This method is the default initializer of the object.

(14) Signature: *[static]* new Edges ptr **new** (const RecursiveShapeIterator shape_iterator, string expr, bool as_pattern = true)

Description: Constructor from a text set

shape_iterator:	The iterator from which to derive the texts
expr:	The selection string
as_pattern:	If true, the selection string is treated as a glob pattern. Otherwise the match is exact.

This special constructor will create dot-like edges from the text objects delivered by the shape iterator. Each text object will give a degenerated edge (a dot) that represents the text origin. Texts can be selected by their strings - either through a glob pattern or by exact comparison with the given string. The following options are available:

```
dots = RBA::Edges::new(iter, "*")           # all texts
dots = RBA::Edges::new(iter, "A*")          # all texts starting with an 'A'
dots = RBA::Edges::new(iter, "A*", false)   # all texts exactly matching 'A*'
```

This method has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

(15) Signature: *[static]* new Edges ptr **new** (const RecursiveShapeIterator shape_iterator, DeepShapeStore dss, string expr, bool as_pattern = true)

Description: Constructor from a text set

shape_iterator:	The iterator from which to derive the texts

dss:	The DeepShapeStore object that acts as a heap for hierarchical operations.
expr:	The selection string
as_pattern:	If true, the selection string is treated as a glob pattern. Otherwise the match is exact.

This special constructor will create a deep edge set from the text objects delivered by the shape iterator. Each text object will give a degenerated edge (a dot) that represents the text origin. Texts can be selected by their strings - either through a glob pattern or by exact comparison with the given string. The following options are available:

```
region = RBA::Region::new(iter, dss, "*")           # all texts
region = RBA::Region::new(iter, dss, "A*")          # all texts starting with
 an 'A'
region = RBA::Region::new(iter, dss, "A*", false)   # all texts exactly
 matching 'A*'
```

This method has been introduced in version 0.26.

Python specific notes:
This method is the default initializer of the object.

not

(1) Signature: *[const]* Edges **not** (const Edges other)

Description: Returns the boolean NOT between self and the other edge collection

Returns:	The result of the boolean NOT operation

The boolean NOT operation will return all parts of the edges in this collection which are not coincident with parts of the edges in the other collection.The result will be a merged edge collection.

The 'not' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'not_' in Python.

(2) Signature: *[const]* Edges **not** (const Region other)

Description: Returns the parts of the edges outside the given region

Returns:	The edges outside the given region

This operation returns the parts of the edges which are outside the given region. Edges on the borders of the polygons are not included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24.The 'not' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'not_' in Python.

not_in

Signature: *[const]* Edges **not_in** (const Edges other)

Description: Returns all edges which are not members of the other edge collection

This method returns all edges in self which can not be found in the other edge collection with exactly the same geometry.

not_inside

(1) Signature: *[const]* Edges **not_inside** (const Edges other)

Description: Returns the edges of this edge collection which are not inside (completely covered by) edges from the other edge collection

Returns: A new edge collection containing the edges not overlapping or touching edges from the other edge collection

This method has been introduced in version 0.28.

(2) Signature: *[const]* Edges **not_inside** (const Region other)

Description: Returns the edges from this edge collection which are not inside (completely covered by) polygons from the region

Returns: A new edge collection containing the edges not overlapping or touching polygons from the region

This method has been introduced in version 0.28.

not_interacting

(1) Signature: *[const]* Edges **not_interacting** (const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Returns the edges of this edge collection which do not overlap or touch edges from the other edge collection

Returns: A new edge collection containing the edges not overlapping or touching edges from the other edge collection

'min_count' and 'max_count' impose a constraint on the number of times an edge of this collection has to interact with (different) edges of the other collection to make the edge selected. An edge is not selected by this method if the number of edges interacting with an edge of this collection is between min_count and max_count (including max_count).

'min_count' and 'max_count' have been introduced in version 0.29.

(2) Signature: *[const]* Edges **not_interacting** (const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Returns the edges from this edge collection which do not overlap or touch polygons from the region

Returns: A new edge collection containing the edges not overlapping or touching polygons from the region

'min_count' and 'max_count' impose a constraint on the number of times an edge of this collection has to interact with (different) polygons of the other region to make the edge selected. An edge is not selected by this method if the number of polygons interacting with an edge of this collection is between min_count and max_count (including max_count).

'min_count' and 'max_count' have been introduced in version 0.29.

not_members_of

Signature: *[const]* Edges **not_members_of** (const Edges other)

Description: Returns all edges which are not members of the other edge collection

This method returns all edges in self which can not be found in the other edge collection with exactly the same geometry.

not_outside

(1) Signature: *[const]* Edges **not_outside** (const Edges other)

Description: Returns the edges of this edge collection which are not outside (completely covered by) edges from the other edge collection

Returns: A new edge collection containing the edges not overlapping or touching edges from the other edge collection

This method has been introduced in version 0.28.

(2) Signature: *[const]* Edges **not_outside** (const Region other)

Description: Returns the edges from this edge collection which are not outside (completely covered by) polygons from the region

Returns: A new edge collection containing the edges not overlapping or touching polygons from the region

This method has been introduced in version 0.28.

not_with

(1) Signature: Edges **not_with** (const Edges other)

Description: Performs the boolean NOT between self and the other edge collection in-place (modifying self)

Returns: The edge collection after modification (self)

The boolean NOT operation will return all parts of the edges in this collection which are not coincident with parts of the edges in the other collection.The result will be a merged edge collection.

Note that in Ruby, the '-=' operator actually does not exist, but is emulated by '-' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'not_with' instead.

The 'not_with' alias has been introduced in version 0.28.12.

(2) Signature: Edges **not_with** (const Region other)

Description: Selects the parts of the edges outside the given region in-place (modifying self)

Returns: The edge collection after modification (self)

This operation selects the parts of the edges which are outside the given region. Edges on the borders of the polygons are not included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

Note that in Ruby, the '-=' operator actually does not exist, but is emulated by '-' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'not_with' instead.

This method has been introduced in version 0.24.The 'not_with' alias has been introduced in version 0.28.12.

or

Signature: *[const]* Edges **or** (const Edges other)

Description: Returns the boolean OR between self and the other edge set

Returns: The resulting edge collection

The boolean OR is implemented by merging the edges of both edge sets. To simply join the edge collections without merging, the + operator is more efficient. The 'or' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'or_' in Python.

or_with

Signature: Edges **or_with** (const Edges other)

Description: Performs the boolean OR between self and the other edge set in-place (modifying self)

Returns: The edge collection after modification (self)

The boolean OR is implemented by merging the edges of both edge sets. To simply join the edge collections without merging, the + operator is more efficient. Note that in Ruby, the '|=' operator actually does not exist, but is emulated by '|' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'or_with' instead.

The 'or_with' alias has been introduced in version 0.28.12.

outside

(1) Signature: *[const]* Edges **outside** (const Edges other)

Description: Returns the edges of this edge collection which are outside (completely covered by) edges from the other edge collection

Returns: A new edge collection containing the edges overlapping or touching edges from the other edge collection

This method has been introduced in version 0.28.

(2) Signature: *[const]* Edges **outside** (const Region other)

Description: Returns the edges from this edge collection which are outside (completely covered by) polygons from the region

Returns: A new edge collection containing the edges overlapping or touching polygons from the region

This method has been introduced in version 0.28.

outside_part

Signature: *[const]* Edges **outside_part** (const Region other)

Description: Returns the parts of the edges of this edge collection which are outside the polygons of the region

Returns: A new edge collection containing the edge parts outside the region

This operation returns the parts of the edges which are not inside the given region. This functionality is similar to the '-' operator, but edges on the borders of the polygons are included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24.

overlap_check

Signature: *[const]* EdgePairs **overlap_check** (const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)

Description: Performs an overlap check with options

d: The minimum distance for which the edges are checked

other: The other edge collection against which to check

whole_edges: If true, deliver the whole edges

metrics: Specify the metrics type

ignore_angle: The threshold angle above which no check is performed

min_projection: The lower threshold of the projected length of one edge onto another

max_projection: The upper threshold of the projected length of one edge onto another

zero_distance_mode: Specifies how to handle edges with zero distance

If "whole_edges" is true, the resulting EdgePairs collection will receive the whole edges which contribute in the width check.

"metrics" can be one of the constants Euclidian, Square or Projection. See there for a description of these constants. Use nil for this value to select the default (Euclidian metrics).

"ignore_angle" specifies the angle threshold of two edges. If two edges form an angle equal or above the given value, they will not contribute in the check. Setting this value to 90 (the default) will exclude edges with an angle of 90 degree or more from the check. Use nil for this value to select the default.

"min_projection" and "max_projection" allow selecting edges by their projected value upon each other. It is sufficient if the projection of one edge on the other matches the specified condition. The projected length must be larger or equal to "min_projection" and less than "max_projection". If you don't want to specify one threshold, pass nil to the respective value.

'zero_distance_mode' has been added in version 0.29.

process

Signature: void **process** (const EdgeOperator ptr process)

Description: Applies a generic edge processor in place (replacing the edges from the Edges collection)

See EdgeProcessor for a description of this feature.

This method has been introduced in version 0.29.

processed

(1) Signature: *[const]* Edges **processed** (const EdgeOperator ptr processed)

Description: Applies a generic edge processor and returns a processed copy

See EdgeProcessor for a description of this feature.

This method has been introduced in version 0.29.

(2) Signature: *[const]* EdgePairs **processed** (const EdgeToEdgePairOperator ptr processed)

Description: Applies a generic edge-to-edge-pair processor and returns an edge pair collection with the results

See EdgeToEdgePairProcessor for a description of this feature.

This method has been introduced in version 0.29.

(3) Signature: *[const]* Region **processed** (const EdgeToPolygonOperator ptr processed)

Description: Applies a generic edge-to-polygon processor and returns an edge collection with the results

See EdgeToPolygonProcessor for a description of this feature.

This method has been introduced in version 0.29.

pull_interacting

(1) Signature: *[const]* Region **pull_interacting** (const Region other)

Description: Returns all polygons of "other" which are interacting with (overlapping, touching) edges of this edge set

Returns: The region after the polygons have been selected (from other)

The "pull_..." methods are similar to "select_..." but work the opposite way: they select shapes from the argument region rather than self. In a deep (hierarchical) context the output region will be hierarchically aligned with self, so the "pull_..." methods provide a way for re-hierarchization.

Merged semantics applies for this method (see merged_semantics= of merged semantics)

This method has been introduced in version 0.26.1

(2) Signature: *[const]* Edges **pull_interacting** (const Edges other)

Description: Returns all edges of "other" which are interacting with polygons of this edge set

Returns: The edge collection after the edges have been selected (from other)

See the other pull_interacting version for more details.

Merged semantics applies for this method (see merged_semantics= of merged semantics)

This method has been introduced in version 0.26.1

remove_properties

Signature: void **remove_properties**

Description: Removes properties for the given container.

This will remove all properties on the given container.

This method has been introduced in version 0.28.4.

select_inside

(1) Signature: Edges **select_inside** (const Edges other)

Description: Selects the edges from this edge collection which are inside (completely covered by) edges from the other edge collection

Returns: The edge collection after the edges have been selected (self)

This method has been introduced in version 0.28.

(2) Signature: Edges **select_inside** (const Region other)

Description: Selects the edges from this edge collection which are inside (completely covered by) polygons from the region

Returns: The edge collection after the edges have been selected (self)

This method has been introduced in version 0.28.

select_inside_part

Signature: Edges **select_inside_part** (const Region other)

Description: Selects the parts of the edges from this edge collection which are inside the polygons of the given region

Returns: The edge collection after the edges have been selected (self)

This operation selects the parts of the edges which are inside the given region. This functionality is similar to the '&=' operator, but edges on the borders of the polygons are not included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24.

select_interacting

(1) Signature: Edges **select_interacting** (const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Selects the edges from this edge collection which overlap or touch edges from the other edge collection

Returns: The edge collection after the edges have been selected (self)

This is the in-place version of interacting - i.e. self is modified rather than a new collection is returned.

'min_count' and 'max_count' have been introduced in version 0.29.

(2) Signature: Edges **select_interacting** (const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Selects the edges from this edge collection which overlap or touch polygons from the region

Returns: The edge collection after the edges have been selected (self)

This is the in-place version of interacting - i.e. self is modified rather than a new collection is returned.

'min_count' and 'max_count' have been introduced in version 0.29.

select_not_inside

(1) Signature: Edges **select_not_inside** (const Edges other)

Description: Selects the edges from this edge collection which are not inside (completely covered by) edges from the other edge collection

Returns: The edge collection after the edges have been selected (self)

This method has been introduced in version 0.28.

(2) Signature: Edges **select_not_inside** (const Region other)

Description: Selects the edges from this edge collection which are not inside (completely covered by) polygons from the region

Returns: The edge collection after the edges have been selected (self)

This method has been introduced in version 0.28.

select_not_interacting

(1) Signature: Edges **select_not_interacting** (const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Selects the edges from this edge collection which do not overlap or touch edges from the other edge collection

Returns: The edge collection after the edges have been selected (self)

This is the in-place version of not_interacting - i.e. self is modified rather than a new collection is returned.

'min_count' and 'max_count' have been introduced in version 0.29.

(2) Signature: Edges **select_not_interacting** (const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Selects the edges from this edge collection which do not overlap or touch polygons from the region

Returns: The edge collection after the edges have been selected (self)

This is the in-place version of not_interacting - i.e. self is modified rather than a new collection is returned.

'min_count' and 'max_count' have been introduced in version 0.29.

select_not_outside

(1) Signature: Edges **select_not_outside** (const Edges other)

Description: Selects the edges from this edge collection which are not outside (completely covered by) edges from the other edge collection

Returns: The edge collection after the edges have been selected (self)

This method has been introduced in version 0.28.

(2) Signature: Edges **select_not_outside** (const Region other)

Description: Selects the edges from this edge collection which are not outside (completely covered by) polygons from the region

Returns: The edge collection after the edges have been selected (self)

This method has been introduced in version 0.28.

select_outside

(1) Signature: Edges **select_outside** (const Edges other)

Description: Selects the edges from this edge collection which are outside (completely covered by) edges from the other edge collection

Returns: The edge collection after the edges have been selected (self)

This method has been introduced in version 0.28.

(2) Signature: Edges **select_outside** (const Region other)

Description: Selects the edges from this edge collection which are outside (completely covered by) polygons from the region

Returns: The edge collection after the edges have been selected (self)

This method has been introduced in version 0.28.

select_outside_part

Signature: Edges **select_outside_part** (const Region other)

Description: Selects the parts of the edges from this edge collection which are outside the polygons of the given region

Returns: The edge collection after the edges have been selected (self)

This operation selects the parts of the edges which are not inside the given region. This functionality is similar to the '-=' operator, but edges on the borders of the polygons are included in the edge set. As a side effect, the edges are made non-intersecting by introducing cut points where edges intersect.

This method has been introduced in version 0.24.

separation_check

Signature: *[const]* EdgePairs **separation_check** (const Edges other, int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)

Description: Performs an overlap check with options

d:	The minimum distance for which the edges are checked
other:	The other edge collection against which to check
whole_edges:	If true, deliver the whole edges
metrics:	Specify the metrics type
ignore_angle:	The threshold angle above which no check is performed
min_projection:	The lower threshold of the projected length of one edge onto another
max_projection:	The upper threshold of the projected length of one edge onto another
zero_distance_mode:	Specifies how to handle edges with zero distance

If "whole_edges" is true, the resulting EdgePairs collection will receive the whole edges which contribute in the width check.

"metrics" can be one of the constants Euclidian, Square or Projection. See there for a description of these constants. Use nil for this value to select the default (Euclidian metrics).

"ignore_angle" specifies the angle threshold of two edges. If two edges form an angle equal or above the given value, they will not contribute in the check. Setting this value to 90 (the default) will exclude edges with an angle of 90 degree or more from the check. Use nil for this value to select the default.

"min_projection" and "max_projection" allow selecting edges by their projected value upon each other. It is sufficient if the projection of one edge on the other matches the specified condition. The projected length must be larger or equal to "min_projection" and less than "max_projection". If you don't want to specify one threshold, pass nil to the respective value.

'zero_distance_mode' has been added in version 0.29.

size

Signature: *[const]* unsigned long **size**

Description: Returns the (flat) number of edges in the edge collection

Use of this method is deprecated. Use count instead

This returns the number of raw edges (not merged edges if merged semantics is enabled). The count is computed 'as if flat', i.e. edges inside a cell are multiplied by the number of times a cell is instantiated.

Starting with version 0.27, the method is called 'count' for consistency with Region. 'size' is still provided as an alias.

Python specific notes:
This method is also available as 'len(object)'.

space_check

Signature: *[const]* EdgePairs **space_check** (int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)

Description: Performs a space check with options

d:	The minimum distance for which the edges are checked
whole_edges:	If true, deliver the whole edges
metrics:	Specify the metrics type
ignore_angle:	The threshold angle above which no check is performed
min_projection:	The lower threshold of the projected length of one edge onto another
max_projection:	The upper threshold of the projected length of one edge onto another
zero_distance_mode:	Specifies how to handle edges with zero distance

If "whole_edges" is true, the resulting EdgePairs collection will receive the whole edges which contribute in the space check.

"metrics" can be one of the constants Euclidian, Square or Projection. See there for a description of these constants. Use nil for this value to select the default (Euclidian metrics).

"ignore_angle" specifies the angle threshold of two edges. If two edges form an angle equal or above the given value, they will not contribute in the check. Setting this value to 90 (the default) will exclude edges with an angle of 90 degree or more from the check. Use nil for this value to select the default.

"min_projection" and "max_projection" allow selecting edges by their projected value upon each other. It is sufficient if the projection of one edge on the other matches the specified condition. The projected length must be larger or equal to "min_projection" and less than "max_projection". If you don't want to specify one threshold, pass nil to the respective value.

'zero_distance_mode' has been added in version 0.29.

split_inside

(1) Signature: *[const]* Edges[] **split_inside** (const Edges other)

Description: Selects the edges from this edge collection which are and are not inside (completely covered by) edges from the other collection

Returns:	A two-element list of edge collections (first: inside, second: non-inside)

This method provides a faster way to compute both inside and non-inside edges compared to using separate methods. It has been introduced in version 0.28.

(2) Signature: *[const]* Edges[] **split_inside** (const Region other)

Description: Selects the edges from this edge collection which are and are not inside (completely covered by) polygons from the other region

Returns:	A two-element list of edge collections (first: inside, second: non-inside)

This method provides a faster way to compute both inside and non-inside edges compared to using separate methods. It has been introduced in version 0.28.

split_interacting

(1) Signature: *[const]* Edges[] **split_interacting** (const Edges other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Selects the edges from this edge collection which do and do not interact with edges from the other collection

Returns: A two-element list of edge collections (first: interacting, second: non-interacting)

This method provides a faster way to compute both interacting and non-interacting edges compared to using separate methods. It has been introduced in version 0.28. 'min_count' and 'max_count' have been introduced in version 0.29.

(2) Signature: *[const]* Edges[] **split_interacting** (const Region other, unsigned long min_count = 1, unsigned long max_count = unlimited)

Description: Selects the edges from this edge collection which do and do not interact with polygons from the other region

Returns: A two-element list of edge collections (first: interacting, second: non-interacting)

This method provides a faster way to compute both interacting and non-interacting edges compared to using separate methods. It has been introduced in version 0.28. 'min_count' and 'max_count' have been introduced in version 0.29.

split_outside

(1) Signature: *[const]* Edges[] **split_outside** (const Edges other)

Description: Selects the edges from this edge collection which are and are not outside (completely covered by) edges from the other collection

Returns: A two-element list of edge collections (first: outside, second: non-outside)

This method provides a faster way to compute both outside and non-outside edges compared to using separate methods. It has been introduced in version 0.28.

(2) Signature: *[const]* Edges[] **split_outside** (const Region other)

Description: Selects the edges from this edge collection which are and are not outside (completely covered by) polygons from the other region

Returns: A two-element list of edge collections (first: outside, second: non-outside)

This method provides a faster way to compute both outside and non-outside edges compared to using separate methods. It has been introduced in version 0.28.

start_segments

Signature: *[const]* Edges **start_segments** (unsigned int length, double fraction)

Description: Returns edges representing a part of the edge after the start point

Returns: A new collection of edges representing the start part

This method allows one to specify the length of these segments in a twofold way: either as a fixed length or by specifying a fraction of the original length:

```
edges = ...  # An edge collection
edges.start_segments(100, 0.0)    # All segments have a length of 100 DBU
```

```
edges.start_segments(0, 50.0)     # All segments have a length of half the
 original length
edges.start_segments(100, 50.0)   # All segments have a length of half the
 original length
                                  # or 100 DBU, whichever is larger
```

It is possible to specify 0 for both values. In this case, degenerated edges (points) are delivered which specify the start positions of the edges but can't participate in some functions.

swap

Signature: void **swap** (Edges other)

Description: Swap the contents of this edge collection with the contents of another one

This method is useful to avoid excessive memory allocation in some cases. For managed memory languages such as Ruby, those cases will be rare.

to_s

(1) Signature: *[const]* string **to_s**

Description: Converts the edge collection to a string

The length of the output is limited to 20 edges to avoid giant strings on large regions. For full output use "to_s" with a maximum count parameter.

Python specific notes:
This method is also available as 'str(object)'.

(2) Signature: *[const]* string **to_s** (unsigned long max_count)

Description: Converts the edge collection to a string

This version allows specification of the maximum number of edges contained in the string.

transform

(1) Signature: Edges **transform** (const Trans t)

Description: Transform the edge collection (modifies self)

t:	The transformation to apply.
Returns:	The transformed edge collection.

Transforms the edge collection with the given transformation. This version modifies the edge collection and returns a reference to self.

(2) Signature: Edges **transform** (const ICplxTrans t)

Description: Transform the edge collection with a complex transformation (modifies self)

t:	The transformation to apply.
Returns:	The transformed edge collection.

Transforms the edge collection with the given transformation. This version modifies the edge collection and returns a reference to self.

(3) Signature: Edges **transform** (const IMatrix2d t)

Description: Transform the edge collection (modifies self)

t:	The transformation to apply.
Returns:	The transformed edge collection.

Transforms the edge collection with the given 2d matrix transformation. This version modifies the edge collection and returns a reference to self.

This variant has been introduced in version 0.27.

(4) Signature: Edges **transform** (const IMatrix3d t)

Description: Transform the edge collection (modifies self)

t: The transformation to apply.

Returns: The transformed edge collection.

Transforms the edge collection with the given 3d matrix transformation. This version modifies the edge collection and returns a reference to self.

This variant has been introduced in version 0.27.

transform_icplx

Signature: Edges **transform_icplx** (const ICplxTrans t)

Description: Transform the edge collection with a complex transformation (modifies self)

t: The transformation to apply.

Returns: The transformed edge collection.

Use of this method is deprecated. Use transform instead

Transforms the edge collection with the given transformation. This version modifies the edge collection and returns a reference to self.

transformed

(1) Signature: *[const]* Edges **transformed** (const Trans t)

Description: Transform the edge collection

t: The transformation to apply.

Returns: The transformed edge collection.

Transforms the edge collection with the given transformation. Does not modify the edge collection but returns the transformed edge collection.

(2) Signature: *[const]* Edges **transformed** (const ICplxTrans t)

Description: Transform the edge collection with a complex transformation

t: The transformation to apply.

Returns: The transformed edge collection.

Transforms the edge collection with the given complex transformation. Does not modify the edge collection but returns the transformed edge collection.

(3) Signature: *[const]* Edges **transformed** (const IMatrix2d t)

Description: Transform the edge collection

t: The transformation to apply.

Returns: The transformed edge collection.

Transforms the edge collection with the given 2d matrix transformation. Does not modify the edge collection but returns the transformed edge collection.

This variant has been introduced in version 0.27.

(4) Signature: *[const]* Edges **transformed** (const IMatrix3d t)

Description: Transform the edge collection

t: The transformation to apply.

Returns: The transformed edge collection.

Transforms the edge collection with the given 3d matrix transformation. Does not modify the edge collection but returns the transformed edge collection.

This variant has been introduced in version 0.27.

transformed_icplx

Signature: *[const]* Edges **transformed_icplx** (const ICplxTrans t)

Description: Transform the edge collection with a complex transformation

t:	The transformation to apply.
Returns:	The transformed edge collection.

Use of this method is deprecated. Use transformed instead

Transforms the edge collection with the given complex transformation. Does not modify the edge collection but returns the transformed edge collection.

width_check

Signature: *[const]* EdgePairs **width_check** (int d, bool whole_edges = false, Metrics metrics = Euclidian, variant ignore_angle = default, variant min_projection = 0, variant max_projection = max, ZeroDistanceMode zero_distance_mode = IncludeZeroDistanceWhenTouching)

Description: Performs a width check with options

d:	The minimum width for which the edges are checked
whole_edges:	If true, deliver the whole edges
metrics:	Specify the metrics type
ignore_angle:	The threshold angle above which no check is performed
min_projection:	The lower threshold of the projected length of one edge onto another
max_projection:	The upper threshold of the projected length of one edge onto another
zero_distance_mode:	Specifies how to handle edges with zero distance

If "whole_edges" is true, the resulting EdgePairs collection will receive the whole edges which contribute in the width check.

"metrics" can be one of the constants Euclidian, Square or Projection. See there for a description of these constants. Use nil for this value to select the default (Euclidian metrics).

"ignore_angle" specifies the angle threshold of two edges. If two edges form an angle equal or above the given value, they will not contribute in the check. Setting this value to 90 (the default) will exclude edges with an angle of 90 degree or more from the check. Use nil for this value to select the default.

"min_projection" and "max_projection" allow selecting edges by their projected value upon each other. It is sufficient if the projection of one edge on the other matches the specified condition. The projected length must be larger or equal to "min_projection" and less than "max_projection". If you don't want to specify one threshold, pass nil to the respective value.

'zero_distance_mode' has been added in version 0.29.

with_angle

(1) Signature: *[const]* Edges **with_angle** (double angle, bool inverse)

Description: Filters the edges by orientation

Filters the edges in the edge collection by orientation. If "inverse" is false, only edges which have the given angle to the x-axis are returned. If "inverse" is true, edges not having the given angle are returned.

This will select horizontal edges:

```
horizontal = edges.with_angle(0, false)
```

(2) Signature: *[const]* Edges **with_angle** (double min_angle, double max_angle, bool inverse, bool include_min_angle = true, bool include_max_angle = false)

Description: Filters the edges by orientation

Filters the edges in the edge collection by orientation. If "inverse" is false, only edges which have an angle to the x-axis larger or equal to "min_angle" (depending on "include_min_angle") and equal or less than "max_angle" (depending on "include_max_angle") are returned. If "inverse" is true, edges which do not conform to this criterion are returned.

With "include_min_angle" set to true (the default), the minimum angle is included in the criterion while with false, the minimum angle itself is not included. Same for "include_max_angle" where the default is false, meaning the maximum angle is not included in the range.

The two "include.." arguments have been added in version 0.27.

(3) Signature: *[const]* Edges **with_angle** (Edges::EdgeType type, bool inverse)

Description: Filters the edges by orientation type

Filters the edges in the edge collection by orientation. If "inverse" is false, only edges which have an angle of the given type are returned. If "inverse" is true, edges which do not conform to this criterion are returned.

This version allows specifying an edge type instead of an angle. Edge types include multiple distinct orientations and are specified using one of the OrthoEdges, DiagonalEdges or OrthoDiagonalEdges types.

This method has been added in version 0.28.

with_length

(1) Signature: *[const]* Edges **with_length** (unsigned int length, bool inverse)

Description: Filters the edges by length

Filters the edges in the edge collection by length. If "inverse" is false, only edges which have the given length are returned. If "inverse" is true, edges not having the given length are returned.

(2) Signature: *[const]* Edges **with_length** (variant min_length, variant max_length, bool inverse)

Description: Filters the edges by length

Filters the edges in the edge collection by length. If "inverse" is false, only edges which have a length larger or equal to "min_length" and less than "max_length" are returned. If "inverse" is true, edges not having a length less than "min_length" or larger or equal than "max_length" are returned.

If you don't want to specify a lower or upper limit, pass nil to that parameter.

write

Signature: *[const]* void **write** (string filename)

Description: Writes the region to a file

This method is provided for debugging purposes. It writes the object to a flat layer 0/0 in a single top cell.

This method has been introduced in version 0.29.

xor

Signature: *[const]* Edges **xor** (const Edges other)

Description: Returns the boolean XOR between self and the other edge collection

Returns: The result of the boolean XOR operation

The boolean XOR operation will return all parts of the edges in this and the other collection except the parts where both are coincident. The result will be a merged edge collection.

The 'xor' alias has been introduced in version 0.28.12.

xor_with

Signature: Edges **xor_with** (const Edges other)

Description: Performs the boolean XOR between self and the other edge collection in-place (modifying self)

Returns: The edge collection after modification (self)

The boolean XOR operation will return all parts of the edges in this and the other collection except the parts where both are coincident. The result will be a merged edge collection.

Note that in Ruby, the '^=' operator actually does not exist, but is emulated by '^' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'xor_with' instead.

The 'xor_with' alias has been introduced in version 0.28.12.

|

Signature: *[const]* Edges **|** (const Edges other)

Description: Returns the boolean OR between self and the other edge set

Returns: The resulting edge collection

The boolean OR is implemented by merging the edges of both edge sets. To simply join the edge collections without merging, the + operator is more efficient. The 'or' alias has been introduced in version 0.28.12.

Python specific notes:
This attribute is available as 'or_' in Python.

|=

Signature: Edges **|=** (const Edges other)

Description: Performs the boolean OR between self and the other edge set in-place (modifying self)

Returns: The edge collection after modification (self)

The boolean OR is implemented by merging the edges of both edge sets. To simply join the edge collections without merging, the + operator is more efficient. Note that in Ruby, the '|=' operator actually does not exist, but is emulated by '|' followed by an assignment. This is less efficient than the in-place operation, so it is recommended to use 'or_with' instead.

The 'or_with' alias has been introduced in version 0.28.12.

4.48. API reference - Class Edges::EdgeType

Notation used in Ruby API documentation

Module: db

Description: This enum specifies the edge type for edge angle filters.

This class is equivalent to the class Edges::EdgeType

This enum was introduced in version 0.28.

Public constructors

new Edges::EdgeType ptr	**new**	(int i)	Creates an enum from an integer value
new Edges::EdgeType ptr	**new**	(string s)	Creates an enum from a string value

Public methods

[const]	bool	**!=**	(const Edges::EdgeType other)	Compares two enums for inequality
[const]	bool	**!=**	(int other)	Compares an enum with an integer for inequality
[const]	bool	**<**	(const Edges::EdgeType other)	Returns true if the first enum is less (in the enum symbol order) than the second
[const]	bool	**<**	(int other)	Returns true if the enum is less (in the enum symbol order) than the integer value
[const]	bool	**==**	(const Edges::EdgeType other)	Compares two enums
[const]	bool	**==**	(int other)	Compares an enum with an integer value
[const]	int	**hash**		Gets the hash value from the enum
[const]	string	**inspect**		Converts an enum to a visual string
[const]	int	**to_i**		Gets the integer value from the enum
[const]	string	**to_s**		Gets the symbolic string from an enum

Public static methods and constants

[static,const]	Edges::EdgeType	**DiagonalEdges**	Diagonal edges are selected (-45 and 45 degree)
[static,const]	Edges::EdgeType	**OrthoDiagonalEdges**	Diagonal or orthogonal edges are selected (0, 90, -45 and 45 degree)
[static,const]	Edges::EdgeType	**OrthoEdges**	Horizontal and vertical edges are selected

Detailed description

!=	**(1) Signature**: *[const]* bool **!=** (const Edges::EdgeType other) **Description**: Compares two enums for inequality **(2) Signature**: *[const]* bool **!=** (int other) **Description**: Compares an enum with an integer for inequality
<	**(1) Signature**: *[const]* bool **<** (const Edges::EdgeType other) **Description**: Returns true if the first enum is less (in the enum symbol order) than the second **(2) Signature**: *[const]* bool **<** (int other) **Description**: Returns true if the enum is less (in the enum symbol order) than the integer value
==	**(1) Signature**: *[const]* bool **==** (const Edges::EdgeType other) **Description**: Compares two enums **(2) Signature**: *[const]* bool **==** (int other) **Description**: Compares an enum with an integer value
DiagonalEdges	**Signature**: *[static,const]* Edges::EdgeType **DiagonalEdges** **Description**: Diagonal edges are selected (-45 and 45 degree) **Python specific notes:** The object exposes a readable attribute 'DiagonalEdges'. This is the getter.
OrthoDiagonalEdges	**Signature**: *[static,const]* Edges::EdgeType **OrthoDiagonalEdges** **Description**: Diagonal or orthogonal edges are selected (0, 90, -45 and 45 degree) **Python specific notes:** The object exposes a readable attribute 'OrthoDiagonalEdges'. This is the getter.
OrthoEdges	**Signature**: *[static,const]* Edges::EdgeType **OrthoEdges** **Description**: Horizontal and vertical edges are selected **Python specific notes:** The object exposes a readable attribute 'OrthoEdges'. This is the getter.
hash	**Signature**: *[const]* int **hash** **Description**: Gets the hash value from the enum **Python specific notes:** This method is also available as 'hash(object)'.
inspect	**Signature**: *[const]* string **inspect** **Description**: Converts an enum to a visual string **Python specific notes:** This method is also available as 'repr(object)'.

new

(1) Signature: *[static]* new Edges::EdgeType ptr **new** (int i)

Description: Creates an enum from an integer value

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new Edges::EdgeType ptr **new** (string s)

Description: Creates an enum from a string value

Python specific notes:
This method is the default initializer of the object.

to_i

Signature: *[const]* int **to_i**

Description: Gets the integer value from the enum

Python specific notes:
This method is also available as 'int(object)'.

to_s

Signature: *[const]* string **to_s**

Description: Gets the symbolic string from an enum

Python specific notes:
This method is also available as 'str(object)'.

4.49. API reference - Class InstElement

Notation used in Ruby API documentation

Module: db

Description: An element in an instantiation path

This objects are used to reference a single instance in a instantiation path. The object is composed of a CellInstArray object (accessible through the cell_inst accessor) that describes the basic instance, which may be an array. The particular instance within the array can be further retrieved using the array_member_trans, specific_trans or specific_cplx_trans methods.

Public constructors

new InstElement ptr	**new**		Default constructor
new InstElement ptr	**new**	(const Instance inst)	Create an instance element from a single instance alone
new InstElement ptr	**new**	(const Instance inst, unsigned long a_index, unsigned long b_index)	Create an instance element from an array instance pointing into a certain array member

Public methods

[const]	bool	**!=**	(const InstElement b)	Inequality of two InstElement objects
[const]	bool	**<**	(const InstElement b)	Provides an order criterion for two InstElement objects
[const]	bool	**==**	(const InstElement b)	Equality of two InstElement objects
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	Trans	**array_member_trans**		Returns the transformation for this array member
	void	**assign**	(const InstElement other)	Assigns another object to self

[const]	const CellInstArray ptr	**cell_inst**	Accessor to the cell instance (array).
[const]	new InstElement ptr	**dup**	Creates a copy of self
[const]	long	**ia**	Returns the 'a' axis index for array instances
[const]	long	**ib**	Returns the 'b' axis index for array instances
[const]	Instance	**inst**	Gets the Instance object held in this instance path element.
[const]	unsigned long	**prop_id**	Accessor to the property attached to this instance.
[const]	ICplxTrans	**specific_cplx_trans**	Returns the specific complex transformation for this instance
[const]	Trans	**specific_trans**	Returns the specific transformation for this instance

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**		Use of this method is deprecated. Use _create instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead
[static]	new InstElement ptr	**new_i**	(const Instance inst)	Use of this method is deprecated. Use new instead
[static]	new InstElement ptr	**new_iab**	(const Instance inst, unsigned long a_index, unsigned long b_index)	Use of this method is deprecated. Use new instead

Detailed description

!=	**Signature**: *[const]* bool **!=** (const InstElement b) **Description**: Inequality of two InstElement objects See the comments on the == operator.
<	**Signature**: *[const]* bool **<** (const InstElement b) **Description**: Provides an order criterion for two InstElement objects Note: this operator is just provided to establish any order, not a particular one.

==	**Signature**: *[const]* bool **==** (const InstElement b) **Description**: Equality of two InstElement objects Note: this operator returns true if both instance elements refer to the same instance, not just identical ones.
_create	**Signature**: void **_create** **Description**: Ensures the C++ object is created Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.
_destroy	**Signature**: void **_destroy** **Description**: Explicitly destroys the object Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.
_destroyed?	**Signature**: *[const]* bool **_destroyed?** **Description**: Returns a value indicating whether the object was already destroyed This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.
_is_const_object?	**Signature**: *[const]* bool **_is_const_object?** **Description**: Returns a value indicating whether the reference is a const reference This method returns true, if self is a const reference. In that case, only const methods may be called on self.
_manage	**Signature**: void **_manage** **Description**: Marks the object as managed by the script side. After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required. Usually it's not required to call this method. It has been introduced in version 0.24.
_unmanage	**Signature**: void **_unmanage** **Description**: Marks the object as no longer owned by the script side. Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur. Usually it's not required to call this method. It has been introduced in version 0.24.
array_member_trans	**Signature**: *[const]* Trans **array_member_trans** **Description**: Returns the transformation for this array member

The array member transformation is the one applicable in addition to the global transformation for the member selected from an array. If this instance is not an array instance, the specific transformation is a unit transformation without displacement.

assign

Signature: void **assign** (const InstElement other)

Description: Assigns another object to self

cell_inst

Signature: *[const]* const CellInstArray ptr **cell_inst**

Description: Accessor to the cell instance (array).

This method is equivalent to "self.inst.cell_inst" and provided for convenience.

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new InstElement ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

ia

Signature: *[const]* long **ia**

Description: Returns the 'a' axis index for array instances

For instance elements describing one member of an array, this attribute will deliver the a axis index addressed by this element. See ib and array_member_trans for further attributes applicable to array members. If the element is a plain instance and not an array member, this attribute is a negative value.

This method has been introduced in version 0.25.

ib

Signature: *[const]* long **ib**

Description: Returns the 'b' axis index for array instances

For instance elements describing one member of an array, this attribute will deliver the a axis index addressed by this element. See ia and array_member_trans for further attributes applicable to array members. If the element is a plain instance and not an array member, this attribute is a negative value.

This method has been introduced in version 0.25.

inst

Signature: *[const]* Instance **inst**

Description: Gets the Instance object held in this instance path element.

This method has been added in version 0.24.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

new

(1) Signature: *[static]* new InstElement ptr **new**

Description: Default constructor

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new InstElement ptr **new** (const Instance inst)

Description: Create an instance element from a single instance alone

Starting with version 0.15, this method takes an Instance object (an instance reference) as the argument.

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new InstElement ptr **new** (const Instance inst, unsigned long a_index, unsigned long b_index)

Description: Create an instance element from an array instance pointing into a certain array member

Starting with version 0.15, this method takes an Instance object (an instance reference) as the first argument.

Python specific notes:
This method is the default initializer of the object.

new_i

Signature: *[static]* new InstElement ptr **new_i** (const Instance inst)

Description: Create an instance element from a single instance alone

Use of this method is deprecated. Use new instead

Starting with version 0.15, this method takes an Instance object (an instance reference) as the argument.

Python specific notes:
This method is the default initializer of the object.

new_iab

Signature: *[static]* new InstElement ptr **new_iab** (const Instance inst, unsigned long a_index, unsigned long b_index)

Description: Create an instance element from an array instance pointing into a certain array member

Use of this method is deprecated. Use new instead

Starting with version 0.15, this method takes an Instance object (an instance reference) as the first argument.

Python specific notes:
This method is the default initializer of the object.

prop_id

Signature: *[const]* unsigned long **prop_id**

Description: Accessor to the property attached to this instance.

This method is equivalent to "self.inst.prop_id" and provided for convenience.

specific_cplx_trans

Signature: *[const]* ICplxTrans **specific_cplx_trans**

Description: Returns the specific complex transformation for this instance

The specific transformation is the one applicable for the member selected from an array. This is the effective transformation applied for this array member. array_member_trans gives the transformation applied additionally to the instances' global transformation (in other words, specific_cplx_trans = array_member_trans * cell_inst.cplx_trans).

specific_trans

Signature: *[const]* Trans **specific_trans**

Description: Returns the specific transformation for this instance

The specific transformation is the one applicable for the member selected from an array. This is the effective transformation applied for this array member. array_member_trans gives the transformation applied additionally to the instances' global transformation (in other words, specific_trans = array_member_trans * cell_inst.trans). This method delivers a simple transformation that does not include magnification components. To get these as well, use specific_cplx_trans.

4.50. API reference - Class LayerMapping

Notation used in Ruby API documentation

Module: db

Description: A layer mapping (source to target layout)

A layer mapping is an association of layers in two layouts forming pairs of layers, i.e. one layer corresponds to another layer in the other layout. The LayerMapping object describes the mapping of layers of a source layout A to a target layout B.

A layer mapping can be set up manually or using the methods create or create_full.

```
lm = RBA::LayerMapping::new
# explicit:
lm.map(2, 1)  # map layer index 2 of source to 1 of target
lm.map(7, 3)  # map layer index 7 of source to 3 of target
...
# or employing the specification identity:
lm.create(target_layout, source_layout)
# plus creating layers which don't exist in the target layout yet:
new_layers = lm.create_full(target_layout, source_layout)
```

A layer might not be mapped to another layer which basically means that there is no corresponding layer. Such layers will be ignored in operations using the layer mapping. Use create_full to ensure all layers of the source layout are mapped.

LayerMapping objects play a role mainly in the hierarchical copy or move operations of Layout. However, use is not restricted to these applications.

This class has been introduced in version 0.23.

Public constructors

new LayerMapping ptr	**new**	Creates a new object of this class

Public methods

	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
	void	**assign**	(const LayerMapping other)	Assigns another object to self
	void	**clear**		Clears the mapping.

	void	**create**	(const Layout layout_a, const Layout layout_b)	Initialize the layer mapping from two layouts
	unsigned int[]	**create_full**	(Layout layout_a, const Layout layout_b)	Initialize the layer mapping from two layouts
[const]	new LayerMapping ptr	**dup**		Creates a copy of self
[const]	bool	**has_mapping?**	(unsigned int layer_index_b)	Determine if a layer in layout_b has a mapping to a layout_a layer.
[const]	unsigned int	**layer_mapping**	(unsigned int layer_index_b)	Determine layer mapping of a layout_b layer to the corresponding layout_a layer.
	void	**map**	(unsigned int layer_index_b, unsigned int layer_index_a)	Explicitly specify a mapping.
[const]	map<unsigned int,unsigned int>	**table**		Returns the mapping table.

Deprecated methods (protected, public, static, non-static and constructors)

	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

assign

Signature: void **assign** (const LayerMapping other)

Description: Assigns another object to self

clear

Signature: void **clear**

Description: Clears the mapping.

create

Signature: void **create** (const Layout layout_a, const Layout layout_b)

Description: Initialize the layer mapping from two layouts

layout_a:	The target layout
layout_b:	The source layout

The layer mapping is created by looking up each layer of layout_b in layout_a. All layers with matching specifications (LayerInfo) are mapped. Layouts without a layer/datatype/name specification will not be mapped. create_full is a version of this method which creates new layers in layout_a if no corresponding layer is found.

create_full

Signature: unsigned int[] **create_full** (Layout layout_a, const Layout layout_b)

Description: Initialize the layer mapping from two layouts

layout_a:	The target layout
layout_b:	The source layout
Returns:	A list of layers created

The layer mapping is created by looking up each layer of layout_b in layout_a. All layers with matching specifications (LayerInfo) are mapped. Layouts without a layer/datatype/name specification will not be mapped. Layers with a valid specification which are not found in layout_a are created there.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new LayerMapping ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

has_mapping?

Signature: *[const]* bool **has_mapping?** (unsigned int layer_index_b)

Description: Determine if a layer in layout_b has a mapping to a layout_a layer.

layer_index_b:	The index of the layer in layout_b whose mapping is requested.
Returns:	true, if the layer has a mapping

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

layer_mapping

Signature: *[const]* unsigned int **layer_mapping** (unsigned int layer_index_b)

Description: Determine layer mapping of a layout_b layer to the corresponding layout_a layer.

layer_index_b:	The index of the layer in layout_b whose mapping is requested.
Returns:	The corresponding layer in layout_a.

map

Signature: void **map** (unsigned int layer_index_b, unsigned int layer_index_a)

Description: Explicitly specify a mapping.

layer_index_b:	The index of the layer in layout B (the "source")
layer_index_a:	The index of the layer in layout A (the "target")

	Beside using the mapping generator algorithms provided through create and create_full, it is possible to explicitly specify layer mappings using this method.
new	**Signature**: *[static]* new LayerMapping ptr **new** **Description**: Creates a new object of this class **Python specific notes:** This method is the default initializer of the object.
table	**Signature**: *[const]* map<unsigned int,unsigned int> **table** **Description**: Returns the mapping table. The mapping table is a dictionary where the keys are source layout layer indexes and the values are the target layout layer indexes. This method has been introduced in version 0.25.

4.51. API reference - Class LayerInfo

Notation used in Ruby API documentation

Module: db

Description: A structure encapsulating the layer properties

The layer properties describe how a layer is stored in a GDS2 or OASIS file for example. The LayerInfo object represents the storage properties that are attached to a layer in the database.

In general, a layer has either a layer and a datatype number (in GDS2), a name (for example in DXF or CIF) or both (in OASIS). In the latter case, the primary identification is through layer and datatype number and the name is some annotation attached to it. A LayerInfo object which specifies just a name returns true on is_named?. The LayerInfo object can also specify an anonymous layer (use LayerInfo#new without arguments). Such a layer will not be stored when saving the layout. They can be employed for temporary layers for example. Use LayerInfo#anonymous? to test whether a layer does not have a specification.

The LayerInfo is used for example in Layout#insert_layer to specify the properties of the new layer that will be created. The is_equivalent? method compares two LayerInfo objects using the layer and datatype numbers with a higher priority over the name.

Public constructors

new LayerInfo ptr	**new**		The default constructor.
new LayerInfo ptr	**new**	(int layer, int datatype)	The constructor for a layer/datatype pair.
new LayerInfo ptr	**new**	(string name)	The constructor for a named layer.
new LayerInfo ptr	**new**	(int layer, int datatype, string name)	The constructor for a named layer with layer and datatype.

Public methods

[const]	bool	**!=**	(const LayerInfo b)	Compares two layer info objects
[const]	bool	**==**	(const LayerInfo b)	Compares two layer info objects
	void	**_create**		Ensures the C++ object is created
	void	**_destroy**		Explicitly destroys the object
[const]	bool	**_destroyed?**		Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**		Returns a value indicating whether the reference is a const reference
	void	**_manage**		Marks the object as managed by the script side.
	void	**_unmanage**		Marks the object as no longer owned by the script side.
[const]	bool	**anonymous?**		Returns true, if the layer has no specification (i.e. is created by the default constructor).

	void	**assign**	(const LayerInfo other)	Assigns another object to self
[const]	int	**datatype**		Gets the datatype
	void	**datatype=**	(int datatype)	Set the datatype
[const]	new LayerInfo ptr	**dup**		Creates a copy of self
[const]	unsigned long	**hash**		Computes a hash value
[const]	bool	**is_equivalent?**	(const LayerInfo b)	Equivalence of two layer info objects
[const]	bool	**is_named?**		Returns true, if the layer is purely specified by name.
[const]	int	**layer**		Gets the layer number
	void	**layer=**	(int layer)	Sets the layer number
[const]	string	**name**		Gets the layer name
	void	**name=**	(string name)	Set the layer name
[const]	string	**to_s**	(bool as_target = false)	Convert the layer info object to a string

Public static methods and constants

LayerInfo	**from_string**	(string s, bool as_target = false)	Create a layer info object from a string

Deprecated methods (protected, public, static, non-static and constructors)

	void	**create**	Use of this method is deprecated. Use _create instead
	void	**destroy**	Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**	Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**	Use of this method is deprecated. Use _is_const_object? instead

Detailed description

!=

Signature: *[const]* bool **!=** (const LayerInfo b)

Description: Compares two layer info objects

Returns: True, if both are not equal

This method was added in version 0.18.

==

Signature: *[const]* bool **==** (const LayerInfo b)

Description: Compares two layer info objects

Returns: True, if both are equal

This method was added in version 0.18.

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

anonymous?

Signature: *[const]* bool **anonymous?**

Description: Returns true, if the layer has no specification (i.e. is created by the default constructor).

Returns: True, if the layer does not have any specification.

This method was added in version 0.23.

assign

Signature: void **assign** (const LayerInfo other)

Description: Assigns another object to self

create

Signature: void **create**

Description: Ensures the C++ object is created

Use of this method is deprecated. Use _create instead

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

datatype

Signature: *[const]* int **datatype**

Description: Gets the datatype

Python specific notes:
The object exposes a readable attribute 'datatype'. This is the getter.

datatype=

Signature: void **datatype=** (int datatype)

Description: Set the datatype

Python specific notes:
The object exposes a writable attribute 'datatype'. This is the setter.

destroy

Signature: void **destroy**

Description: Explicitly destroys the object

Use of this method is deprecated. Use _destroy instead

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

destroyed?

Signature: *[const]* bool **destroyed?**

Description: Returns a value indicating whether the object was already destroyed

Use of this method is deprecated. Use _destroyed? instead

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

dup

Signature: *[const]* new LayerInfo ptr **dup**

Description: Creates a copy of self

Python specific notes:
This method also implements '__copy__' and '__deepcopy__'.

from_string

Signature: *[static]* LayerInfo **from_string** (string s, bool as_target = false)

Description: Create a layer info object from a string

The: string

Returns: The LayerInfo object

If 'as_target' is true, relative specifications such as '*+1' for layer or datatype are permitted.

This method will take strings as produced by to_s and create a LayerInfo object from them. The format is either "layer", "layer/datatype", "name" or "name (layer/datatype)".

This method was added in version 0.23. The 'as_target' argument has been added in version 0.26.5.

hash

Signature: *[const]* unsigned long **hash**

Description: Computes a hash value

Returns a hash value for the given layer info object. This method enables layer info objects as hash keys.

This method has been introduced in version 0.25.

Python specific notes:
This method is also available as 'hash(object)'.

is_const_object?

Signature: *[const]* bool **is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

Use of this method is deprecated. Use _is_const_object? instead

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

is_equivalent?

Signature: *[const]* bool **is_equivalent?** (const LayerInfo b)

Description: Equivalence of two layer info objects

Returns: True, if both are equivalent

First, layer and datatype are compared. The name is of second order and used only if no layer or datatype is given for one of the operands. This is basically a weak comparison that reflects the search preferences. It is the basis for Layout#find_layer. Here are some examples:

```
# no match as layer/datatypes or names differ:
RBA::LayerInfo::new(1, 17).is_equivalent?(RBA::LayerInfo::new(1, 18)) -> false
RBA::LayerInfo::new('metal1').is_equivalent?(RBA::LayerInfo::new('m1')) ->
 false
# exact match for numbered or named layers:
RBA::LayerInfo::new(1, 17).is_equivalent?(RBA::LayerInfo::new(1, 17)) -> true
RBA::LayerInfo::new('metal1').is_equivalent?(RBA::LayerInfo::new('metal1')) ->
 true
# match as names are second priority over layer/datatypes:
RBA::LayerInfo::new(1, 17, 'metal1').is_equivalent?(RBA::LayerInfo::new(1, 17,
 'm1')) -> true
# match as name matching is fallback:
RBA::LayerInfo::new(1, 17, 'metal1').is_equivalent?
(RBA::LayerInfo::new('metal1')) -> true
# no match as neither names or layer/datatypes match:
RBA::LayerInfo::new(1, 17, 'metal1').is_equivalent?(RBA::LayerInfo::new('m1'))
 -> false
```

This method was added in version 0.18 and modified to compare non-named vs. named layers in version 0.28.11.

is_named?

Signature: *[const]* bool **is_named?**

Description: Returns true, if the layer is purely specified by name.

Returns: True, if no layer or datatype is given.

This method was added in version 0.18.

layer

Signature: *[const]* int **layer**

Description: Gets the layer number

Python specific notes:
The object exposes a readable attribute 'layer'. This is the getter.

layer=

Signature: void **layer=** (int layer)

Description: Sets the layer number

Python specific notes:
The object exposes a writable attribute 'layer'. This is the setter.

name

Signature: *[const]* string **name**

Description: Gets the layer name

Python specific notes:
The object exposes a readable attribute 'name'. This is the getter.

name=

Signature: void **name=** (string name)

Description: Set the layer name

The name is set on OASIS input for example, if the layer has a name.

Python specific notes:
The object exposes a writable attribute 'name'. This is the setter.

new

(1) Signature: *[static]* new LayerInfo ptr **new**

Description: The default constructor.

Creates a default LayerInfo object.

This method was added in version 0.18.

Python specific notes:
This method is the default initializer of the object.

(2) Signature: *[static]* new LayerInfo ptr **new** (int layer, int datatype)

Description: The constructor for a layer/datatype pair.

layer: The layer number

datatype: The datatype number

Creates a LayerInfo object representing a layer and datatype.

This method was added in version 0.18.

Python specific notes:
This method is the default initializer of the object.

(3) Signature: *[static]* new LayerInfo ptr **new** (string name)

Description: The constructor for a named layer.

name: The name

Creates a LayerInfo object representing a named layer.

This method was added in version 0.18.

Python specific notes:

This method is the default initializer of the object.

(4) Signature: *[static]* new LayerInfo ptr **new** (int layer, int datatype, string name)

Description: The constructor for a named layer with layer and datatype.

layer:	The layer number
datatype:	The datatype number
name:	The name

Creates a LayerInfo object representing a named layer with layer and datatype.

This method was added in version 0.18.

Python specific notes:
This method is the default initializer of the object.

to_s

Signature: *[const]* string **to_s** (bool as_target = false)

Description: Convert the layer info object to a string

Returns:	The string

If 'as_target' is true, wildcard and relative specifications are formatted such such.

This method was added in version 0.18. The 'as_target' argument has been added in version 0.26.5.

Python specific notes:
This method is also available as 'str(object)'.

4.52. API reference - Class Layout

Notation used in Ruby API documentation

Module: db

Description: The layout object

This object represents a layout. The layout object contains the cell hierarchy and adds functionality for managing cell names and layer names. The cell hierarchy can be changed by adding cells and cell instances. Cell instances will virtually put the content of a cell into another cell. Many cell instances can be put into a cell thus forming repetitions of the cell content. This process can be repeated over multiple levels. In effect a cell graphs is created with parent cells and child cells. The graph must not be recursive, so there is at least one top cell, which does not have a parent cell. Multiple top cells can be present.

Layout is the very basic class of the layout database. It has a rich set of methods to manipulate and query the layout hierarchy, the geometrical objects, the meta information and other features of the layout database. For a discussion of the basic API and the related classes see The Database API.

Usually layout objects have already been created by KLayout's application core. You can address such a layout via the CellView object inside the LayoutView class. For example:

```
active_layout = RBA::CellView::active.layout
puts "Top cell of current layout is #{active_layout.top_cell.name}"
```

However, a layout can also be used standalone:

```
layout = RBA::Layout::new
cell = layout.create_cell("TOP")
layer = layout.layer(RBA::LayerInfo::new(1, 0))
cell.shapes(layer).insert(RBA::Box::new(0, 0, 1000, 1000))
layout.write("single_rect.gds")
```

Public constructors

new Layout ptr	**new**	(Manager manager)	Creates a layout object attached to a manager
new Layout ptr	**new**		Creates a layout object
new Layout ptr	**new**	(bool editable, Manager manager)	Creates a layout object attached to a manager
new Layout ptr	**new**	(bool editable)	Creates a layout object

Public methods

	void	**_create**	Ensures the C++ object is created
	void	**_destroy**	Explicitly destroys the object
[const]	bool	**_destroyed?**	Returns a value indicating whether the object was already destroyed
[const]	bool	**_is_const_object?**	Returns a value indicating whether the reference is a const reference

	void	_manage		Marks the object as managed by the script side.
	void	_unmanage		Marks the object as no longer owned by the script side.
	unsigned int	add_lib_cell	(Library ptr library, unsigned int lib_cell_index)	Imports a cell from the library
	void	add_meta_info	(const LayoutMetaInfo info)	Adds meta information to the layout
	unsigned int	add_pcell_variant	(unsigned int pcell_id, map<string,variant> parameters)	Creates a PCell variant for the given PCell ID with the parameters given as a name/value dictionary
	unsigned int	add_pcell_variant	(unsigned int pcell_id, variant[] parameters)	Creates a PCell variant for the given PCell ID with the given parameters
	unsigned int	add_pcell_variant	(Library ptr library, unsigned int pcell_id, map<string,variant> parameters)	Creates a PCell variant for a PCell located in an external library with the parameters given as a name/value dictionary
	unsigned int	add_pcell_variant	(Library ptr library, unsigned int pcell_id, variant[] parameters)	Creates a PCell variant for a PCell located in an external library
	void	assign	(const Layout other)	Assigns another object to self
[const]	RecursiveShapeIterator	begin_shapes	(const Cell ptr cell, unsigned int layer)	Delivers a recursive shape iterator for the shapes below the given cell on the given layer
	Cell ptr	cell	(string name)	Gets a cell object from the cell name
	Cell ptr	cell	(unsigned int i)	Gets a cell object from the cell index
[const]	string	cell_name	(unsigned int index)	Gets the name for a cell with the given index
[const]	unsigned int	cells		Returns the number of cells
	Cell ptr[]	cells	(string name_filter)	Gets the cell objects for a given name filter
	void	cleanup	(unsigned int[] cell_indexes_to_keep = [])	Cleans up the layout
	void	clear		Clears the layout
	void	clear_all_meta_info		Clears all meta information of the layout (cell specific and global)
	void	clear_layer	(unsigned int layer_index)	Clears a layer
	void	clear_layer	(unsigned int layer_index, unsigned int flags)	Clears a layer (given shape types only)

	void	**clear_meta_info**		Clears the meta information of the layout
	unsigned int	**clip**	(unsigned int cell, const Box box)	Clips the given cell by the given rectangle and produce a new cell with the clip
	unsigned int	**clip**	(unsigned int cell, const DBox box)	Clips the given cell by the given rectangle and produce a new cell with the clip
	Cell ptr	**clip**	(const Cell cell, const Box box)	Clips the given cell by the given rectangle and produce a new cell with the clip
	Cell ptr	**clip**	(const Cell cell, const DBox box)	Clips the given cell by the given rectangle and produce a new cell with the clip
[const]	unsigned int	**clip_into**	(unsigned int cell, Layout ptr target, const Box box)	Clips the given cell by the given rectangle and produce a new cell with the clip
[const]	unsigned int	**clip_into**	(unsigned int cell, Layout ptr target, const DBox box)	Clips the given cell by the given rectangle and produce a new cell with the clip
[const]	Cell ptr	**clip_into**	(const Cell cell, Layout ptr target, const Box box)	Clips the given cell by the given rectangle and produce a new cell with the clip
[const]	Cell ptr	**clip_into**	(const Cell cell, Layout ptr target, const DBox box)	Clips the given cell by the given rectangle and produce a new cell with the clip
	unsigned int	**convert_cell_to_static**	(unsigned int cell_index)	Converts a PCell or library cell to a usual (static) cell
	void	**copy_layer**	(unsigned int src, unsigned int dest)	Copies a layer
	void	**copy_layer**	(unsigned int src, unsigned int dest, unsigned int flags)	Copies a layer (selected shape types only)
	void	**copy_meta_info**	(const Layout other)	Copies the meta information from the other layout into this layout
	void	**copy_meta_info**	(const Layout other, const CellMapping cm)	Copies the meta information from the other layout into this layout for the cells given by the cell mapping
	void	**copy_tree_shapes**	(const Layout source_layout, const CellMapping cell_mapping)	Copies the shapes for all given mappings in the CellMapping object
	void	**copy_tree_shapes**	(const Layout source_layout, const CellMapping cell_mapping, const LayerMapping layer_mapping)	Copies the shapes for all given mappings in the CellMapping object using the given layer mapping

	Cell ptr	**create_cell**	(string name)	Creates a cell with the given name
	Cell ptr	**create_cell**	(string pcell_name, map<string,variant> params)	Creates a cell as a PCell variant for the PCell with the given name
	Cell ptr	**create_cell**	(string name, string lib_name)	Creates a cell with the given name
	Cell ptr	**create_cell**	(string pcell_name, string lib_name, map<string,variant> params)	Creates a cell for a PCell with the given PCell name from the given library
[const]	double	**dbu**		Gets the database unit
	void	**dbu=**	(double dbu)	Sets the database unit
	void	**delete_cell**	(unsigned int cell_index)	Deletes a cell
	void	**delete_cell_rec**	(unsigned int cell_index)	Deletes a cell plus all subcells
	void	**delete_cells**	(unsigned int[] cell_index_list)	Deletes multiple cells
	void	**delete_layer**	(unsigned int layer_index)	Deletes a layer
	void	**delete_property**	(variant key)	Deletes the user property with the given key
[const]	new Layout ptr	**dup**		Creates a copy of self
[iter]	Cell	**each_cell**		Iterates the unsorted cell list
[iter]	unsigned int	**each_cell_bottom_up**		Iterates the bottom-up sorted cell list
[iter]	unsigned int	**each_cell_top_down**		begin iterator of the top-down sorted cell list
[const,iter]	LayoutMetaInfo	**each_meta_info**		Iterates over the meta information of the layout
[iter]	unsigned int	**each_top_cell**		Iterates the top cells
	void	**end_changes**		Cancels the "in changes" state (see "start_changes")
[const]	unsigned int	**error_layer**		Returns the index of the error layer
	variant	**find_layer**	(const LayerInfo info)	Finds a layer with the given properties
	variant	**find_layer**	(string name)	Finds a layer with the given name
	variant	**find_layer**	(int layer, int datatype)	Finds a layer with the given layer and datatype number
	variant	**find_layer**	(int layer, int datatype, string name)	Finds a layer with the given layer and datatype number and name
	void	**flatten**	(unsigned int cell_index,	Flattens the given cell

			int levels, bool prune)	
	void	**flatten_into**	(unsigned int source_cell_index, unsigned int target_cell_index, const ICplxTrans trans, int levels)	Flattens the given cell into another cell
[const]	LayerInfo	**get_info**	(unsigned int index)	Gets the info structure for a specified layer
[const]	unsigned int	**guiding_shape_layer**		Returns the index of the guiding shape layer
	bool	**has_cell?**	(string name)	Returns true if a cell with a given name exists
[const]	bool	**has_prop_id?**		Returns true, if the layout has user properties
	void	**insert**	(unsigned int cell_index, int layer, const Region region)	Inserts a region into the given cell and layer
	void	**insert**	(unsigned int cell_index, int layer, const Edges edges)	Inserts an edge collection into the given cell and layer
	void	**insert**	(unsigned int cell_index, int layer, const EdgePairs edge_pairs)	Inserts an edge pair collection into the given cell and layer
	void	**insert**	(unsigned int cell_index, int layer, const Texts texts)	Inserts an text collection into the given cell and layer
	unsigned int	**insert_layer**	(const LayerInfo props)	Inserts a new layer with the given properties
	void	**insert_layer_at**	(unsigned int index, const LayerInfo props)	Inserts a new layer with the given properties at the given index
	unsigned int	**insert_special_layer**	(const LayerInfo props)	Inserts a new special layer with the given properties
	void	**insert_special_layer_a**	(unsigned int index, const LayerInfo props)	Inserts a new special layer with the given properties at the given index
[const]	bool	**is_editable?**		Returns a value indicating whether the layout is editable.
[const]	bool	**is_free_layer?**	(unsigned int layer_index)	Returns true, if a layer index is a free (unused) layer index
[const]	bool	**is_special_layer?**	(unsigned int layer_index)	Returns true, if a layer index is a special layer index

[const]	bool	**is_valid_cell_index?**	(unsigned int cell_index)	Returns true, if a cell index is a valid index
[const]	bool	**is_valid_layer?**	(unsigned int layer_index)	Returns true, if a layer index is a valid normal layout layer index
	unsigned int	**layer**		Creates a new internal layer
	unsigned int	**layer**	(const LayerInfo info)	Finds or creates a layer with the given properties
	unsigned int	**layer**	(string name)	Finds or creates a layer with the given name
	unsigned int	**layer**	(int layer, int datatype)	Finds or creates a layer with the given layer and datatype number
	unsigned int	**layer**	(int layer, int datatype, string name)	Finds or creates a layer with the given layer and datatype number and name
[const]	unsigned int[]	**layer_indexes**		Gets a list of valid layer's indices
[const]	LayerInfo[]	**layer_infos**		Gets a list of valid layer's properties
[const]	unsigned int	**layers**		Returns the number of layers
[const]	Library ptr	**library**		Gets the library this layout lives in or nil if the layout is not part of a library
	void	**merge_meta_info**	(const Layout other)	Merges the meta information from the other layout into this layout
	void	**merge_meta_info**	(const Layout other, const CellMapping cm)	Merges the meta information from the other layout into this layout for the cells given by the cell mapping
	new LayoutMetaInfo ptr	**meta_info**	(string name)	Gets the meta information for a given name
	variant	**meta_info_value**	(string name)	Gets the meta information value for a given name
	void	**move_layer**	(unsigned int src, unsigned int dest)	Moves a layer
	void	**move_layer**	(unsigned int src, unsigned int dest, unsigned int flags)	Moves a layer (selected shape types only)
	void	**move_tree_shapes**	(Layout source_layout, const CellMapping cell_mapping)	Moves the shapes for all given mappings in the CellMapping object
	void	**move_tree_shapes**	(Layout source_layout, const CellMapping cell_mapping, const LayerMapping layer_mapping)	Moves the shapes for all given mappings in the CellMapping object using the given layer mapping

	unsigned int[]	**multi_clip**	(unsigned int cell, Box[] boxes)	Clips the given cell by the given rectangles and produces new cells with the clips, one for each rectangle.
	unsigned int[]	**multi_clip**	(unsigned int cell, DBox[] boxes)	Clips the given cell by the given rectangles and produces new cells with the clips, one for each rectangle.
	Cell ptr[]	**multi_clip**	(const Cell cell, Box[] boxes)	Clips the given cell by the given rectangles and produces new cells with the clips, one for each rectangle.
	Cell ptr[]	**multi_clip**	(const Cell cell, DBox[] boxes)	Clips the given cell by the given rectangles and produces new cells with the clips, one for each rectangle.
	unsigned int[]	**multi_clip_into**	(unsigned int cell, Layout ptr target, Box[] boxes)	Clips the given cell by the given rectangles and produces new cells with the clips, one for each rectangle.
	unsigned int[]	**multi_clip_into**	(unsigned int cell, Layout ptr target, DBox[] boxes)	Clips the given cell by the given rectangles and produces new cells with the clips, one for each rectangle.
	Cell ptr[]	**multi_clip_into**	(const Cell cell, Layout ptr target, Box[] boxes)	Clips the given cell by the given rectangles and produces new cells with the clips, one for each rectangle.
	Cell ptr[]	**multi_clip_into**	(const Cell cell, Layout ptr target, DBox[] boxes)	Clips the given cell by the given rectangles and produces new cells with the clips, one for each rectangle.
[const]	const PCellDeclaration ptr	**pcell_declaration**	(string name)	Gets a reference to the PCell declaration for the PCell with the given name
[const]	const PCellDeclaration ptr	**pcell_declaration**	(unsigned int pcell_id)	Gets a reference to the PCell declaration for the PCell with the given PCell ID.
[const]	unsigned int	**pcell_id**	(string name)	Gets the ID of the PCell with the given name
[const]	unsigned int[]	**pcell_ids**		Gets the IDs of the PCells registered in the layout
[const]	string[]	**pcell_names**		Gets the names of the PCells registered in the layout
[const]	unsigned long	**prop_id**		Gets the properties ID associated with the layout
	void	**prop_id=**	(unsigned long id)	Sets the properties ID associated with the layout
[const]	variant[]	**properties**	(unsigned long properties_id)	Gets the properties set for a given properties ID

	unsigned long	**properties_id**	(variant[] properties)	Gets the properties ID for a given properties set
	variant	**property**	(variant key)	Gets the user property with the given key
	void	**prune_cell**	(unsigned int cell_index, int levels)	Deletes a cell plus subcells not used otherwise
	void	**prune_subcells**	(unsigned int cell_index, int levels)	Deletes all sub cells of the cell which are not used otherwise down to the specified level of hierarchy
	LayerMap	**read**	(string filename)	Load the layout from the given file
	LayerMap	**read**	(string filename, const LoadLayoutOptions options)	Load the layout from the given file with options
	void	**refresh**		Calls Cell#refresh on all cells inside this layout
	unsigned int	**register_pcell**	(string name, PCellDeclaration ptr declaration)	Registers a PCell declaration under the given name
	void	**remove_meta_info**	(string name)	Removes meta information from the layout
	void	**rename_cell**	(unsigned int index, string name)	Renames the cell with given index
	void	**scale_and_snap**	(Cell cell, int grid, int mult, int div)	Scales and snaps the layout below a given cell by the given rational factor and snaps to the given grid
	void	**scale_and_snap**	(unsigned int cell_index, int grid, int mult, int div)	Scales and snaps the layout below a given cell by the given rational factor and snaps to the given grid
	void	**set_info**	(unsigned int index, const LayerInfo props)	Sets the info structure for a specified layer
	void	**set_property**	(variant key, variant value)	Sets the user property with the given key to the given value
	void	**start_changes**		Signals the start of an operation bringing the layout into invalid state
	void	**swap_layers**	(unsigned int a, unsigned int b)	Swap two layers
[const]	const Technology ptr	**technology**		Gets the Technology object of the technology this layout is associated with or nil if the layout is not associated with a technology
[const]	string	**technology_name**		Gets the name of the technology this layout is associated with

	void	technology_name=	(string name)	Sets the name of the technology this layout is associated with
	Cell ptr	top_cell		Returns the top cell object
	Cell ptr[]	top_cells		Returns the top cell objects
	void	transform	(const Trans trans)	Transforms the layout with the given transformation
	void	transform	(const ICplxTrans trans)	Transforms the layout with the given complex integer transformation
	void	transform	(const DTrans trans)	Transforms the layout with the given transformation, which is in micrometer units
	void	transform	(const DCplxTrans trans)	Transforms the layout with the given complex integer transformation, which is in micrometer units
[const]	bool	under_construction?		Returns true if the layout object is under construction
[const]	string	unique_cell_name	(string name)	Creates a new unique cell name from the given name
	void	update		Updates the internals of the layout
	void	write	(string filename, const SaveLayoutOptions options)	Writes the layout to a stream file
	void	write	(string filename)	Writes the layout to a stream file

Deprecated methods (protected, public, static, non-static and constructors)

	unsigned int	add_cell	(string name)	Use of this method is deprecated
[const]	RecursiveShapeIterator	begin_shapes	(unsigned int cell_index, unsigned int layer)	Use of this method is deprecated
[const]	RecursiveShapeIterator	begin_shapes_overlap	(unsigned int cell_index, unsigned int layer, Box region)	Use of this method is deprecated
[const]	RecursiveShapeIterator	begin_shapes_overlapping	(const Cell ptr cell_index, unsigned int layer, Box region)	Use of this method is deprecated
[const]	RecursiveShapeIterator	begin_shapes_overlap	(unsigned int cell_index, unsigned int layer, DBox region)	Use of this method is deprecated
[const]	RecursiveShapeIterator	begin_shapes_overlapping	(const Cell ptr cell, unsigned int layer, DBox region)	Use of this method is deprecated
[const]	RecursiveShapeIterator	begin_shapes_touchin	(unsigned int cell_index,	Use of this method is deprecated

			unsigned int layer, Box region)	
[const]	RecursiveShapeIterator	**begin_shapes_touching**	(const Cell ptr cell, unsigned int layer, Box region)	Use of this method is deprecated
[const]	RecursiveShapeIterator	**begin_shapes_touchir**	(unsigned int cell_index, unsigned int layer, DBox region)	Use of this method is deprecated
[const]	RecursiveShapeIterator	**begin_shapes_touching**	(const Cell ptr cell, unsigned int layer, DBox region)	Use of this method is deprecated
	unsigned int	**cell_by_name**	(string name)	Use of this method is deprecated
	void	**create**		Use of this method is deprecated. Use _create instead
	void	**destroy**		Use of this method is deprecated. Use _destroy instead
[const]	bool	**destroyed?**		Use of this method is deprecated. Use _destroyed? instead
[const]	bool	**is_const_object?**		Use of this method is deprecated. Use _is_const_object? instead
[const]	unsigned int[]	**layer_indices**		Use of this method is deprecated. Use layer_indexes instead
	void	**write**	(string filename, bool gzip, const SaveLayoutOptions options)	Use of this method is deprecated

Detailed description

_create

Signature: void **_create**

Description: Ensures the C++ object is created

Use this method to ensure the C++ object is created, for example to ensure that resources are allocated. Usually C++ objects are created on demand and not necessarily when the script object is created.

_destroy

Signature: void **_destroy**

Description: Explicitly destroys the object

Explicitly destroys the object on C++ side if it was owned by the script interpreter. Subsequent access to this object will throw an exception. If the object is not owned by the script, this method will do nothing.

_destroyed?

Signature: *[const]* bool **_destroyed?**

Description: Returns a value indicating whether the object was already destroyed

This method returns true, if the object was destroyed, either explicitly or by the C++ side. The latter may happen, if the object is owned by a C++ object which got destroyed itself.

_is_const_object?

Signature: *[const]* bool **_is_const_object?**

Description: Returns a value indicating whether the reference is a const reference

This method returns true, if self is a const reference. In that case, only const methods may be called on self.

_manage

Signature: void **_manage**

Description: Marks the object as managed by the script side.

After calling this method on an object, the script side will be responsible for the management of the object. This method may be called if an object is returned from a C++ function and the object is known not to be owned by any C++ instance. If necessary, the script side may delete the object if the script's reference is no longer required.

Usually it's not required to call this method. It has been introduced in version 0.24.

_unmanage

Signature: void **_unmanage**

Description: Marks the object as no longer owned by the script side.

Calling this method will make this object no longer owned by the script's memory management. Instead, the object must be managed in some other way. Usually this method may be called if it is known that some C++ object holds and manages this object. Technically speaking, this method will turn the script's reference into a weak reference. After the script engine decides to delete the reference, the object itself will still exist. If the object is not managed otherwise, memory leaks will occur.

Usually it's not required to call this method. It has been introduced in version 0.24.

add_cell

Signature: unsigned int **add_cell** (string name)

Description: Adds a cell with the given name

Returns: The index of the newly created cell.

Use of this method is deprecated

From version 0.23 on this method is deprecated because another method exists which is more convenient because is returns a Cell object (create_cell).

add_lib_cell

Signature: unsigned int **add_lib_cell** (Library ptr library, unsigned int lib_cell_index)

Description: Imports a cell from the library

library: The reference to the library from which to import the cell

lib_cell_index: The index of the imported cell in the library

Returns: The cell index of the new proxy cell in this layout

This method imports the given cell from the library and creates a new proxy cell. The proxy cell acts as a pointer to the actual cell which still resides in the library (precisely: in library.layout). The name of the new cell will be the name of library cell.

This method has been introduced in version 0.22.

add_meta_info

Signature: void **add_meta_info** (const LayoutMetaInfo info)

Description: Adds meta information to the layout

See LayoutMetaInfo for details about layouts and meta information. This method has been introduced in version 0.25.

add_pcell_variant

(1) Signature: unsigned int **add_pcell_variant** (unsigned int pcell_id, map<string,variant> parameters)

Description: Creates a PCell variant for the given PCell ID with the parameters given as a name/value dictionary

Returns: The cell index of the pcell variant proxy cell

This method will create a PCell variant proxy for a local PCell definition. It will create the PCell variant for the given parameters. Note that this method does not allow one to create PCell instances for PCells located in a library. Use add_pcell_variant with the library parameter for that purpose. Unlike the variant using a list of parameters, this version allows specification of the parameters with a key/value dictionary. The keys are the parameter names as given by the PCell declaration.

The parameters are a sequence of variants which correspond to the parameters declared by the PCellDeclaration object.

The name of the new cell will be the name of the PCell. If a cell with that name already exists, a new unique name is generated.

This method has been introduced in version 0.22.

(2) Signature: unsigned int **add_pcell_variant** (unsigned int pcell_id, variant[] parameters)

Description: Creates a PCell variant for the given PCell ID with the given parameters

Returns: The cell index of the pcell variant proxy cell

This method will create a PCell variant proxy for a local PCell definition. It will create the PCell variant for the given parameters. Note that this method does not allow one to create PCell instances for PCells located in a library. Use add_pcell_variant with the library parameter for that purpose.

The parameters are a sequence of variants which correspond to the parameters declared by the PCellDeclaration object.

The name of the new cell will be the name of the PCell. If a cell with that name already exists, a new unique name is generated.

This method has been introduced in version 0.22.

(3) Signature: unsigned int **add_pcell_variant** (Library ptr library, unsigned int pcell_id, map<string,variant> parameters)

Description: Creates a PCell variant for a PCell located in an external library with the parameters given as a name/value dictionary

Returns: The cell index of the new proxy cell in this layout

This method will import a PCell from a library and create a variant for the given parameter set. Technically, this method creates a proxy to the library and creates the variant inside that library. Unlike the variant using a list of parameters, this version allows specification of the parameters with a key/value dictionary. The keys are the parameter names as given by the PCell declaration.

The parameters are a sequence of variants which correspond to the parameters declared by the PCellDeclaration object.

The name of the new cell will be the name of the PCell. If a cell with that name already exists, a new unique name is generated.

This method has been introduced in version 0.22.

(4) Signature: unsigned int **add_pcell_variant** (Library ptr library, unsigned int pcell_id, variant[] parameters)

Description: Creates a PCell variant for a PCell located in an external library

Returns: The cell index of the new proxy cell in this layout

This method will import a PCell from a library and create a variant for the given parameter set. Technically, this method creates a proxy to the library and creates the variant inside that library.

The parameters are a sequence of variants which correspond to the parameters declared by the PCellDeclaration object.

The name of the new cell will be the name of the PCell. If a cell with that name already exists, a new unique name is generated.

This method has been introduced in version 0.22.

assign

Signature: void **assign** (const Layout other)

Description: Assigns another object to self

begin_shapes

(1) Signature: *[const]* RecursiveShapeIterator **begin_shapes** (const Cell ptr cell, unsigned int layer)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer

cell:	The cell object of the initial (top) cell
layer:	The layer from which to get the shapes
Returns:	A suitable iterator

For details see the description of the RecursiveShapeIterator class. This version is convenience overload which takes a cell object instead of a cell index.

This method is deprecated. Use Cell#begin_shapes_rec instead.

This method has been added in version 0.24.

(2) Signature: *[const]* RecursiveShapeIterator **begin_shapes** (unsigned int cell_index, unsigned int layer)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer

cell_index:	The index of the initial (top) cell
layer:	The layer from which to get the shapes
Returns:	A suitable iterator

Use of this method is deprecated

For details see the description of the RecursiveShapeIterator class.

This method is deprecated. Use Cell#begin_shapes_rec instead.

This method has been added in version 0.18.

begin_shapes_overlapping

(1) Signature: *[const]* RecursiveShapeIterator **begin_shapes_overlapping** (unsigned int cell_index, unsigned int layer, Box region)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer using a region search

cell_index:	The index of the starting cell
layer:	The layer from which to get the shapes
region:	The search region
Returns:	A suitable iterator

Use of this method is deprecated

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box overlaps the given region.

This method is deprecated. Use Cell#begin_shapes_rec_overlapping instead.

This method has been added in version 0.18.

(2) Signature: *[const]* RecursiveShapeIterator **begin_shapes_overlapping** (const Cell ptr cell_index, unsigned int layer, Box region)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer using a region search

cell:	The cell object for the starting cell
layer:	The layer from which to get the shapes
region:	The search region
Returns:	A suitable iterator

Use of this method is deprecated

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box overlaps the given region. It is convenience overload which takes a cell object instead of a cell index.

This method is deprecated. Use Cell#begin_shapes_rec_overlapping instead.

This method has been added in version 0.24.

(3) Signature: *[const]* RecursiveShapeIterator **begin_shapes_overlapping** (unsigned int cell_index, unsigned int layer, DBox region)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer using a region search, the region given in micrometer units

cell_index:	The index of the starting cell
layer:	The layer from which to get the shapes
region:	The search region as a DBox object in micrometer units
Returns:	A suitable iterator

Use of this method is deprecated

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box overlaps the given region.

This method is deprecated. Use Cell#begin_shapes_rec_overlapping instead.

This variant has been added in version 0.25.

(4) Signature: *[const]* RecursiveShapeIterator **begin_shapes_overlapping** (const Cell ptr cell, unsigned int layer, DBox region)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer using a region search, the region given in micrometer units

cell:	The cell object for the starting cell
layer:	The layer from which to get the shapes
region:	The search region as a DBox object in micrometer units
Returns:	A suitable iterator

Use of this method is deprecated

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box overlaps the given region. It is convenience overload which takes a cell object instead of a cell index.

This method is deprecated. Use Cell#begin_shapes_rec_overlapping instead.

This variant has been added in version 0.25.

begin_shapes_touching

(1) Signature: *[const]* RecursiveShapeIterator **begin_shapes_touching** (unsigned int cell_index, unsigned int layer, Box region)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer using a region search

cell_index:	The index of the starting cell
layer:	The layer from which to get the shapes
region:	The search region
Returns:	A suitable iterator

Use of this method is deprecated

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box touches the given region.

This method is deprecated. Use Cell#begin_shapes_rec_touching instead.

This method has been added in version 0.18.

(2) Signature: *[const]* RecursiveShapeIterator **begin_shapes_touching** (const Cell ptr cell, unsigned int layer, Box region)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer using a region search

cell:	The cell object for the starting cell
layer:	The layer from which to get the shapes
region:	The search region
Returns:	A suitable iterator

Use of this method is deprecated

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box touches the given region. It is convenience overload which takes a cell object instead of a cell index.

This method is deprecated. Use Cell#begin_shapes_rec_touching instead.

This method has been added in version 0.24.

(3) Signature: *[const]* RecursiveShapeIterator **begin_shapes_touching** (unsigned int cell_index, unsigned int layer, DBox region)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer using a region search, the region given in micrometer units

cell_index:	The index of the starting cell
layer:	The layer from which to get the shapes
region:	The search region as a DBox object in micrometer units
Returns:	A suitable iterator

Use of this method is deprecated

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box touches the given region.

This method is deprecated. Use Cell#begin_shapes_rec_touching instead.

This variant has been added in version 0.25.

(4) Signature: *[const]* RecursiveShapeIterator **begin_shapes_touching** (const Cell ptr cell, unsigned int layer, DBox region)

Description: Delivers a recursive shape iterator for the shapes below the given cell on the given layer using a region search, the region given in micrometer units

cell:	The cell object for the starting cell
layer:	The layer from which to get the shapes
region:	The search region as a DBox object in micrometer units
Returns:	A suitable iterator

Use of this method is deprecated

For details see the description of the RecursiveShapeIterator class. This version gives an iterator delivering shapes whose bounding box touches the given region. It is convenience overload which takes a cell object instead of a cell index.

This method is deprecated. Use Cell#begin_shapes_rec_touching instead.

This variant has been added in version 0.25.

cell

(1) Signature: Cell ptr **cell** (string name)

Description: Gets a cell object from the cell name

name:	The cell name
Returns:	A reference to the cell (a Cell object)

If name is not a valid cell name, this method will return "nil". This method has been introduced in version 0.23 and replaces cell_by_name.

(2) Signature: Cell ptr **cell** (unsigned int i)

Description: Gets a cell object from the cell index

i:	The cell index
Returns:	A reference to the cell (a Cell object)

If the cell index is not a valid cell index, this method will raise an error. Use is_valid_cell_index? to test whether a given cell index is valid.

cell_by_name

Signature: unsigned int **cell_by_name** (string name)

Description: Gets the cell index for a given name

Use of this method is deprecated

Returns the cell index for the cell with the given name. If no cell with this name exists, an exception is thrown. From version 0.23 on, a version of the cell method is provided which returns a Cell object for the cell with the given name or "nil" if the name is not valid. This method replaces cell_by_name and has_cell?

cell_name

Signature: *[const]* string **cell_name** (unsigned int index)

Description: Gets the name for a cell with the given index

cells

(1) Signature: *[const]* unsigned int **cells**

Description: Returns the number of cells

Returns:	The number of cells (the maximum cell index)

(2) Signature: Cell ptr[] **cells** (string name_filter)

Description: Gets the cell objects for a given name filter

name_filter:	The cell name filter (glob pattern)
Returns:	A list of Cell object of the cells matching the pattern

This method has been introduced in version 0.27.3.

cleanup

Signature: void **cleanup** (unsigned int[] cell_indexes_to_keep = [])

Description: Cleans up the layout

This method will remove proxy objects that are no longer in use. After changing PCell parameters such proxy objects may still be present in the layout and are cached for later reuse. Usually they are cleaned up automatically, but in a scripting context it may be useful to clean up these cells explicitly.

Use 'cell_indexes_to_keep' for specifying a list of cell indexes of PCell variants or library proxies you don't want to be cleaned up.

This method has been introduced in version 0.25.

clear

Signature: void **clear**

Description: Clears the layout

Clears the layout completely.

clear_all_meta_info

Signature: void **clear_all_meta_info**

Description: Clears all meta information of the layout (cell specific and global)

See LayoutMetaInfo for details about layouts and meta information. This method has been introduced in version 0.28.16.

clear_layer

(1) Signature: void **clear_layer** (unsigned int layer_index)

Description: Clears a layer

layer_index:	The index of the layer to delete.

Clears the layer: removes all shapes.

This method was introduced in version 0.19.

(2) Signature: void **clear_layer** (unsigned int layer_index, unsigned int flags)

Description: Clears a layer (given shape types only)

layer_index:	The index of the layer to delete.
flags:	The type selector for the shapes to delete (see Shapes class, S... constants).

Clears the layer: removes all shapes for the given shape types.

This method was introduced in version 0.28.9.

clear_meta_info

Signature: void **clear_meta_info**

Description: Clears the meta information of the layout

See LayoutMetaInfo for details about layouts and meta information. This method has been introduced in version 0.28.8.

clip

(1) Signature: unsigned int **clip** (unsigned int cell, const Box box)

Description: Clips the given cell by the given rectangle and produce a new cell with the clip

cell: The cell index of the cell to clip

box: The clip box in database units

Returns: The index of the new cell

This method will cut a rectangular region given by the box from the given cell. The clip will be stored in a new cell whose index is returned. The clip will be performed hierarchically. The resulting cell will hold a hierarchy of child cells, which are potentially clipped versions of child cells of the original cell. This method has been added in version 0.21.

(2) Signature: unsigned int **clip** (unsigned int cell, const DBox box)

Description: Clips the given cell by the given rectangle and produce a new cell with the clip

cell: The cell index of the cell to clip

box: The clip box in micrometer units

Returns: The index of the new cell

This variant which takes a micrometer-unit box has been added in version 0.28.

(3) Signature: Cell ptr **clip** (const Cell cell, const Box box)

Description: Clips the given cell by the given rectangle and produce a new cell with the clip

cell: The cell reference of the cell to clip

box: The clip box in database units

Returns: The reference to the new cell

This variant which takes cell references instead of cell indexes has been added in version 0.28.

(4) Signature: Cell ptr **clip** (const Cell cell, const DBox box)

Description: Clips the given cell by the given rectangle and produce a new cell with the clip

cell: The cell reference of the cell to clip

box: The clip box in micrometer units

Returns: The reference to the new cell

This variant which takes a micrometer-unit box and cell references has been added in version 0.28.

clip_into

(1) Signature: *[const]* unsigned int **clip_into** (unsigned int cell, Layout ptr target, const Box box)

Description: Clips the given cell by the given rectangle and produce a new cell with the clip

cell: The cell index of the cell to clip

box: The clip box in database units

target: The target layout

Returns: The index of the new cell in the target layout

This method will cut a rectangular region given by the box from the given cell. The clip will be stored in a new cell in the target layout. The clip will be performed hierarchically. The resulting cell will hold a hierarchy of child cells, which are potentially clipped versions of child cells of the original cell.
